Annals of the
Missouri Botanical Garden

The Annals, published quarterly, contains papers, primarily in systematic botany, contributed from the Missouri Botanical Garden, St. Louis. Papers originating outside the Garden will also be accepted. Authors should write the Editor for information concerning arrangements for publishing in the ANNALS. Instructions to Authors are printed on the inside back cover of the last issue of each volume.

CHANGES IN PLANT COMMUNITY DIVERSITY AND FLORISTIC COMPOSITION ON ENVIRONMENTAL AND GEOGRAPHICAL GRADIENTS[1,2]

Alwyn H. Gentry[3]

---

[1] *This and the following five papers comprise the proceedings of the Missouri Botanical Garden's 33rd Annual Systematics Symposium—Species Diversity. The symposium took place in St. Louis, Missouri on October 10 and 11, 1986.*

[2] *I thank the National Geographic Society for a series of grants that supported much of the research summarized here. Collection of the Madagascar data set was funded by the World Wildlife Fund. The coastal Colombian and Ecuadorian data sets and some of the Amazonian Peru data were gathered incidental to floristic projects funded by the National Science Foundation. Additional Peruvian data sets were funded by USAID (DAN-5542-G-SS-1086-00) and the Mellon Foundation; study of the Tambopata tree plots was in part funded by a grant from the Smithsonian Institution to T. Erwin. The data sets from eastern Brazil and Paraguay were gathered as part of an NSF-sponsored monographic study of Bignoniaceae (BSR 83-05040, BSR 86-07113). The Osa Peninsula, Costa Rica, data were obtained as an OTS class project; the Los Tuxtlas, Mexico, data came from a similar class project for the Universidad Nacional Autónoma de México; parts of the Colombian data were gathered as a project of the Curso Pos-Grado de Botánica of the Universidad Nacional de Colombia. Among the many friends and colleagues who collaborated in gathering the data summarized here were R. Neumann, R. Palacios, C. Cristóbal, and A. Schinini (Argentina); K. Kubitzki, M. Fallen, H. Popppendieck, and W. Lippert (Germany); J. Miller, D. Faber-Langendoen, E. Zardini, and C. Burnett (U.S.A.); C. Ramírez (Chile); E. Lott (Mexico); D. Stevens, P. Moreno, and A. Grijalva (Nicaragua); H. Cuadros, E. Renteria, A. Cogollo, M. Monsalve, A. Juncosa, C. Restrepo, J. Ramos, P. Silverstone, and O. de Benavides (Colombia); C. Dodson (Ecuador); B. Stein, R. G. Troth-Ovrebo, and P. Berry (Venezuela); F. Ayala, C. Díaz, R. Vasquez, N. Jaramillo, D. Smith, R. Tredwell, K. Young, and D. Alfaro (Peru); A. Peixoto and O. Peixoto (Brazil); V. Vera, J. Dávalos, and S. Keel (Paraguay); G. Pilz (Nigeria); D. Thomas (Cameroon); L. Dorr, L. Barnett, and A. Rakotozafy (Madagascar); J. Connell and J. Tracy (Queensland); J. Tagai (Sarawak); G. McPherson (New Caledonia); and V. Kapos (Jamaica). Additional original data using the same or comparable techniques were made available by E. Lott (Mexico), D. Lorence (Mauritius), and J. Miller and P. White (U.S.A.). I also thank R. Perrozzi, S. McCaslin, G. Fulton, and especially J. Miller for computational and technical expertise, E. Zardini for help in the field and with the illustrations, and J. Hall and D. Thomas for providing African data. I thank S. Hubbell, T. Givnish, L. Emmons, P. Ashton, P. Raven, and D. Thomas for review comments.*

ANN. MISSOURI BOT. GARD. 75: 1–34. 1988.

ABSTRACT

Trends in community composition and diversity of neotropical forests as measured by a series of samples of (1) plants ≥ 2.5 cm dbh in 0.1 ha, (2) plants over 10 cm dbh in 1-ha plots, and (3) complete local florulas are analyzed as a function of various environmental parameters. These trends are also compared with those found in similar data sets from other continents. Altogether the basic 0.1-ha data sets are reported for 87 sites in 25 countries on six continents and several islands. New data from ten 1-ha tree plots in upper Amazonia are also compared with each other and with similar data from the literature. Some noteworthy trends include: (1) Lowland neotropical plant species richness is generally far more tightly correlated with precipitation than with edaphic factors. (2) The nearly linear increase of lowland neotropical plant species richness with precipitation reaches an asymptote (community saturation?) at about 4,000 mm of annual rainfall. (3) Although the species represented in adjacent forest types on different substrates may change dramatically, diversity tends to change relatively little in upper Amazonia. (4) The species present at different sites are very different but the families represented and their diversities are highly predictable from environmental parameters. (5) On an altitudinal gradient in the tropical Andes there is a sharp, essentially linear decrease in diversity from about 1,500 m to near the upper limit of forest above 3,000 m. (6) There is no indication of a "mid-elevation bulge" in diversity, at least not in the sampled habit groups. (7) Even near timberline, montane tropical forests are as diverse as the most diverse temperate forests. (8) Moist subtropical forests are markedly less diverse than their inner-tropical equivalents, but dry subtropical forests in Mexico are apparently richer in species than inner-tropical dry forests. (9) Central African forests are about as species rich as neotropical forests with similar amounts of precipitation, but forests in tropical West Africa are relatively depauperate. (10) Tropical Australasian forests are no more diverse than equivalent neotropical forests; the world's highest tree species diversity is in upper Amazonia, not Southeast Asia. (11) Contrary to accepted opinion, equivalent forests on the three continents are similar in plant species richness and (with a very few notable exceptions) floristic composition but are markedly different in structure. The predictability of the floristic compositions and diversities of tropical forest plant communities seems strong, albeit circumstantial, evidence that these communities are at ecological and perhaps evolutionary equilibrium, despite indications that certain aspects of their diversity are generated and maintained stochastically.

Comparisons of the species richness (or other facets) of different forests or different vegetation types are often difficult because of the dissimilarity of the available data. In tropical Asia there is a wealth of data for trees in large sample areas (Ashton, 1964, in press; Whitmore, 1984; Proctor et al., 1983; Kartawinata et al., 1981) but few published data on nontrees. In the Neotropics there are several local florulas (Croat, 1978; Dodson & Gentry, 1978; Janzen & Liesner, 1980; Dodson et al., 1985), but until recently there have been no tree-plot data from high diversity regions based on reliable identifications. Africa has far more extensive coverage by regional and country-wide floras but no local florulas nor large-plot data from high-diversity regions.

Recently, a series of 0.1-ha samples of many of the world's most diverse extra-tropical plant communities has been accumulating (e.g., Naveh & Whittaker, 1979; Cowling, 1983; Peet & Christensen, 1980; Rice & Westoby, 1983; Eiten, 1978). Elsewhere we have reported the first comparable data set for tropical forests (Gentry & Dodson, 1987a, b). A standardized sampling technique that includes only plants ≥ 2.5 cm in diameter in 0.1 ha has also been developed and applied to a series of tropical forests (Gentry, 1982b, 1986b; Lott et al., 1987; Stallings et al., in press; Lorence & Sussman, 1988); the methodology for obtaining these 0.1-ha samples, each the sum of ten 2 × 50 m belt transects, is discussed in detail elsewhere (Gentry, 1982b, in prep.). The primary data set on which this paper is based are these 0.1-ha samples, which are now available for 38 lowland neotropical sites, 11 montane neotropical sites, and 13 subtropical and 9 temperate-zone sites in the Americas. Similar data sets are available from 6 sites in tropical Africa, 3 sites in tropical Australasia, 2 sites in Europe, and from several tropical islands: New Caledonia, Madagascar, Mauritius, Jamaica (Tables 1, 2; Fig. 1). Supplementary data are taken from local florulas in the Neotropics (Dodson & Gentry, 1978, 1988; Croat, 1978;

FIGURE 1. *Locations of study sites. Dots = 0.1-ha samples (see Tables 1, 2). Arrows = local florulas. For location of 1-ha tree plots see Gentry, 1988.*

Janzen & Liesner, 1980; Dodson et al., 1985; Hammel, pers. comm. (La Selva, Costa Rica)) and from the Makokou region of northwestern Gabon (Halle, 1964, 1965; Halle & Le Thomas, 1967, 1970; Florence & Hladik, 1980; Hladik & Halle, 1973; Hladik & Gentry, in prep.). A supplemental data set is provided by a series of 1-ha tree plots in various parts of the Neotropics (Gentry, 1988; Prance et al., 1976; Campbell et al., 1986; see also Gentry, 1982b) and Paleotropics (e.g., Ashton, 1964, 1977, in press; Gartlan et al., 1986).

Here I first review how the species richness of plant communities changes on five different environmental gradients: latitudinal, precipitational, edaphic, altitudinal, and intercontinental. Observations on a few noteworthy trends in forest structure are also included. Second, I analyze some patterns of floristic change along the same environmental gradients. Finally, I use these analyses to examine briefly the question of why some plant communities have so many more species than others.

In all of these analyses I will use number of species as the simplest and most appropriate measure of diversity, as suggested by Whittaker (1977). Shannon-Wiener H′ values are reported in Tables 1 and 2, but are so tightly correlated ($R^2 = 0.93$) with the absolute number of species that their use would add little to the analysis. Moreover, the wet-forest H′ values of 7 to 8 are far above the levels at which H′ has been statistically analyzed (cf. May, 1975).

TEMPERATE-TROPICAL PATTERNS

Figure 2 summarizes the latitudinal trends in species richness, based on the 74 lowland (= < 1,000 m) 0.1-ha sites for which comparable samples are available. It is well known that tropical forests are generally far richer than temperate forests in species (e.g., see Richards, 1952; MacArthur, 1972). Figure 2 indicates that for vascular plants species-rich tropical forests are typically an order of magnitude more diverse. Also apparent in Figure 2 are several much less well-known corollaries to the general latitudinal diversity gradient. 1) The difference in species richness between different tropical forests is far greater than the difference between temperate zone and species-poor tropical forests. Whereas the temperate forest samples have 15–25 species and tropical dry forest ones mostly 50–60 species, the samples of moist and wet tropical forests average about 150 species and pluvial forests over 250 species (Gentry,

[a] Extrapolated from number of species in sample of < 1,000 m^2.

1986b). 2) The latitudinal decrease in species richness seems to be asymmetrical about the equator; in the Southern Hemisphere it begins near the Tropic of Capricorn, but in the north it begins well inside the Tropic of Cancer, apparently near 12°N latitude. 3) Temperate zone forests are very similar in species richness of woody plants, compared with the massive differences in species richness between temperate and tropical forests or between different tropical forests. Temperate zone forests are so massively depauperate that even if boreal forests with two or three species ≥ 2.5 cm dbh in 0.1 ha were included in Figure 2, they would not significantly change it, even though the reported values are for some of the reputedly richest temperate zone forests. 4) Species-poor tropical forests with single-species dominance are generally still much more diverse than any temperate-zone forest. 5) South temperate forests, at least in Chile, where data sets are available, have fewer species than temperate forests in North America, contrary to the popular perception of the "rich" Valdivian forest; a major reason for this diffference is that Valdivian forests do not have sympatric congeners like the up to seven *Quercus* and four *Carya* species typical of 0.1-ha samples of eastern North American forests. 6) Subtropical dry forests can have more species than do full-tropical dry forests, even though wet or moist forests usually have fewer species in the subtropics than in the inner tropics.

TABLE 2. *Site characteristics for 0.1-ha samples from upland Neotropics (≥ 1,000 m, 12°N to 12°S). Parentheses indicate sites too incompletely sampled for a meaningful estimate of number of species in 0.1 ha.*

[a] Extrapolated from number of species in sample of < 1,000 m^2.

There are also latitudinal differences in forest structure. In general, tropical forests, far from being open and cathedral-like, are denser than temperate forests. This difference is almost entirely due to small-diameter plants, lianas, and trees less than 10 cm dbh (also see Gentry, 1982b). Biomass (as extrapolated from basal area) is roughly equivalent among different tropical forests ($\bar{X}$ = 34.9 m^2/ha, N = 36 (excluding Africa; $\bar{X}$ = 70.7 m^2/ha, N = 6)) and north temperate deciduous forests ($\bar{X}$ = 29.6 m^2/ha, N = 5) but markedly greater in the Valdivian forests ($\bar{X}$ = 155.7 m^2/ha, N = 3) as well as in their north temperate equivalent, the northwestern coniferous forests (Waring & Franklin, 1979).

DIVERSITY VS. PRECIPITATION

In the Neotropics, plant species richness is strongly correlated with absolute annual precipitation (Gentry, 1982b). However, this relationship is more complex than originally suggested (Gentry, 1982b), and the correlation may not exist at all in the Paleotropics. In tropical Asia, high rainfall areas such as Mt. Cherrapunji, Assam, often have relatively low plant species richness (Ashton, in press). In tropical Africa, two high rainfall sites (> 5,000 mm per year) in southwestern Cameroon (Korup, Mt. Cameroon) have only marginally more species in 0.1-ha samples than do samples from northeastern Gabon that receive < 2,000 mm of annual rainfall. Moreover, a more monsoonal climate site in Nigeria (Omo Forest) had many fewer species than the Gabon sites despite having similar precipitation values. Thus, it seems likely that the generalization that diversity increases linearly with precipitation (Gentry, 1982b) applies only in the special case of the Neotropics, where total annual rainfall and strength of

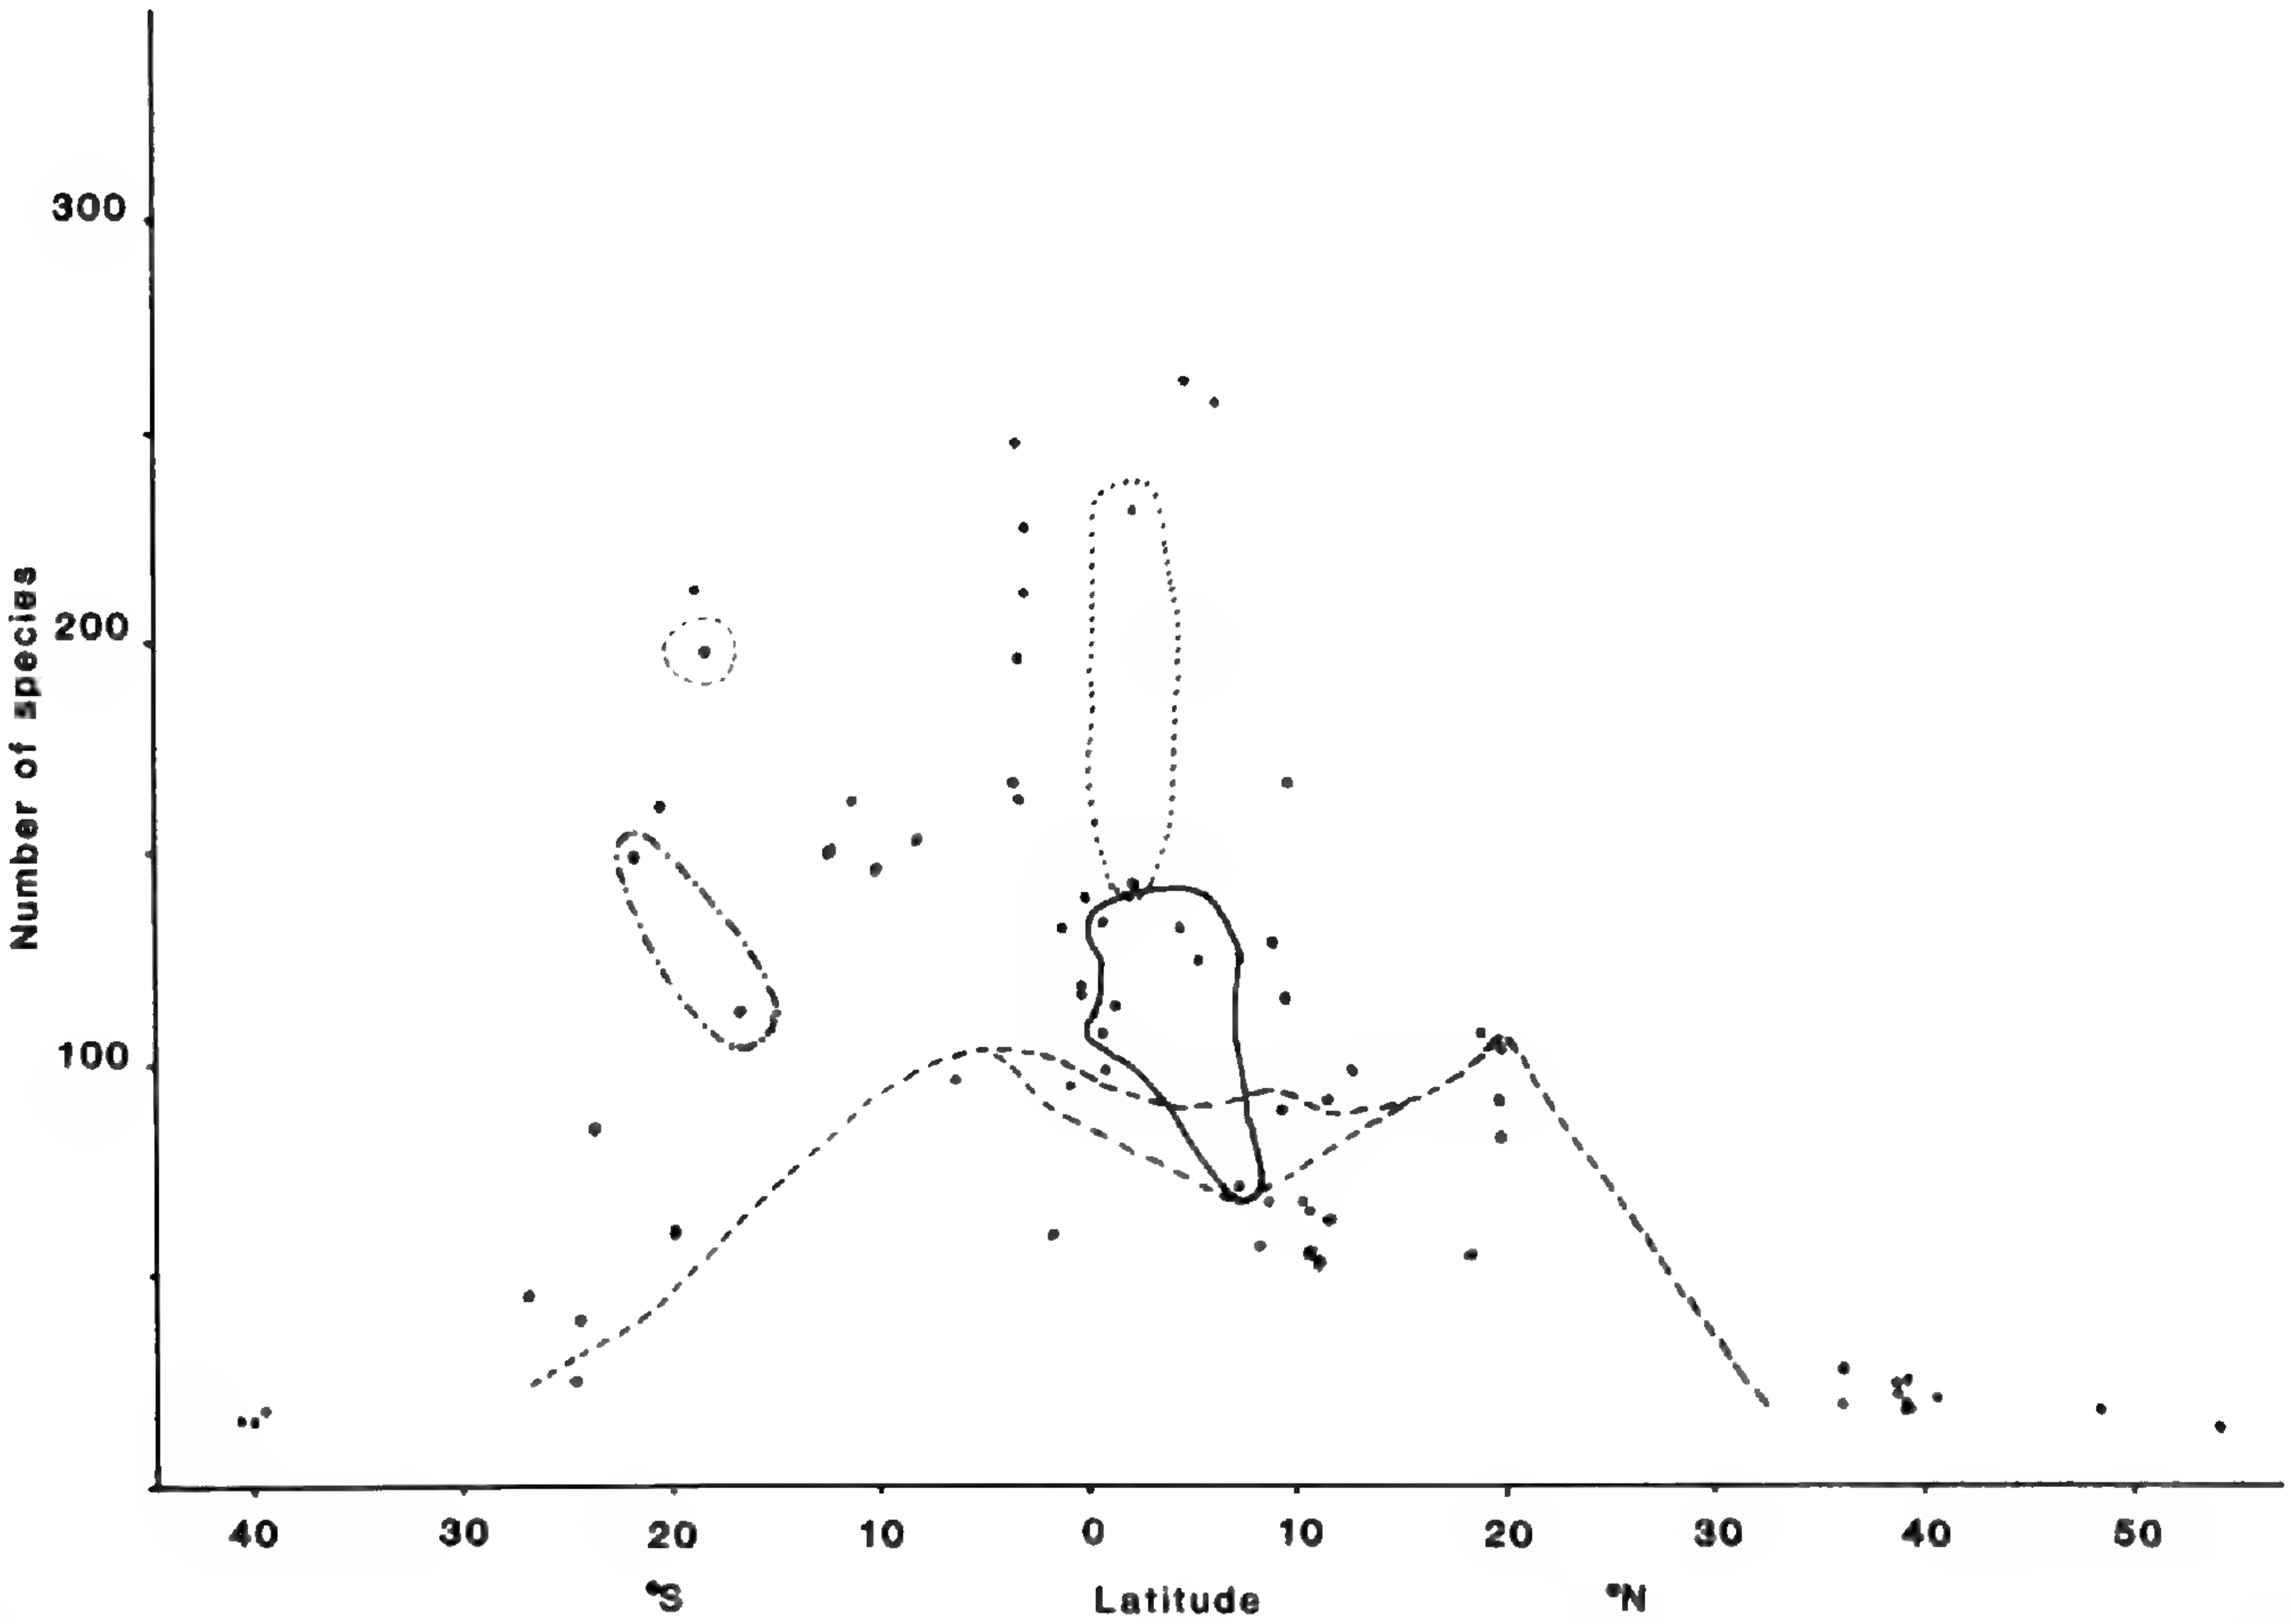

FIGURE 2. *Species richness of 1,000 m² samples of lowland (< 1,000 m) forest as a function of latitude. Closed line encloses continental African points; dotted line encloses Asian points; dash-dot line encloses Australian and New Caledonian samples; other tropical and subtropical points all neotropical except anomalously high diversity Madagascar point at 19°S, (circled). Dashed line separates dry forest (bottom) from moist and wet forest (top) with three intermediate sites (moist forest physiognomy despite relatively strong dry season) indicated by alternate lines.*

the dry season are strongly correlated. A potential test of the relative importance of distribution and amount of precipitation comes from a single 0.1-ha site in coastal Brazil (Linhares), which has the unusual (for the Neotropics) condition of low, evenly distributed annual rainfall. Although analysis of the Linhares diversity data is not completed (Peixoto & Gentry, in prep.) and the site is thus not included in Figure 3, it is obvious that its estimated 212 species in 0.1 ha are far more than would be expected from its 1,400 mm of annual precipitation.

While the many additional 0.1-ha samples now available from the lowland Neotropics generally strengthen the previously reported relationship between neotropical plant species richness and precipitation (Gentry, 1982b), additional data sets at the upper end of the precipitation scale strongly indicate that the relationship becomes nonlinear, reaching a marked asymptote at around 4,000–4,500 mm of annual precipitation (Fig. 3). The relationship is significantly curvilinear ($F = 4.299$, $P < 0.05$). From 4,000 mm to near the wettest place in the world (Tutunendo, Colombia) there is little or no change in the species richness of neotropical plant communities as measured by the 0.1-ha sampling protocol. The regularity of species richness patterns, and especially the apparent lid on community richness suggested by this asymptote, seem strong circumstantial evidence of the kind that zoologists (e.g., MacArthur, 1965, 1969) have construed as representing niche saturation and community equilibrium.

It is also possible that part of the apparent lid on plant community richness merely reflects the intrinsic limitations of the sampling technique. Figure 4 compares the accumulation of species with sample area for several representative sites. In low-diversity forests the species area curves level off below 500 m² indicating that most of the species present

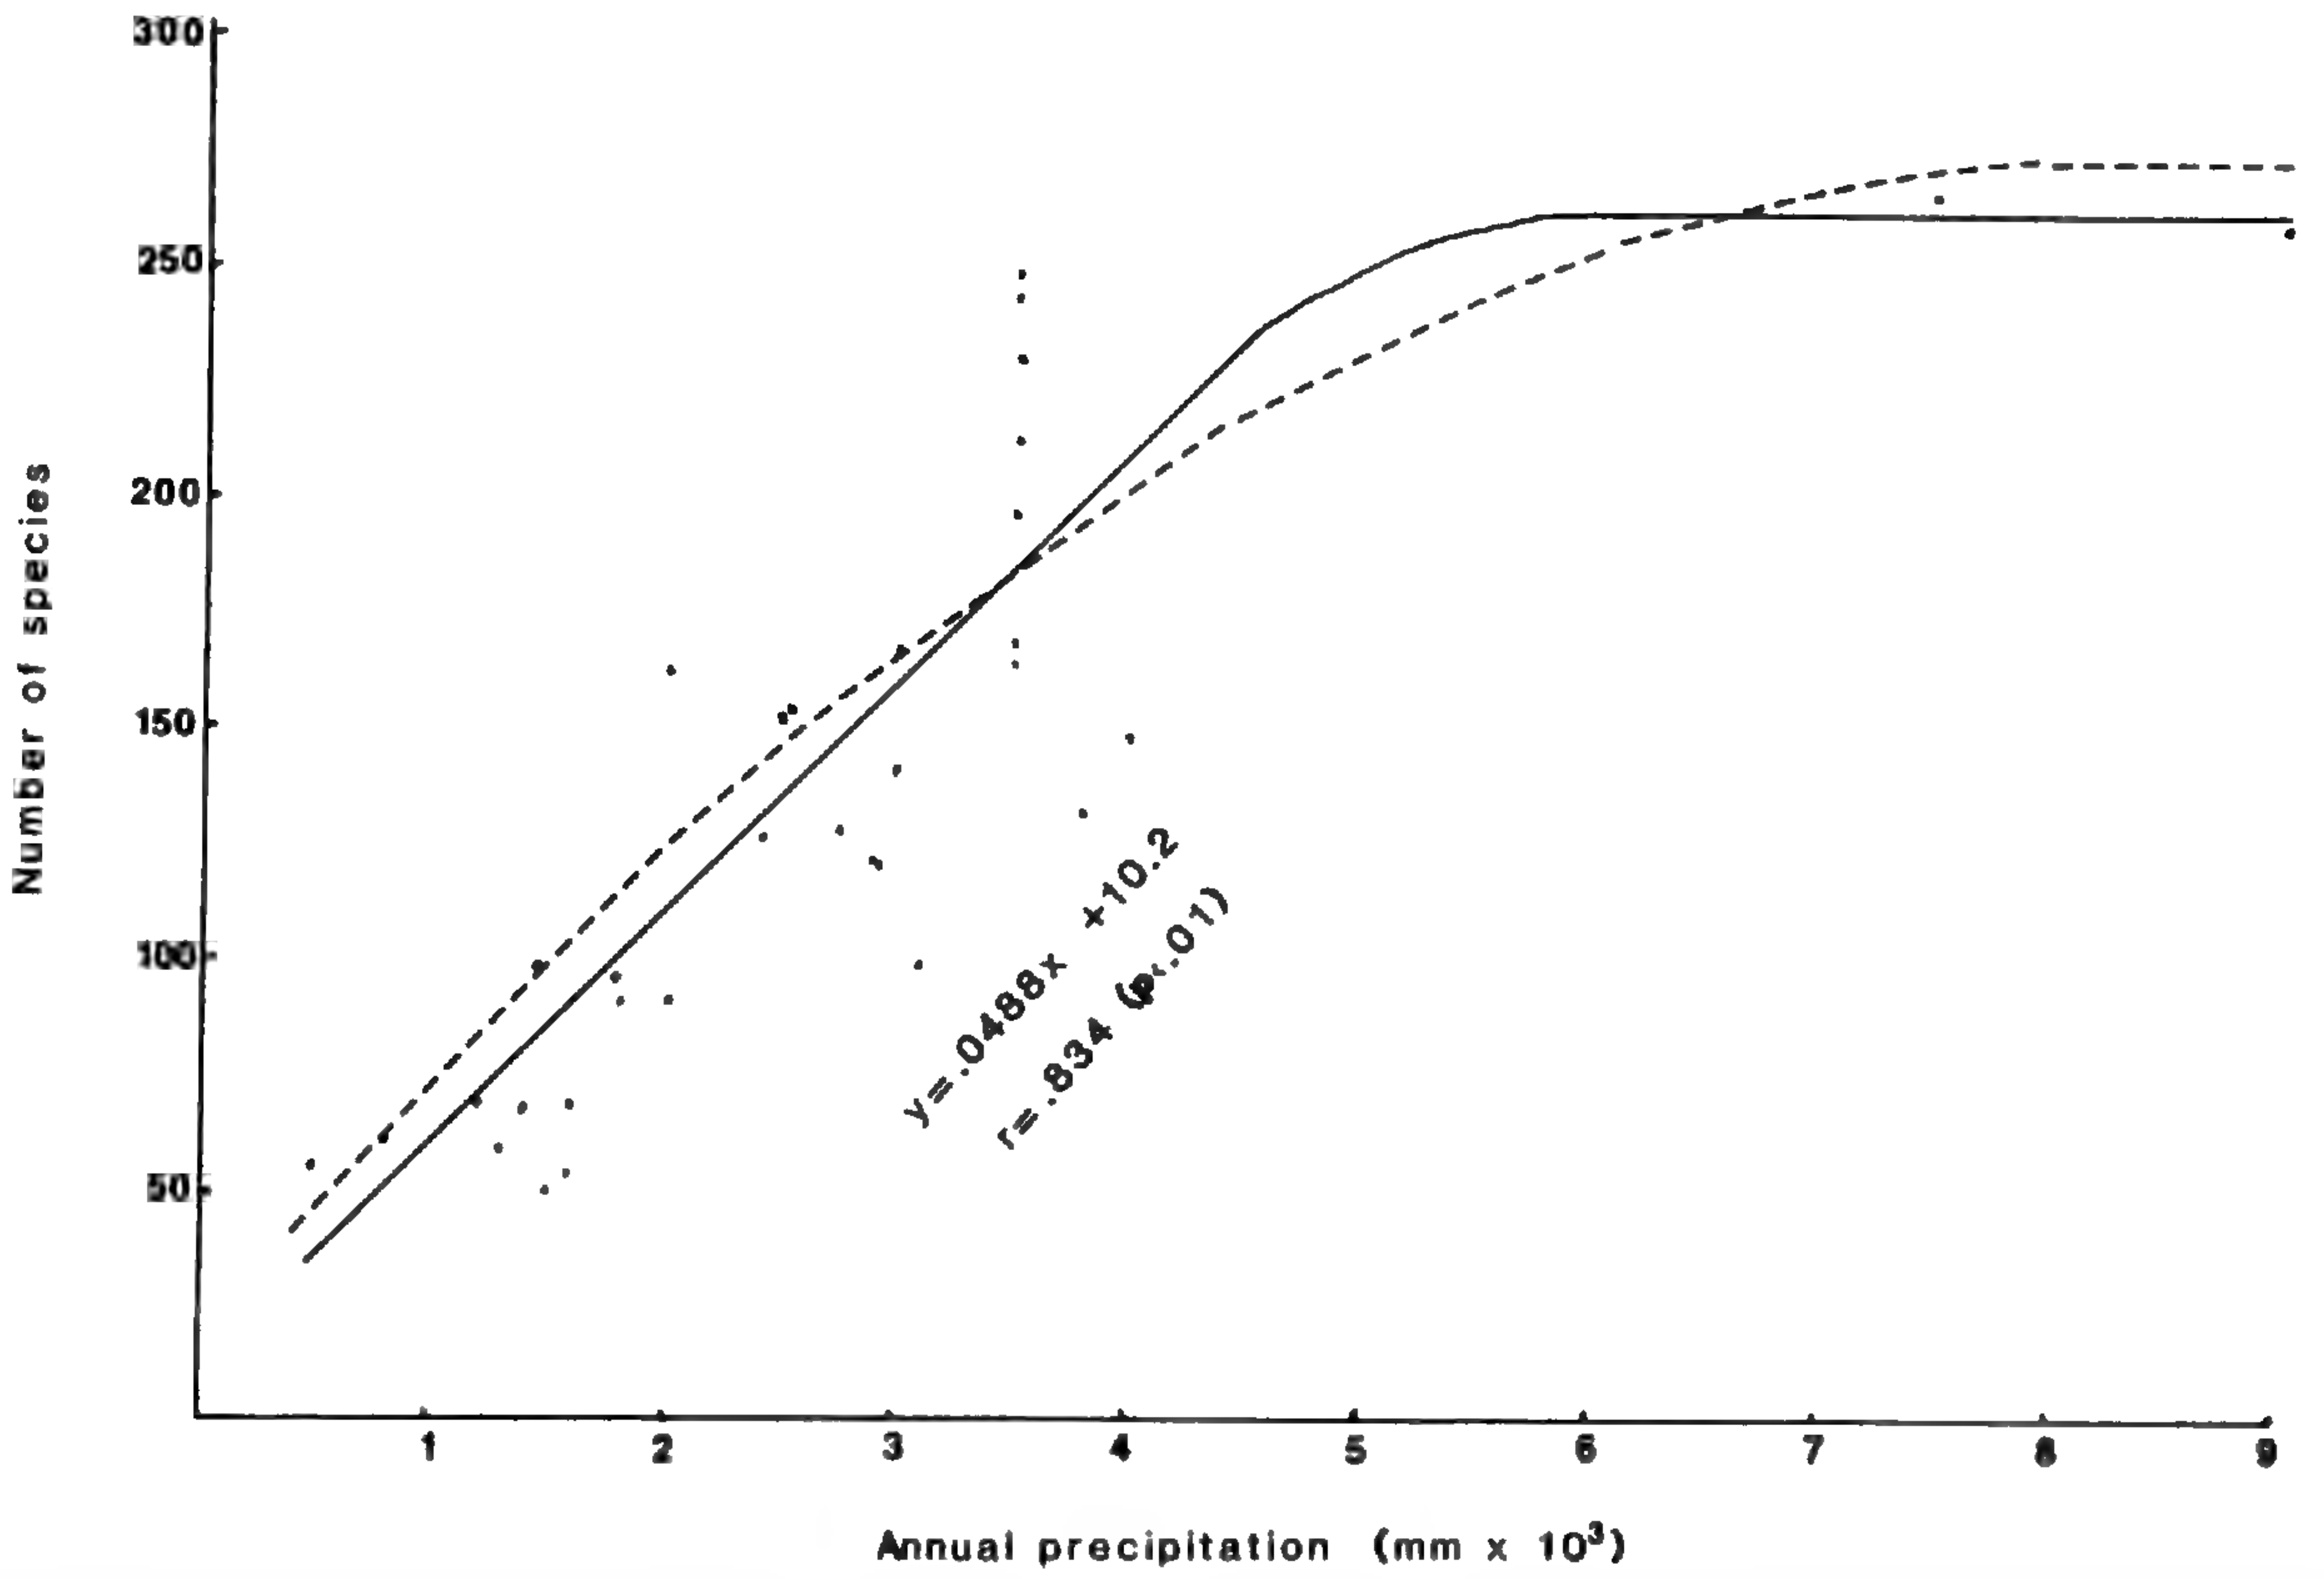

FIGURE 3. *Numbers of species in 0.1-ha samples of lowland neotropical forest vs. annual precipitation. Solid line = straight line regression for sites with < 5,000 mm annual precipitation with visually estimated asymptote. Dashed line = computer generated curve:* $y = 12.37 + 0.0613x - 0.000003598x^2$. *The curve is displaced slightly upward from the data points, since questionable morphospecies and lost specimens are treated as distinct species by the computer while the data points represent best estimates of species numbers. Data from Table 1 with subtropical sites excluded.*

in a given community have been sampled, but in species-rich vegetations the species–area curves show little sign of leveling off. To what extent a larger sampling area might reveal significant diversity differences between the different high rainfall sites remains unknown.

The strong relationship of species richness to precipitation in neotropical forests is further supported by preliminary data from 1-ha tree plots in upper Amazonia (Gentry, 1988). In these samples only trees and large lianas ≥ 10 cm in diameter were censused (Fig. 5). The two most species-rich sites are from the everwet high rainfall (3,000–4,000 mm) Iquitos area of northern Amazonian Peru, where diversity reaches almost ridiculous ex-

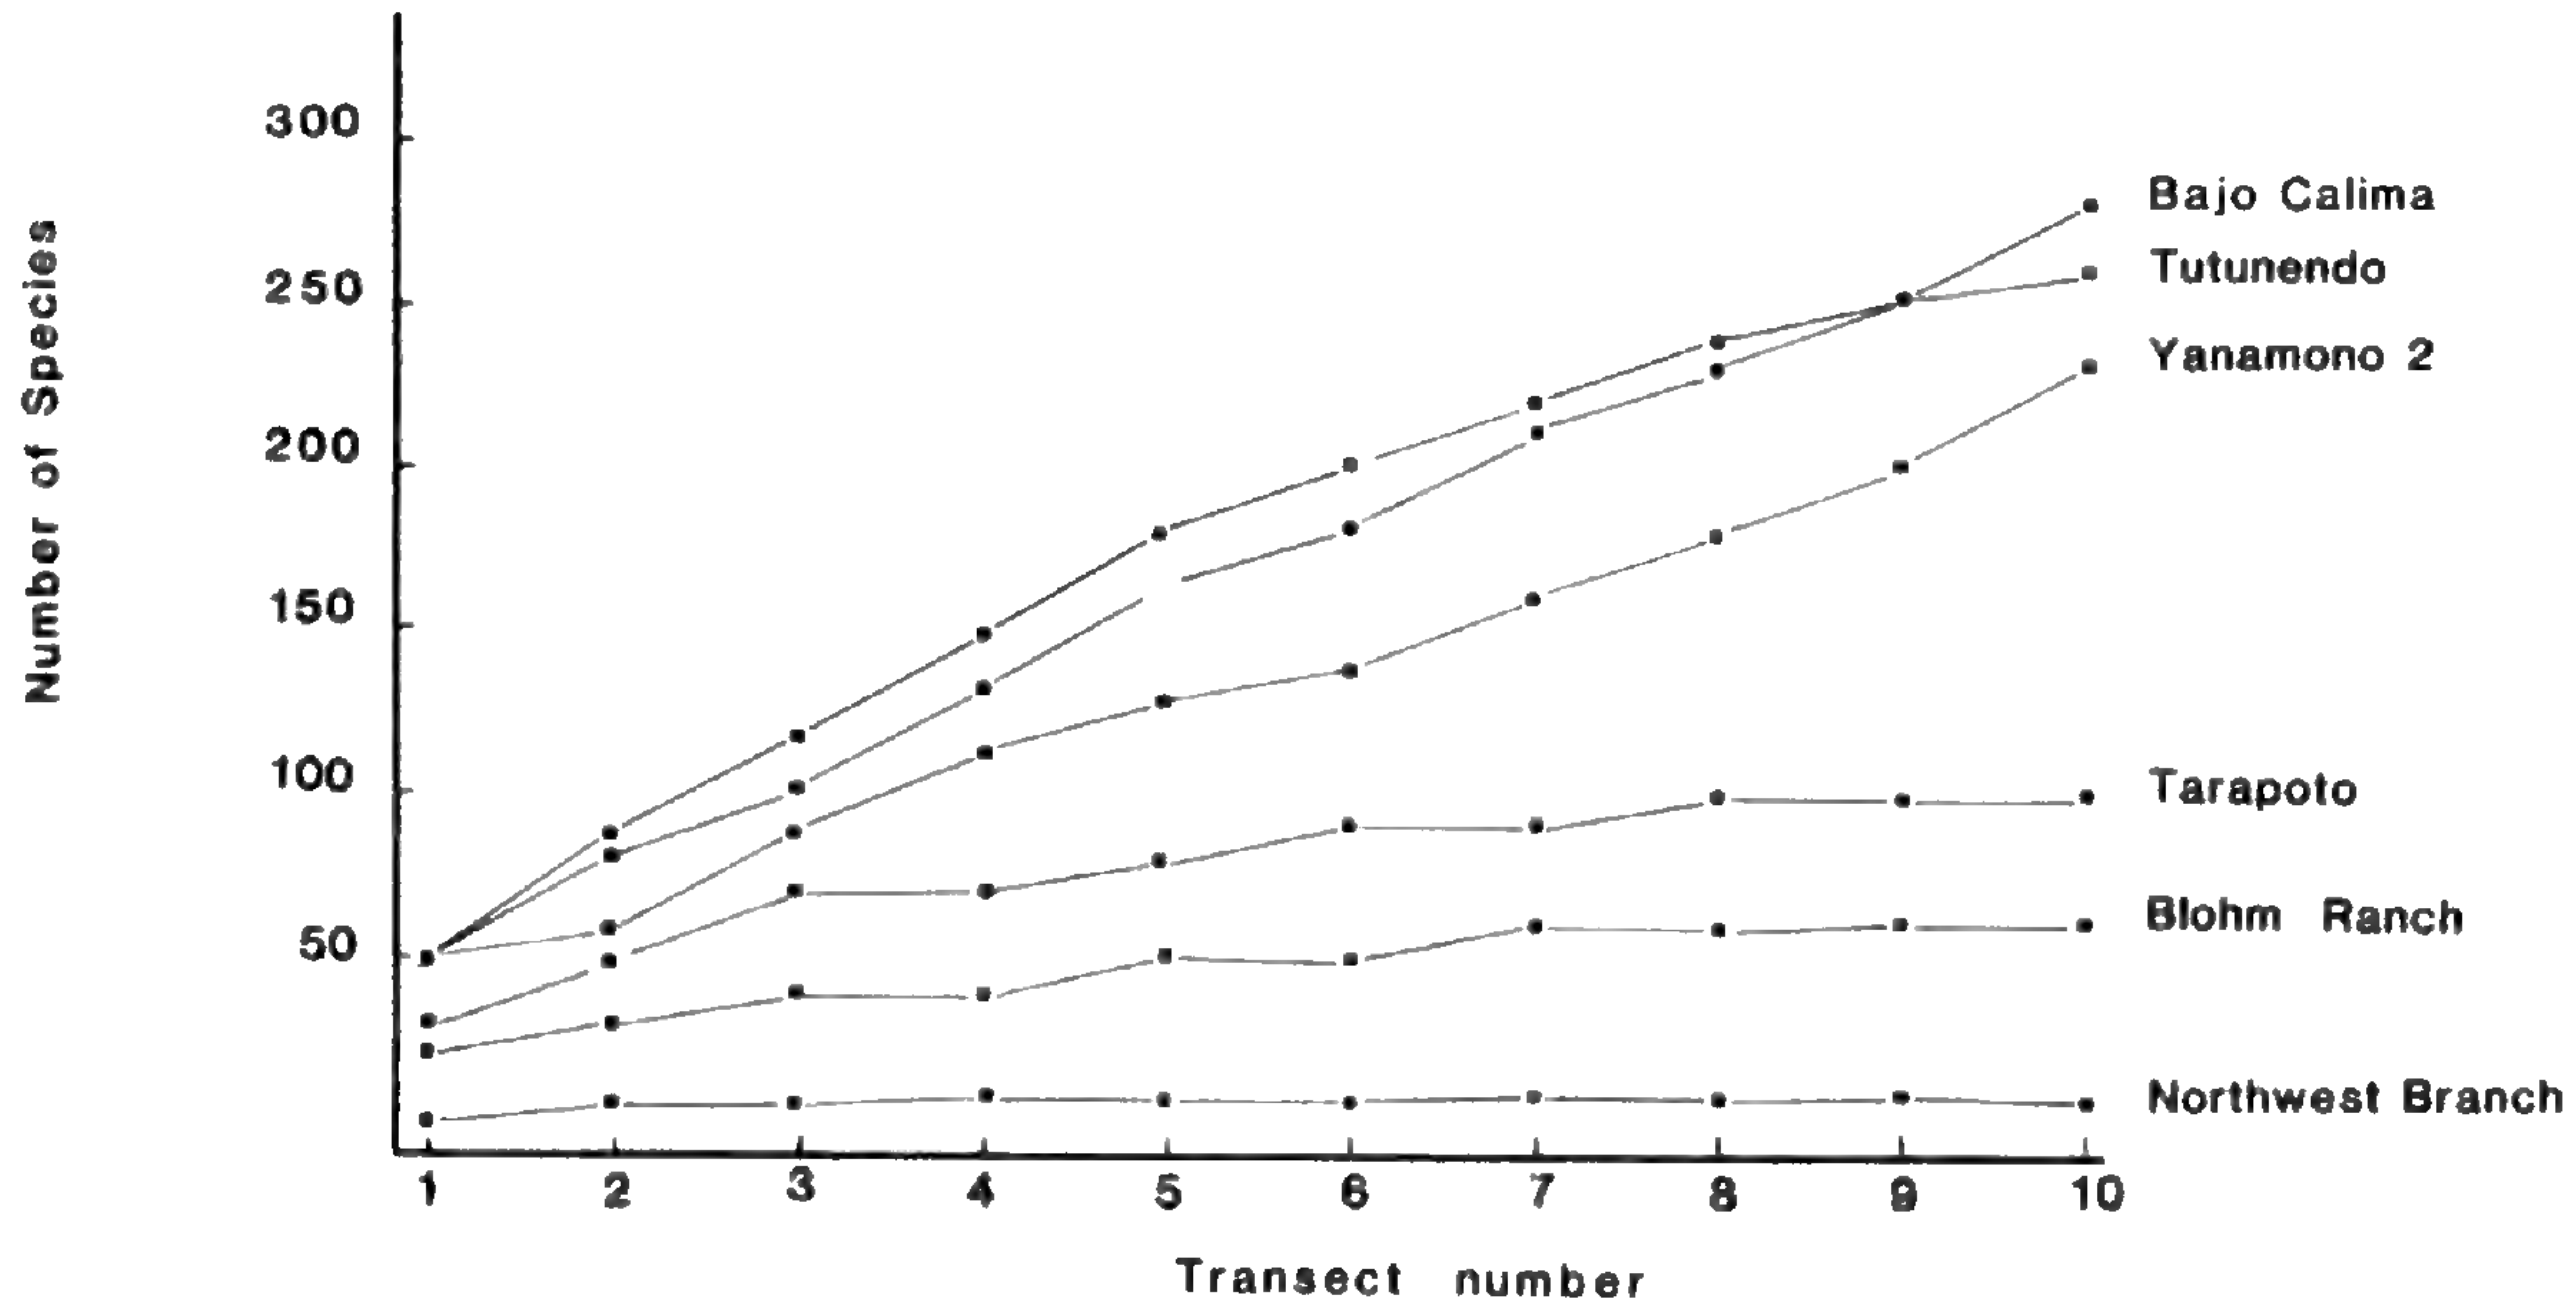

FIGURE 4. *Species–area curve for 100 m² subsamples of representative high- and low-diversity 0.1-ha samples.*

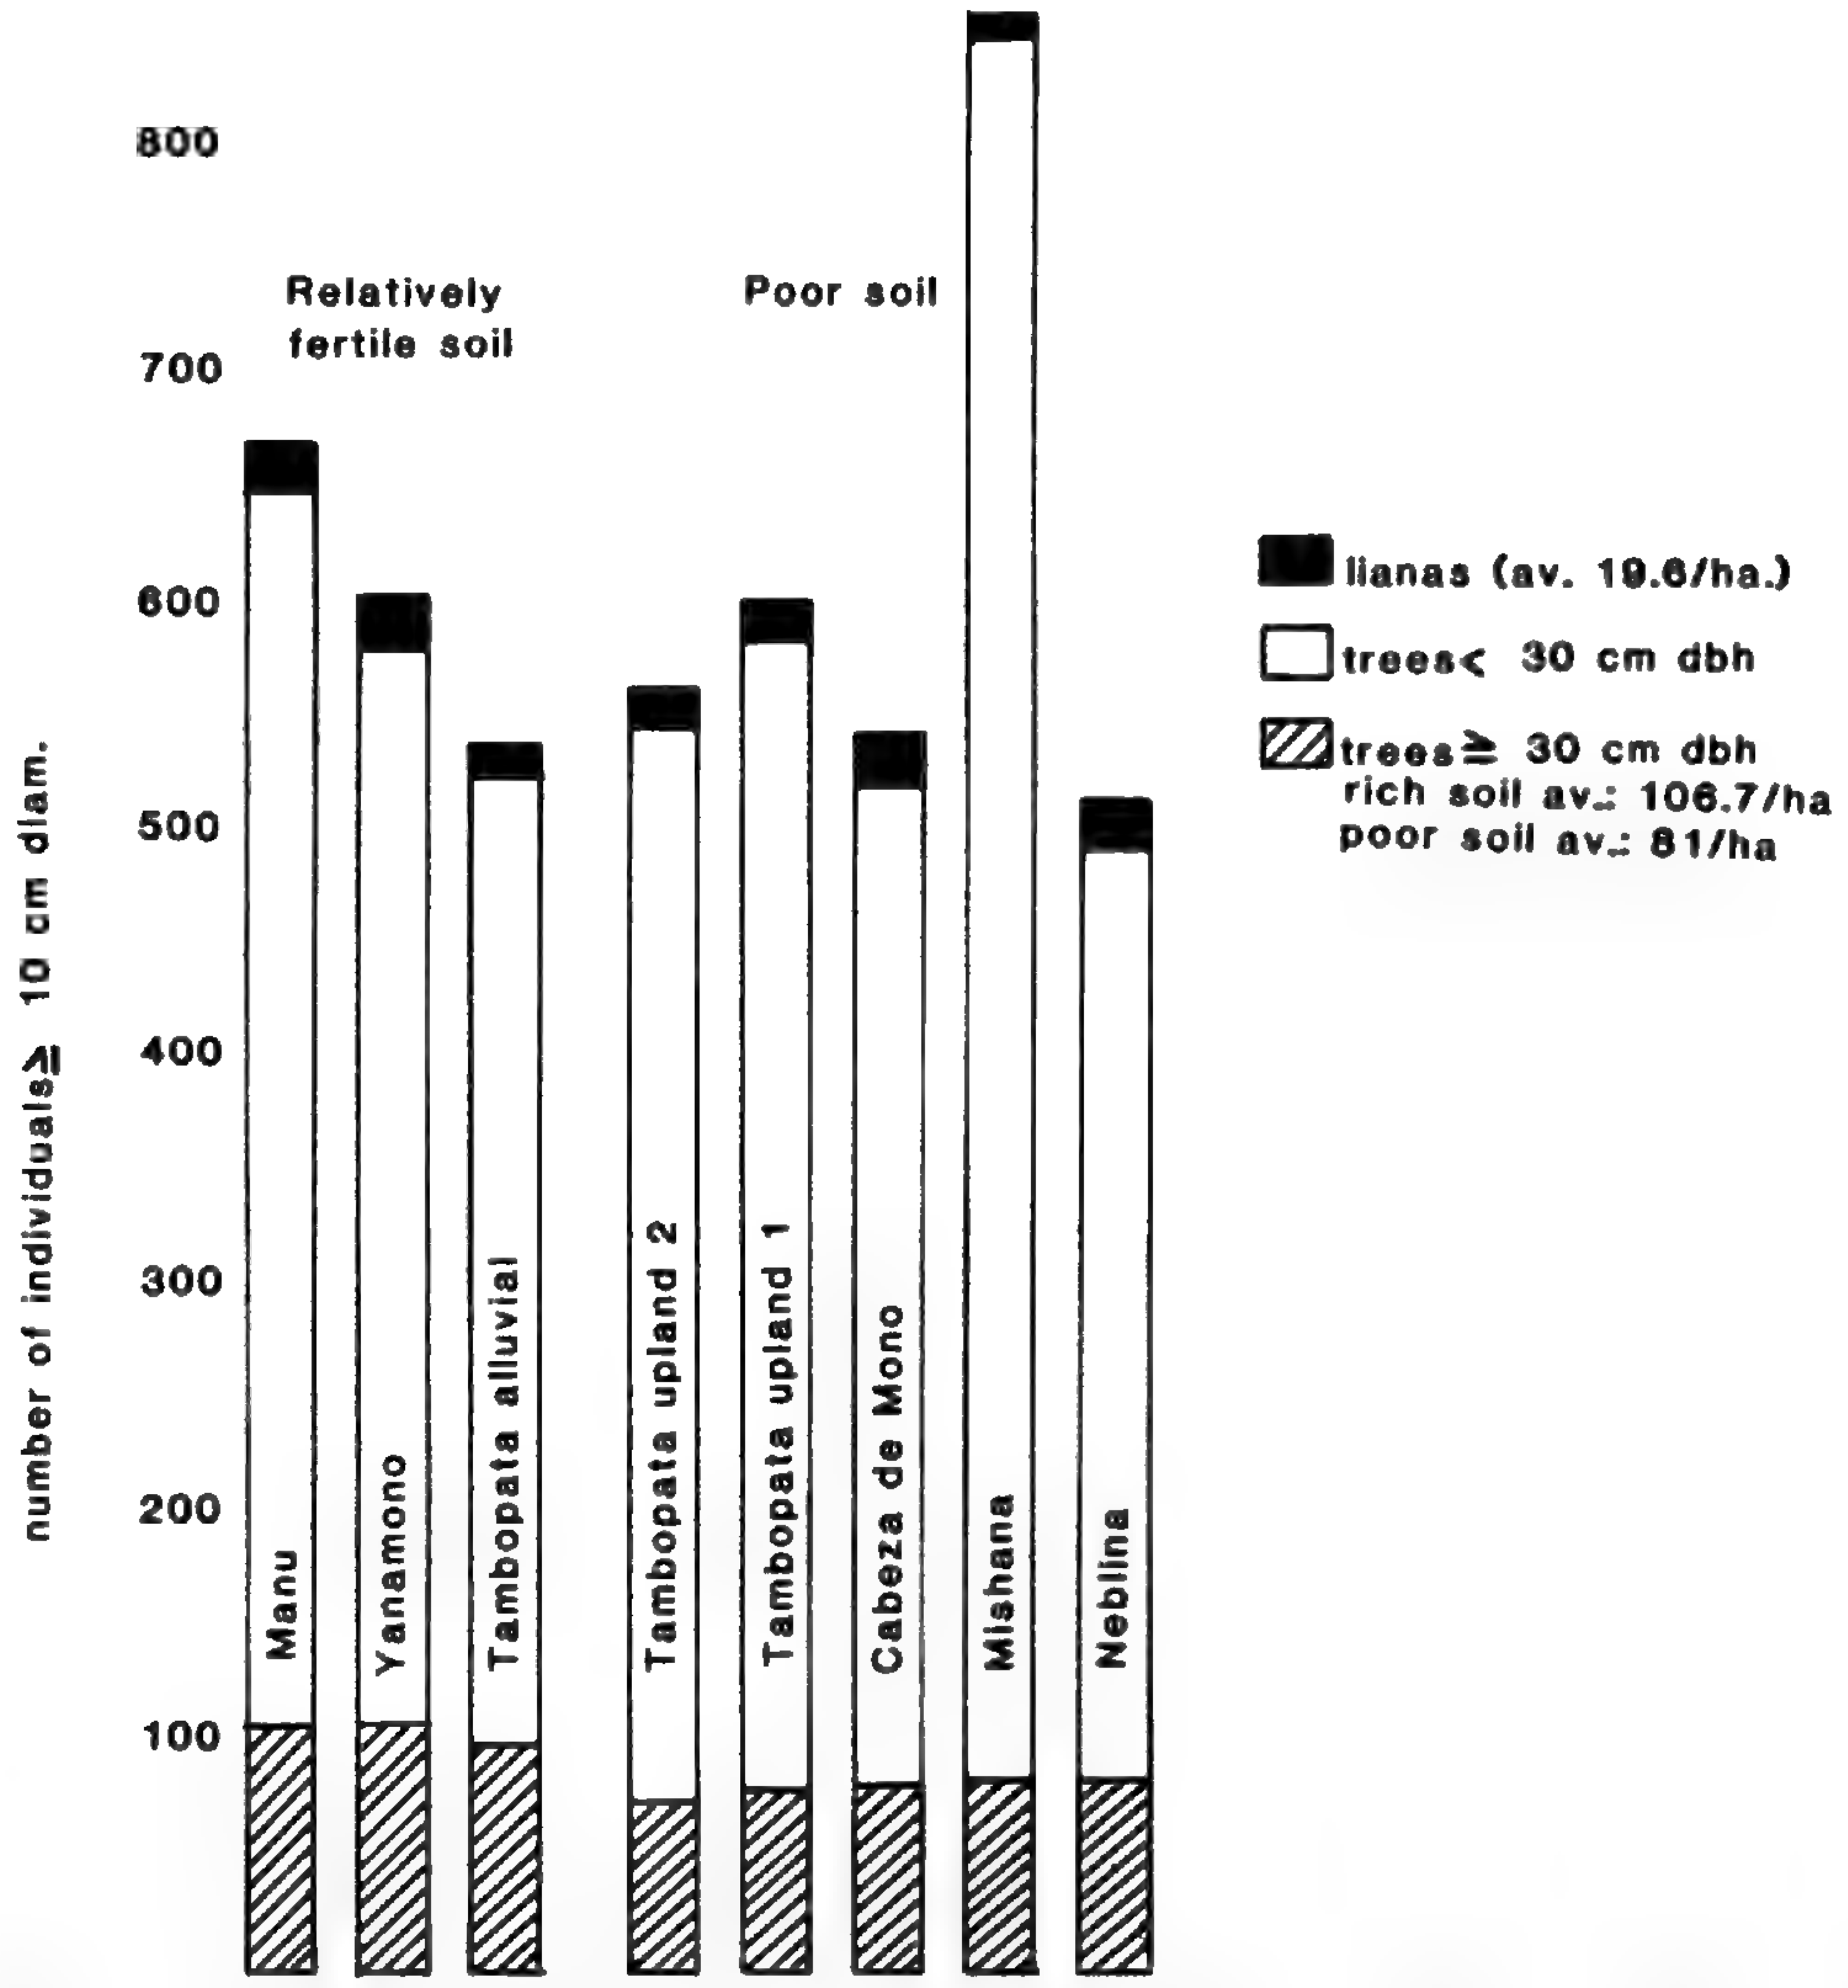

FIGURE 5. *Density of trees and large lianas in 1-ha Amazonian plots. Black = lianas; hatched = trees > 30 cm dbh; white = trees 10–30 cm dbh.*

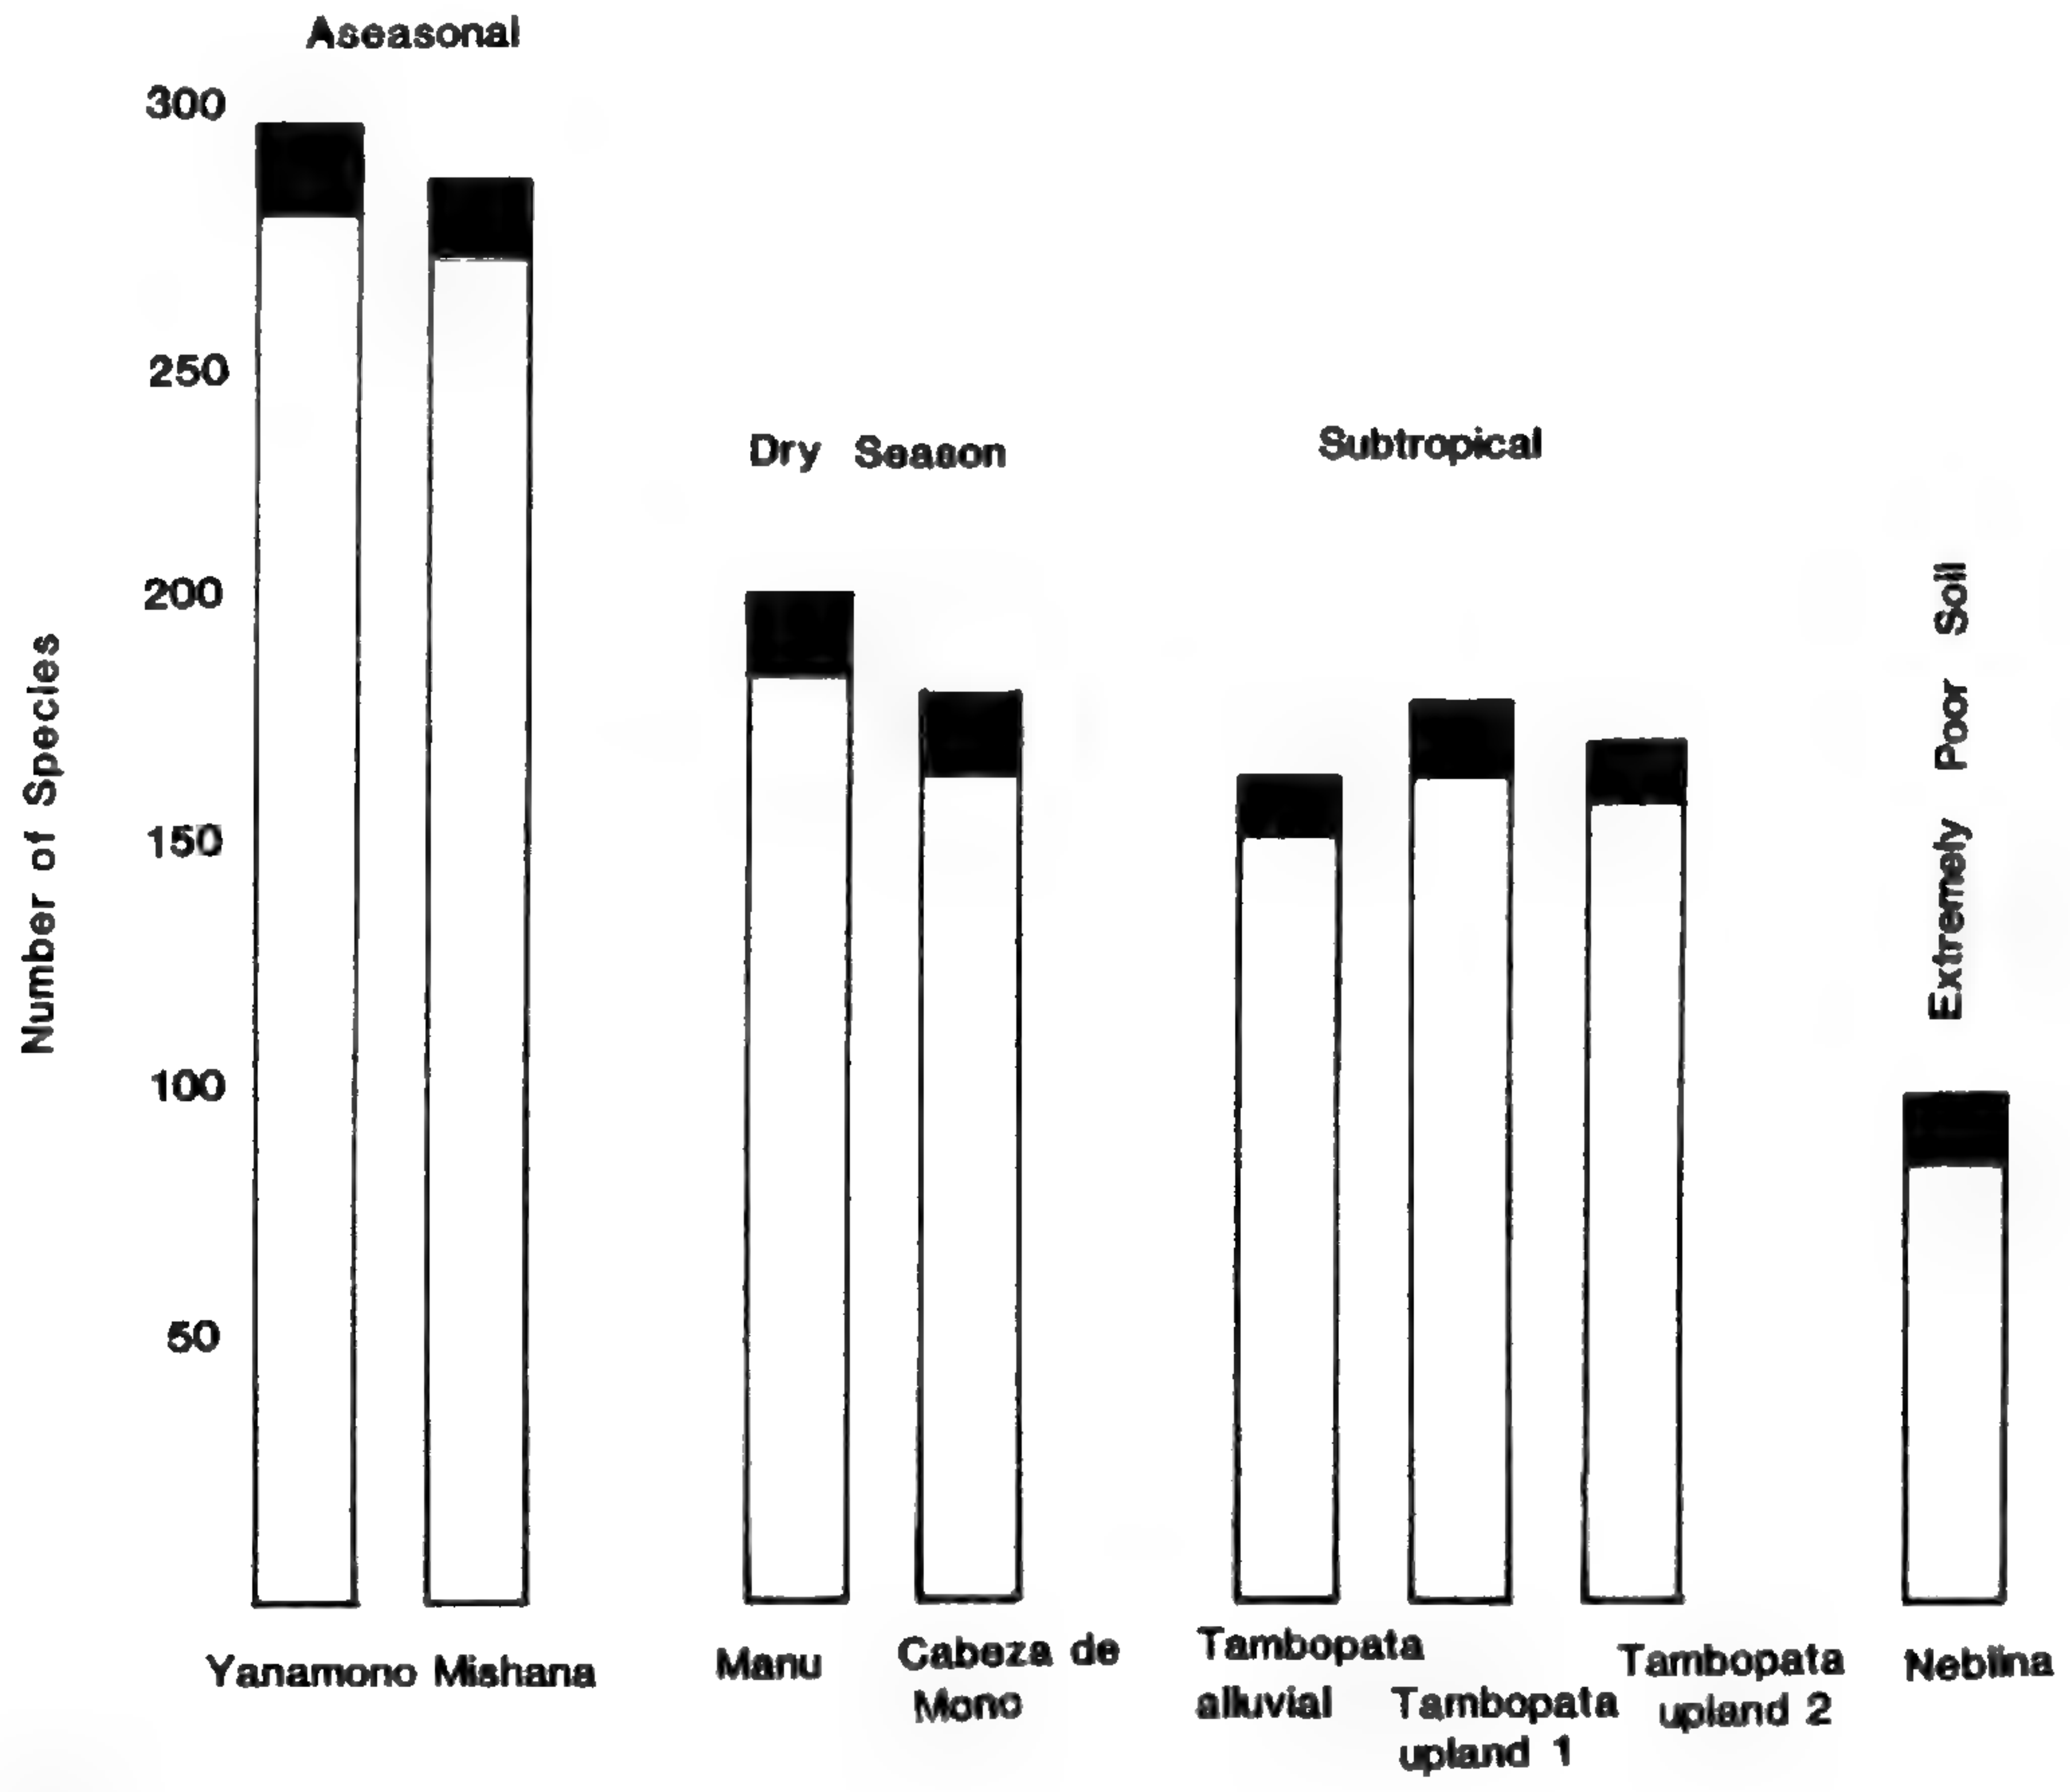

FIGURE 6. *Number of species in 1-ha Amazonian tree plots (plants ≥ 10 cm dbh). Black area = lianas ≥ 10 cm greatest diameter.*

tremes (Fig. 6). At Yanamono there are 300 species ≥ 10 cm in diameter out of the 606 individual plants in a hectare plot! The other 1-ha plots in Amazonian Peru are in areas with generally greater dry season stress and less overall precipitation. Two sites between 10° and 12°S latitude have about 200 species ≥ 10 cm dbh, while several 1-ha plots in different habitat types at Tambopata Reserve in southeastern Madre de Dios (12°50′S) have between 153 and 181 species. Thus tree species richness also appears to be greatest in aseasonal high rainfall areas, at least within Amazonia.

Epiphyte diversity likewise increases in wetter areas. While epiphytes can be well represented in areas with high atmospheric humidity but relatively low rainfall, our data indicate that absolute precipitation is generally a remarkably good predictor of epiphyte diversity (Gentry & Dodson, 1987b). We have data sets from a series of local florulas in western Ecuador and southern Central America; epiphytes vary from 9–24 species (2–4% of the total flora) in dry-forest sites to 72–216 species (12–16% of the total flora) in moist-forest sites to 238–368 species (23–24% of the total flora) in wet-forest sites (Gentry & Dodson, 1987a, b). For a series of 1,000 m^2 samples in which all plant species were identified and tabulated in three western Ecuadorian forests, 3 epiphytes constituted 2% of the species in a dry forest, 13 epiphytes constituted 8% of the species in a moist forest, and 127 epiphytes constituted 35% of the species in a wet forest (Gentry & Dodson, 1987b). The wet forest at Rio Palenque is so diverse in plant species that, even excluding tree species, it has more species of herbs (including herbaceous epiphytes) or of shrubs in 0.1 ha than any nontropical plant community in the world (Gentry & Dodson, 1987a).

DIVERSITY VS. SOIL NUTRIENTS

There has been much recent interest in the relationships between tropical soil nutrient levels and plant community richness (Ashton, 1977, in press; Gartlan et al., 1986). These authors suggest that phosphorus, magnesium, and potassium are among the nutrients whose levels are most strongly correlated with tropical plant community diversity. Nevertheless, at least in the Neotropics, soil nutrients are far less important than biogeographic factors or precipitation in determining plant species richness (Gentry, 1982b; Stark et al., submitted ms.). Multiple regression of a series of 31 lowland neotropical sites for which we have both soil and species richness data for 0.1-ha samples produced the equation: Species Richness = 84.48 + 0.025(mean annual precipitation) − 0.100(extractable soil K). $R^2 = 0.76$, N = 31 (Stark et al., submitted ms.).

Thus our data indicate that the nutrient most closely correlated with neotropical species richness is K. The importance of K agrees with what Ashton (1977, in press) found for a large series of tree plots in Borneo, Gartlan et al. (1986) also found available K to be highly and significantly correlated with floristic diversity in a series of sites in Cameroon. Our data contrast with those of Ashton (1977, in press) and Gartlan et al. (1986) in that we do not find phosphorus to be strongly correlated with diversity. This may be due in part to different techniques of nutrient extraction (ammonium acetate vs. HCl). It is also related to the fact that the most species-rich 0.1-ha sample (Bajo Calima, Colombia) comes from a peculiar white clay soil with 0 phosphorus as measured by our technique.

Whereas Ashton's (in press) data sets indicate greatest diversity at intermediate nutrient values, a "humped" nutrient/diversity curve that fits the model proposed by Tilman (1982, 1984), I see no indication in my data of a general decrease in diversity on richer soils in the Neotropics. Quite the contrary, the most species-rich tree plot in the world at Yanamono, Peru, is on relatively rich soil (Gentry, 1988; Stark et al., submitted ms.); further south, in an area with a strong dry season, the 0.1-ha Cocha Cashu sample on unusually rich alluvial soil is farther above the precipitation–diversity regression line than

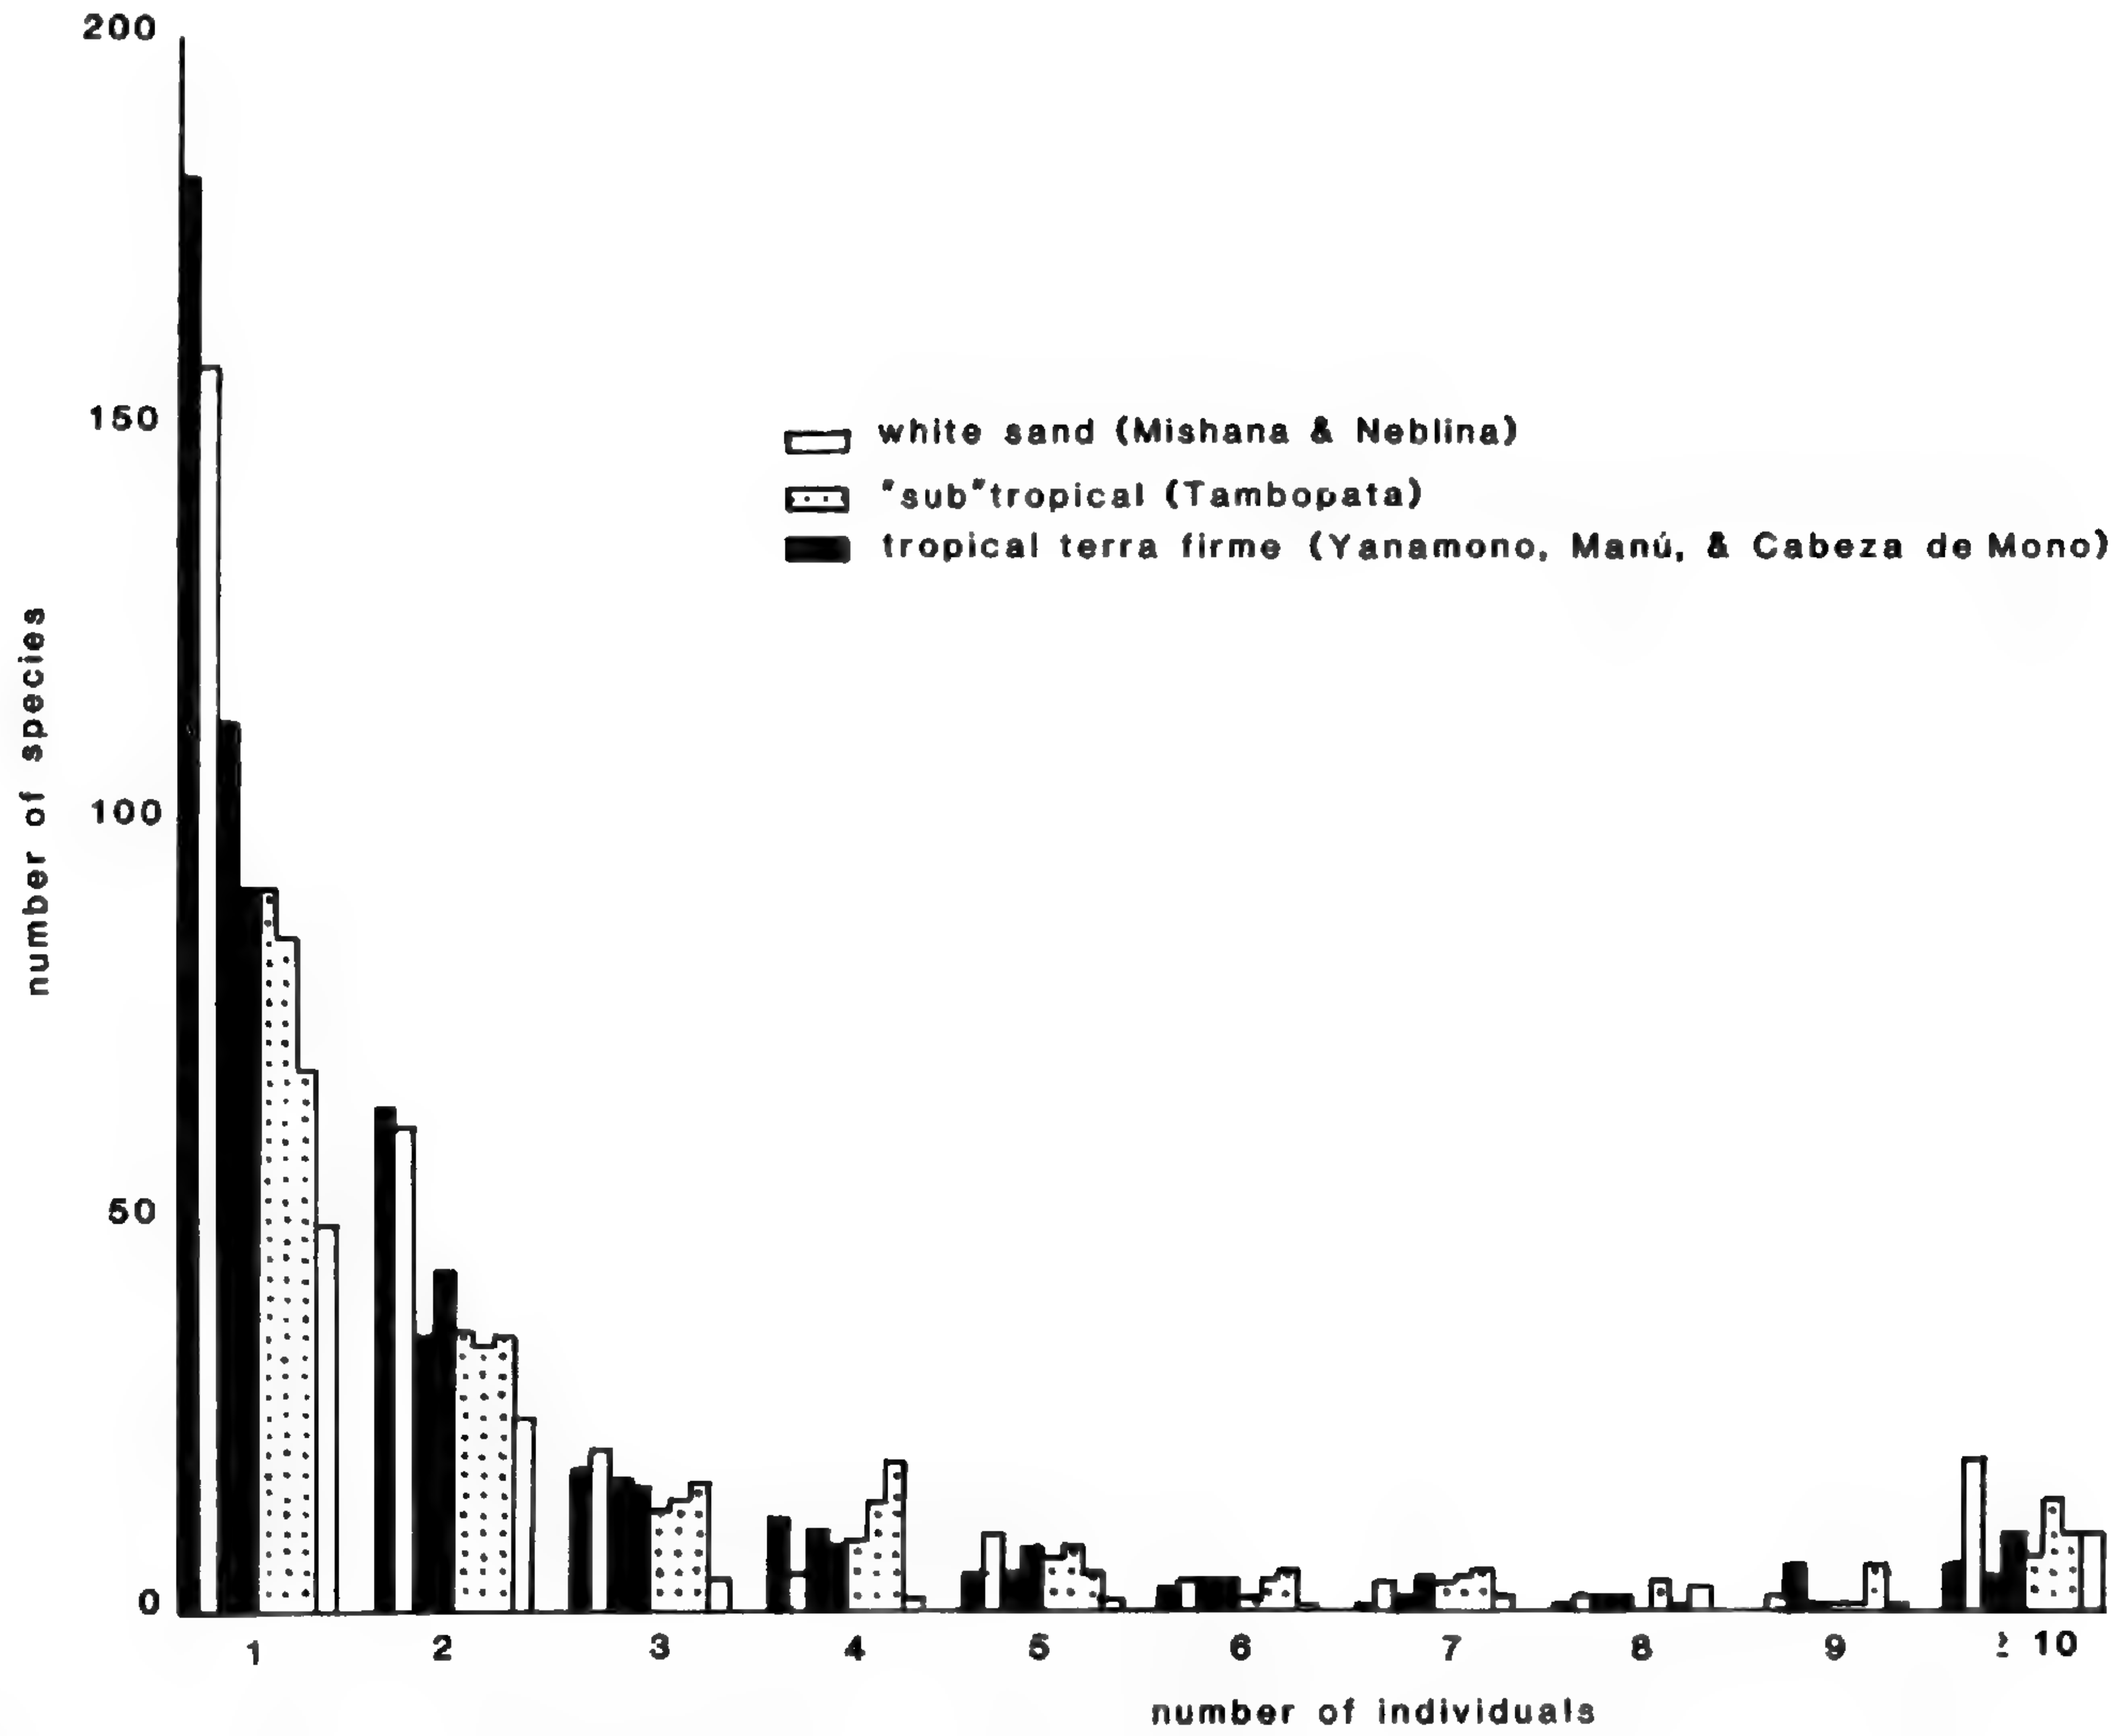

FIGURE 7. *Number of individuals/species in 1-ha Amazonian tree plots (plants ≥ 10 cm diam.).*

any other site (Gentry, 1985a). My data do fit well with Ashton's along the low nutrient end of the diversity–soil nutrient gradient, where there is a general increase in species richness from nutrient-poor to intermediate sites, contrary to the suggestions of Huston (1979, 1980).

Another way of comparing the effects of soil fertility on diversity is by comparing otherwise approximately matched site pairs on fertile and poor soils. The series of six tree plots in Amazonian Peru fall into three natural groups based on latitude and strength of the dry season (Gentry, 1988). Of the two plots in the everwet Iquitos area, one on rich soil has (marginally) more species than a nearby site on white sand; on a species per individual basis the difference would be much stronger (Figs. 7, 8). Of two sites from central Peru, the one on rich alluvial soil (Manú Park) has more species than one on poor soil (Iscozacin). Several plots at Tambopata south of the Holdridge system tropical–subtropical demarcation have fewer species than the full-tropical ones on either rich or poor soils. Moreover, the site with the most nutrient-poor soil of all, Cerro Neblina, on pure white sand, has many fewer species than do any of the other sites. Thus the Amazonian tree plot data generally support the idea that relatively rich soil correlates with relative richness in tree species.

Especially noteworthy in the context of the relative importance of soil nutrients and precipitation as determinants of species richness is the series of 0.1-ha samples from different substrates in the Iquitos area (Table 3). All of the sites have the high species richness (168–212 species) that would be expected (Gentry, 1982b) in a region with high rainfall and no dry season. While samples from the forests subjectively judged likely to be subjected to greater stress (i.e., seasonally inundated tahuampa or white-sand campinarana) have slightly lower species richness, all

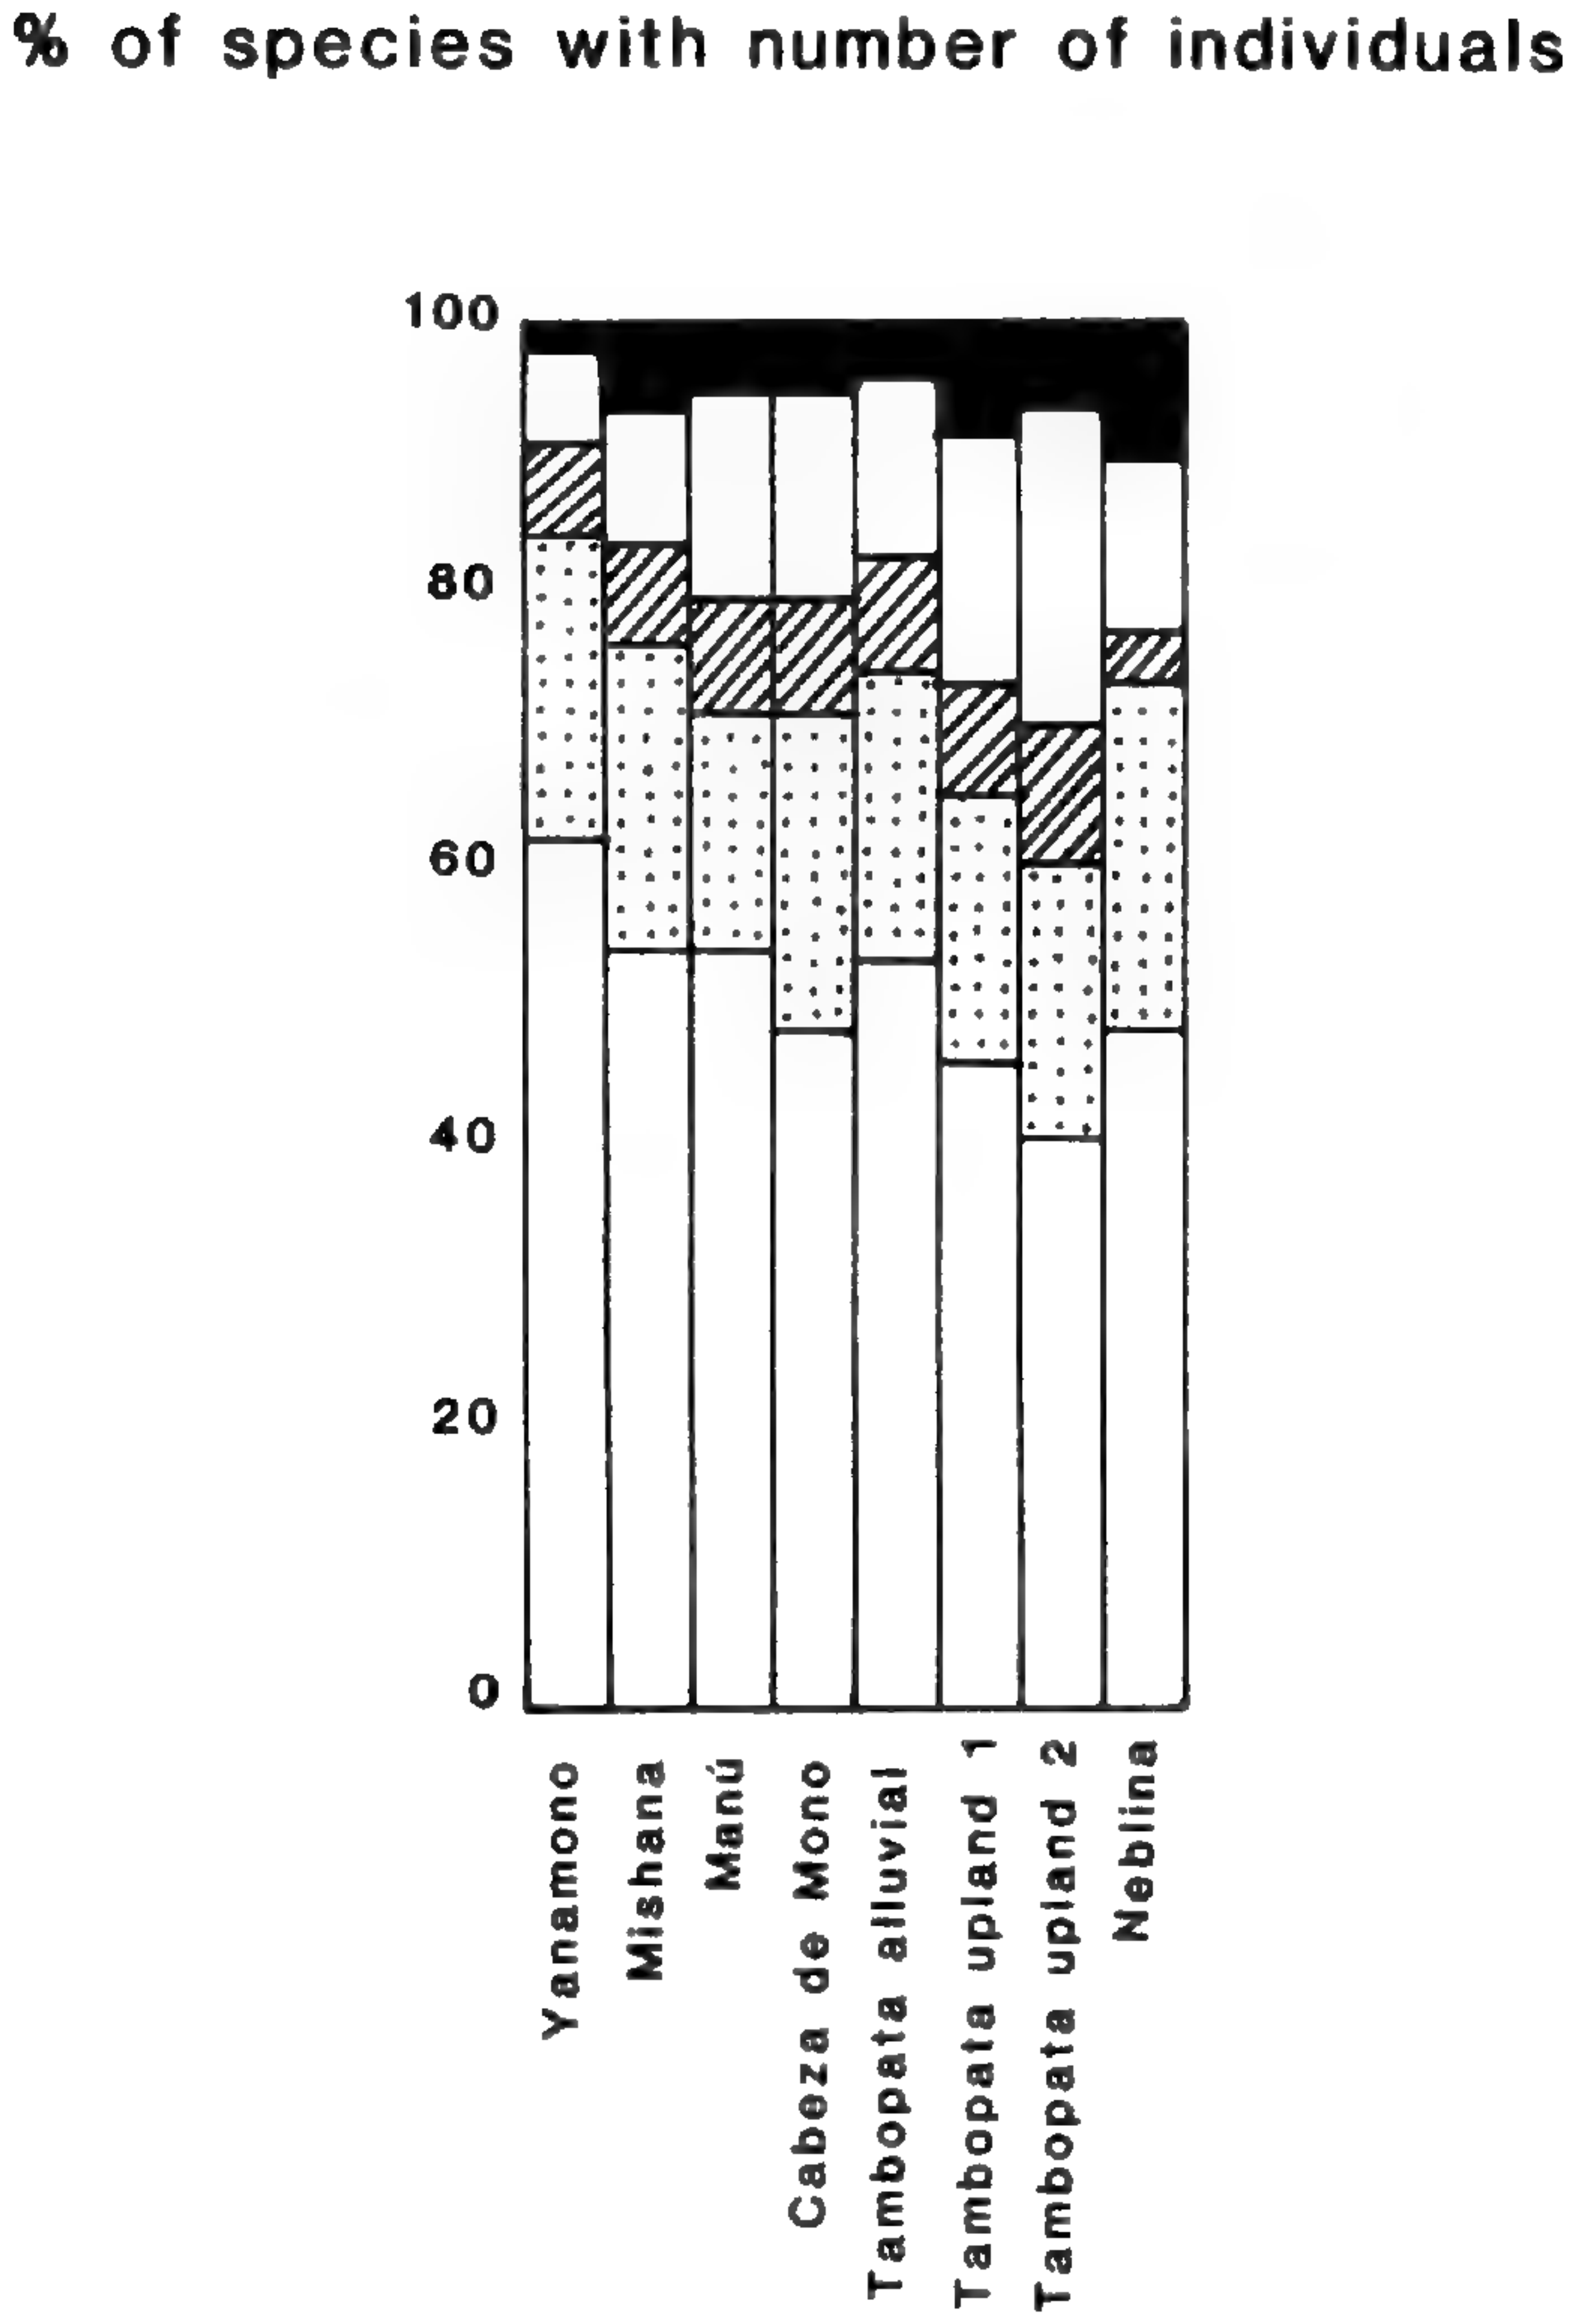

FIGURE 8. *Percent of species with different numbers of individuals in Amazonian tree plots (plants ≥ 10 cm diam.). Lower white bar = 1 individual; dotted bar = 2 individuals; hatched bar = 3 individuals; black bar = 10 or more individuals. Note that an average across all plots of 50% of the species are represented by single individuals.*

sites are very diverse compared with moisture-stressed sites with a strong dry season or low annual precipitation.

I conclude that the species richness of neotropical plant communities generally increases with soil fertility and with precipitation, when such broader-scale biogeographic factors as latitude and altitude are controlled. This relationship would predict that the highest neotropical α-diversities should be found in upper Amazonia, where the soils are relatively rich, compared with those of comparably high rainfall areas of the Guayana Shield. My data for 0.1-ha samples and for 1-ha tree plots both appear to fit this prediction. Moreover, many other kinds of organisms, including birds, reptiles and amphibians, butterflies, and bats, appear to show excactly the same pattern of greatest diversity in areas with relatively fertile soils near the base of the Andes, suggesting that this relationship is a general biogeographic trend (Gentry, 1988). It is possible that increased productivity on the generally richer soils of this region makes possible finer niche partitioning and specialization in otherwise marginal habitats (cf. Emmons, 1984; Gentry & Emmons, 1987).

Even though the effect of soil nutrients on α-diversity may be relatively minor, soil nutrients undoubtedly do play a major role in contributing to the high overall diversity of Amazonian forests through their effect on β-diversity (e.g., Gentry, 1981, 1986a, c). Much of upper Amazonia, probably more than any other part of the lowland Neotropics, constitutes a conspicuous habitat mosaic, with very different sets of plant species occurring in adjacent communities on different substrates (Salo et al., 1986; Gentry, 1986a, c). Table 3 shows how little overlap in species there is between different, more or less equally diverse plant communities on different substrates in the Iquitos area. Only 3–24 species

out of the ca. 200 species sampled for any habitat are shared by a different adjacent habitat. The one exception is the Mishana white-sand and floodplain samples (55 species overlap), but these two vegetation types have similar substrates and are not very well differentiated. While some of this lack of overlap might be due to inadequacy of the sampling technique in such diverse plant communities, a repeat sample of the same forest at Yanamono gave a much greater, almost 50% overlap in species; in other species-rich moist and wet forests similar repeat samples of the same vegetation always give the same ca. 50% overlap in sampled species (Gentry, 1982b), contrasting strongly with the ≤ 20% overlaps between different communities. Similarly, for two 1-ha tree plots on terra firme forest on poor sandy soil at Tambopata, 83 species (46% of the 181 species in plot 1 and 48% of the 172 species in plot 2) were shared with the other plot, for a coefficient of association of 44%. Only 16–18% of the species of either poor soil plot were shared with a nearby tree plot on rich alluvial soil (coefficients of correlation of 10–11%) (Fig. 9). Incompletely analyzed data for additional plots in other forest types at Tambopata indicate that they, too, will show little overlap in species with sandy soil or alluvial forests. The uniquely high species richness of the Tambopata reserve for such well-known groups as birds (Donahue et al., in press) and butterflies (Lamas, 1985) has been suggested as largely due to the reserve's habitat diversity, a conclusion that clearly accords with the botanical evidence.

Thus the high species richness of woody plants in Amazonia as compared with the rest of the Neotropics (Gentry, 1982a) is largely β-diversity due to habitat specialization. Typically, related species may fill similar niches in forests on different upper Amazonian substrates (Gentry, 1981, 1986c). Dramatic differences in specific composition, though not intracommunity diversity, accompany spe-

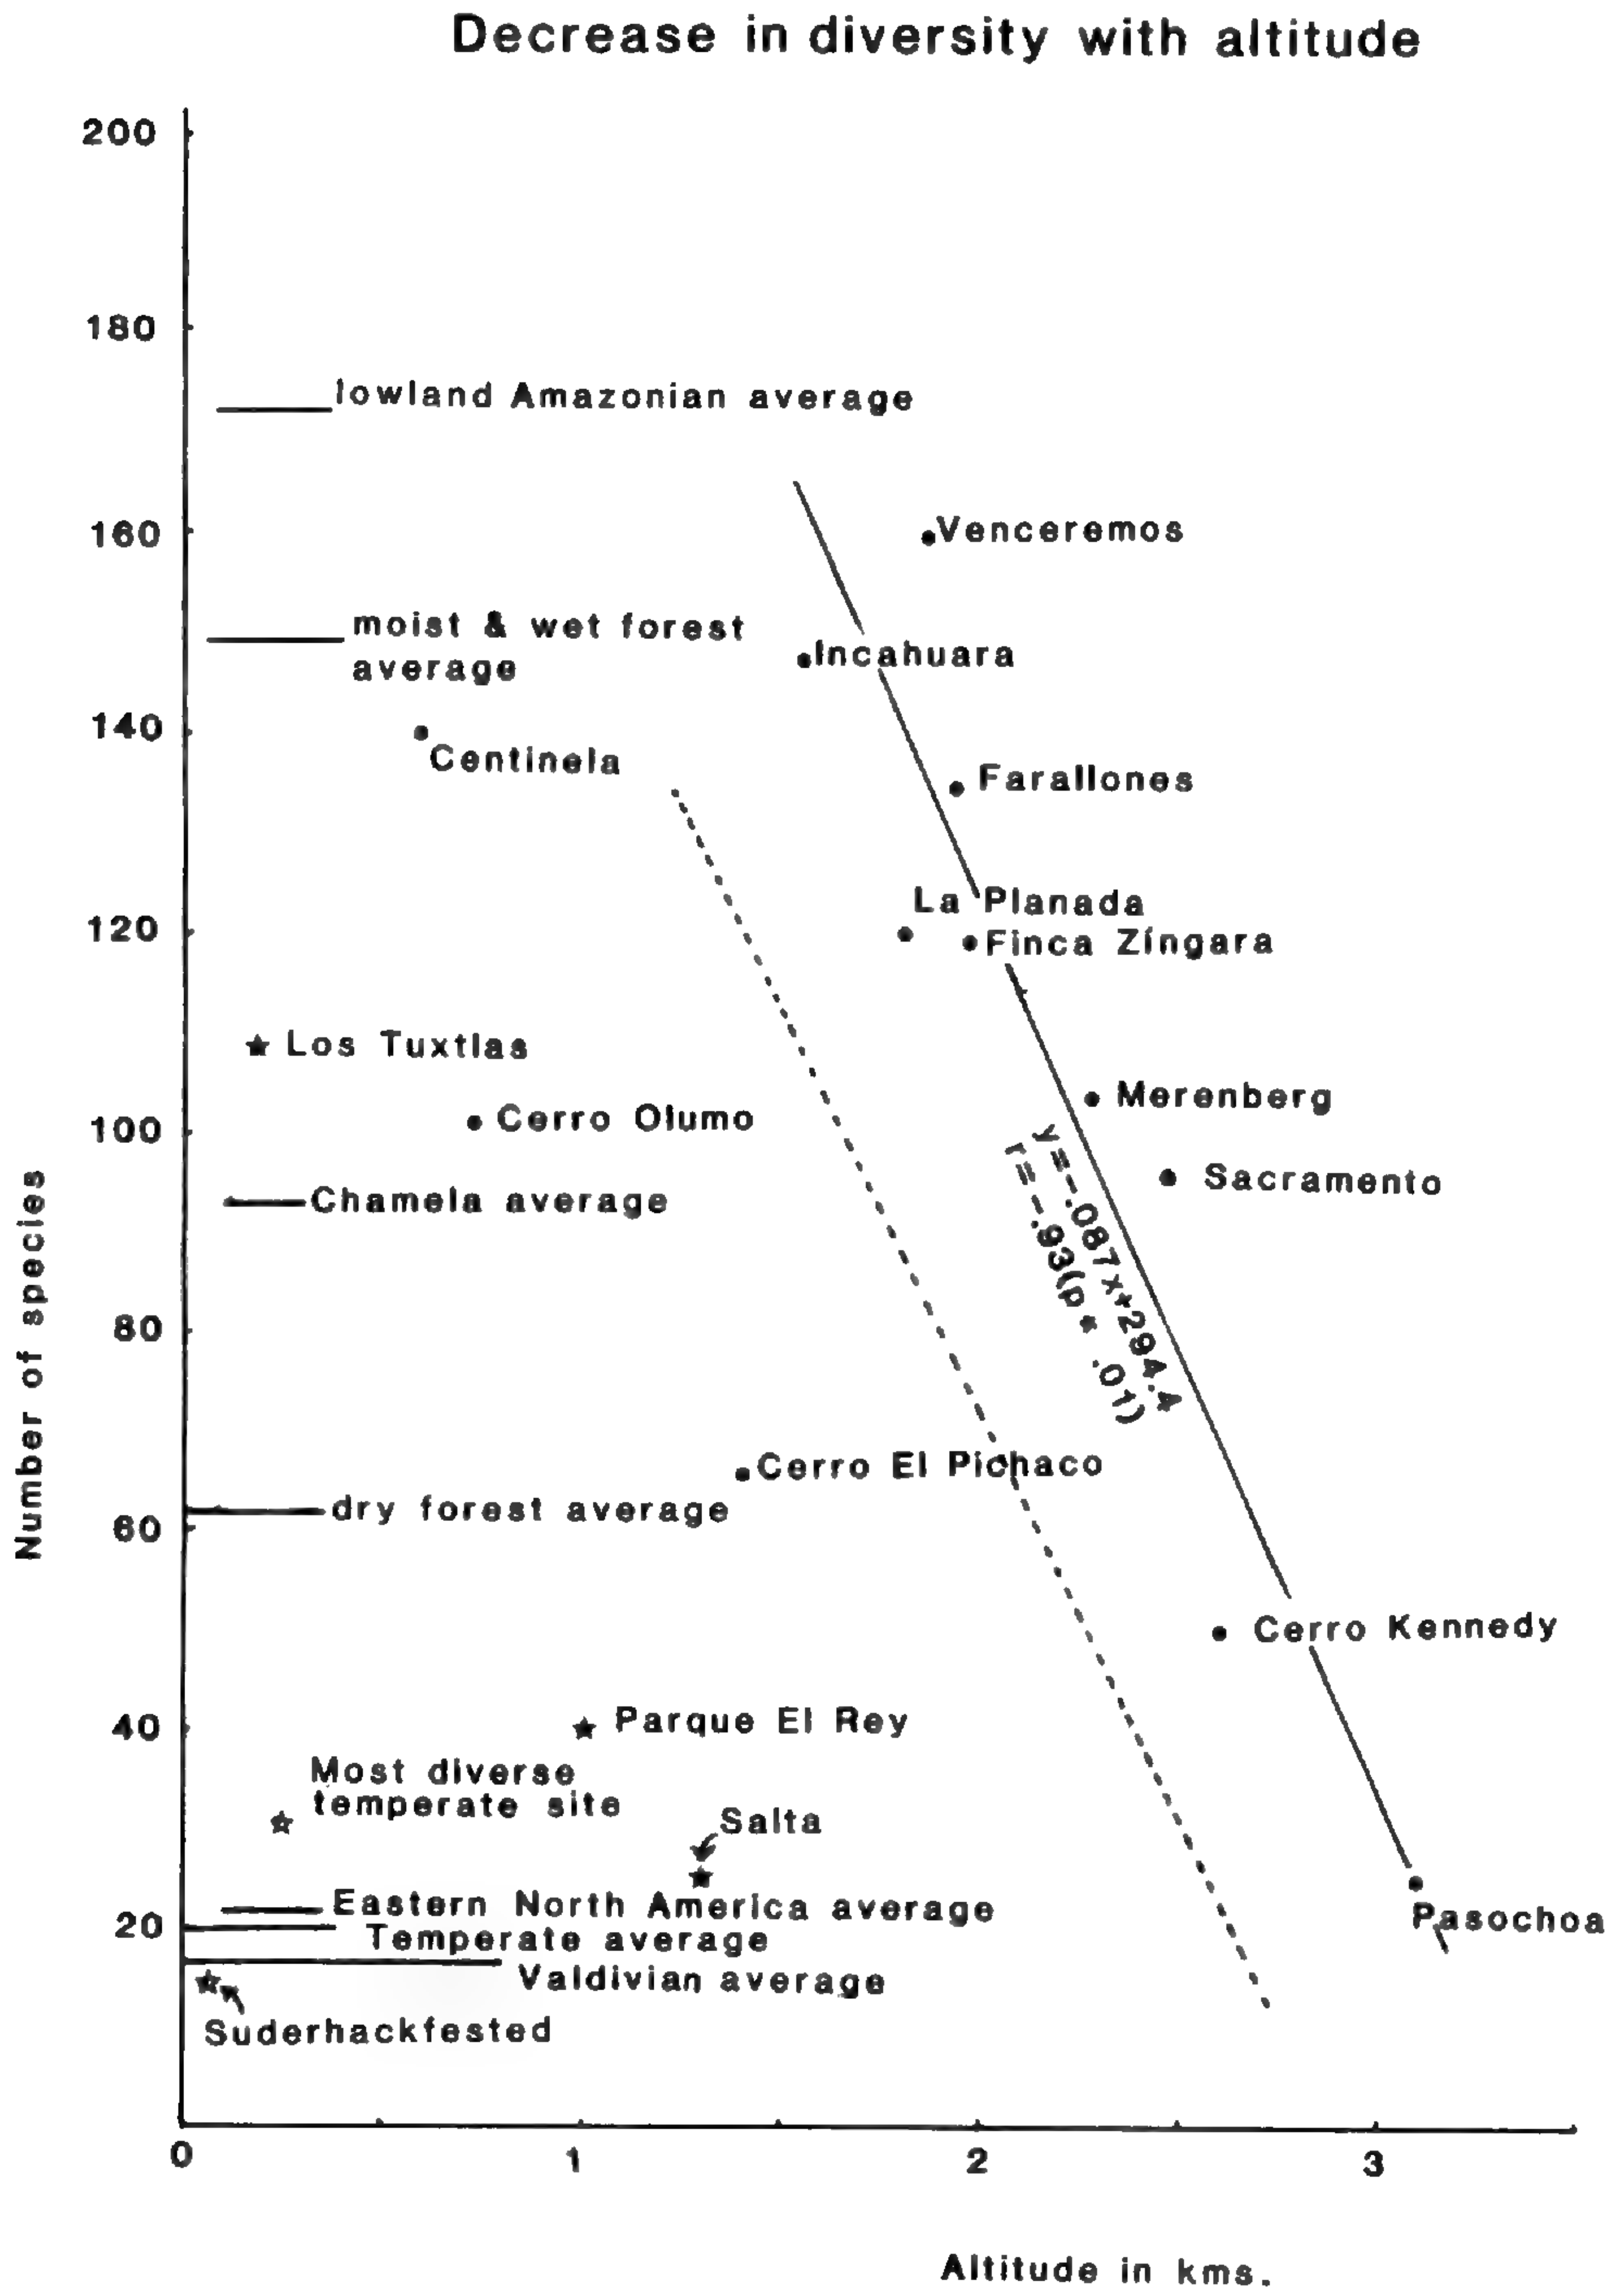

FIGURE 10. *Species richness of 0.1-ha samples vs. altitude. Points to right of dashed line and the calculated regression are for Andean sites. Comparative data from other selected sites to left of dashed line. Stars are for individual temperate and subtropical sites: Süderhackfestedt is in Germany; Salta and Parque El Rey are in northwest Argentina; Los Tuxtlas is in Veracruz, Mexico; Cerro Olumo and Cerro El Pichaco are in Nicaragua; Centinela is an isolated ridge west of the Andean Cordillera Occidental in Ecuador. cializations for different edaphic conditions, often related to different soil-nutrient availability in different Amazonian habitats.

ALTITUDINAL TRENDS

Eleven sites in tropical forests between 1,500 and 3,100 m altitude, mostly in the Andes, are included in Table 2. Although the available data set for upland sites is very incomplete, the trend of decreasing diversity with increasing altitude is clear. At least within the Andes, this inverse correlation is linear (Fig. 10), but the relatively low diversity of two Central American lower montane sites suggests that the extra-Andean decrease in diversity with altitude may not follow the same rules; certainly Central American montane forests have very different floristic compositions as well. Although there has been much

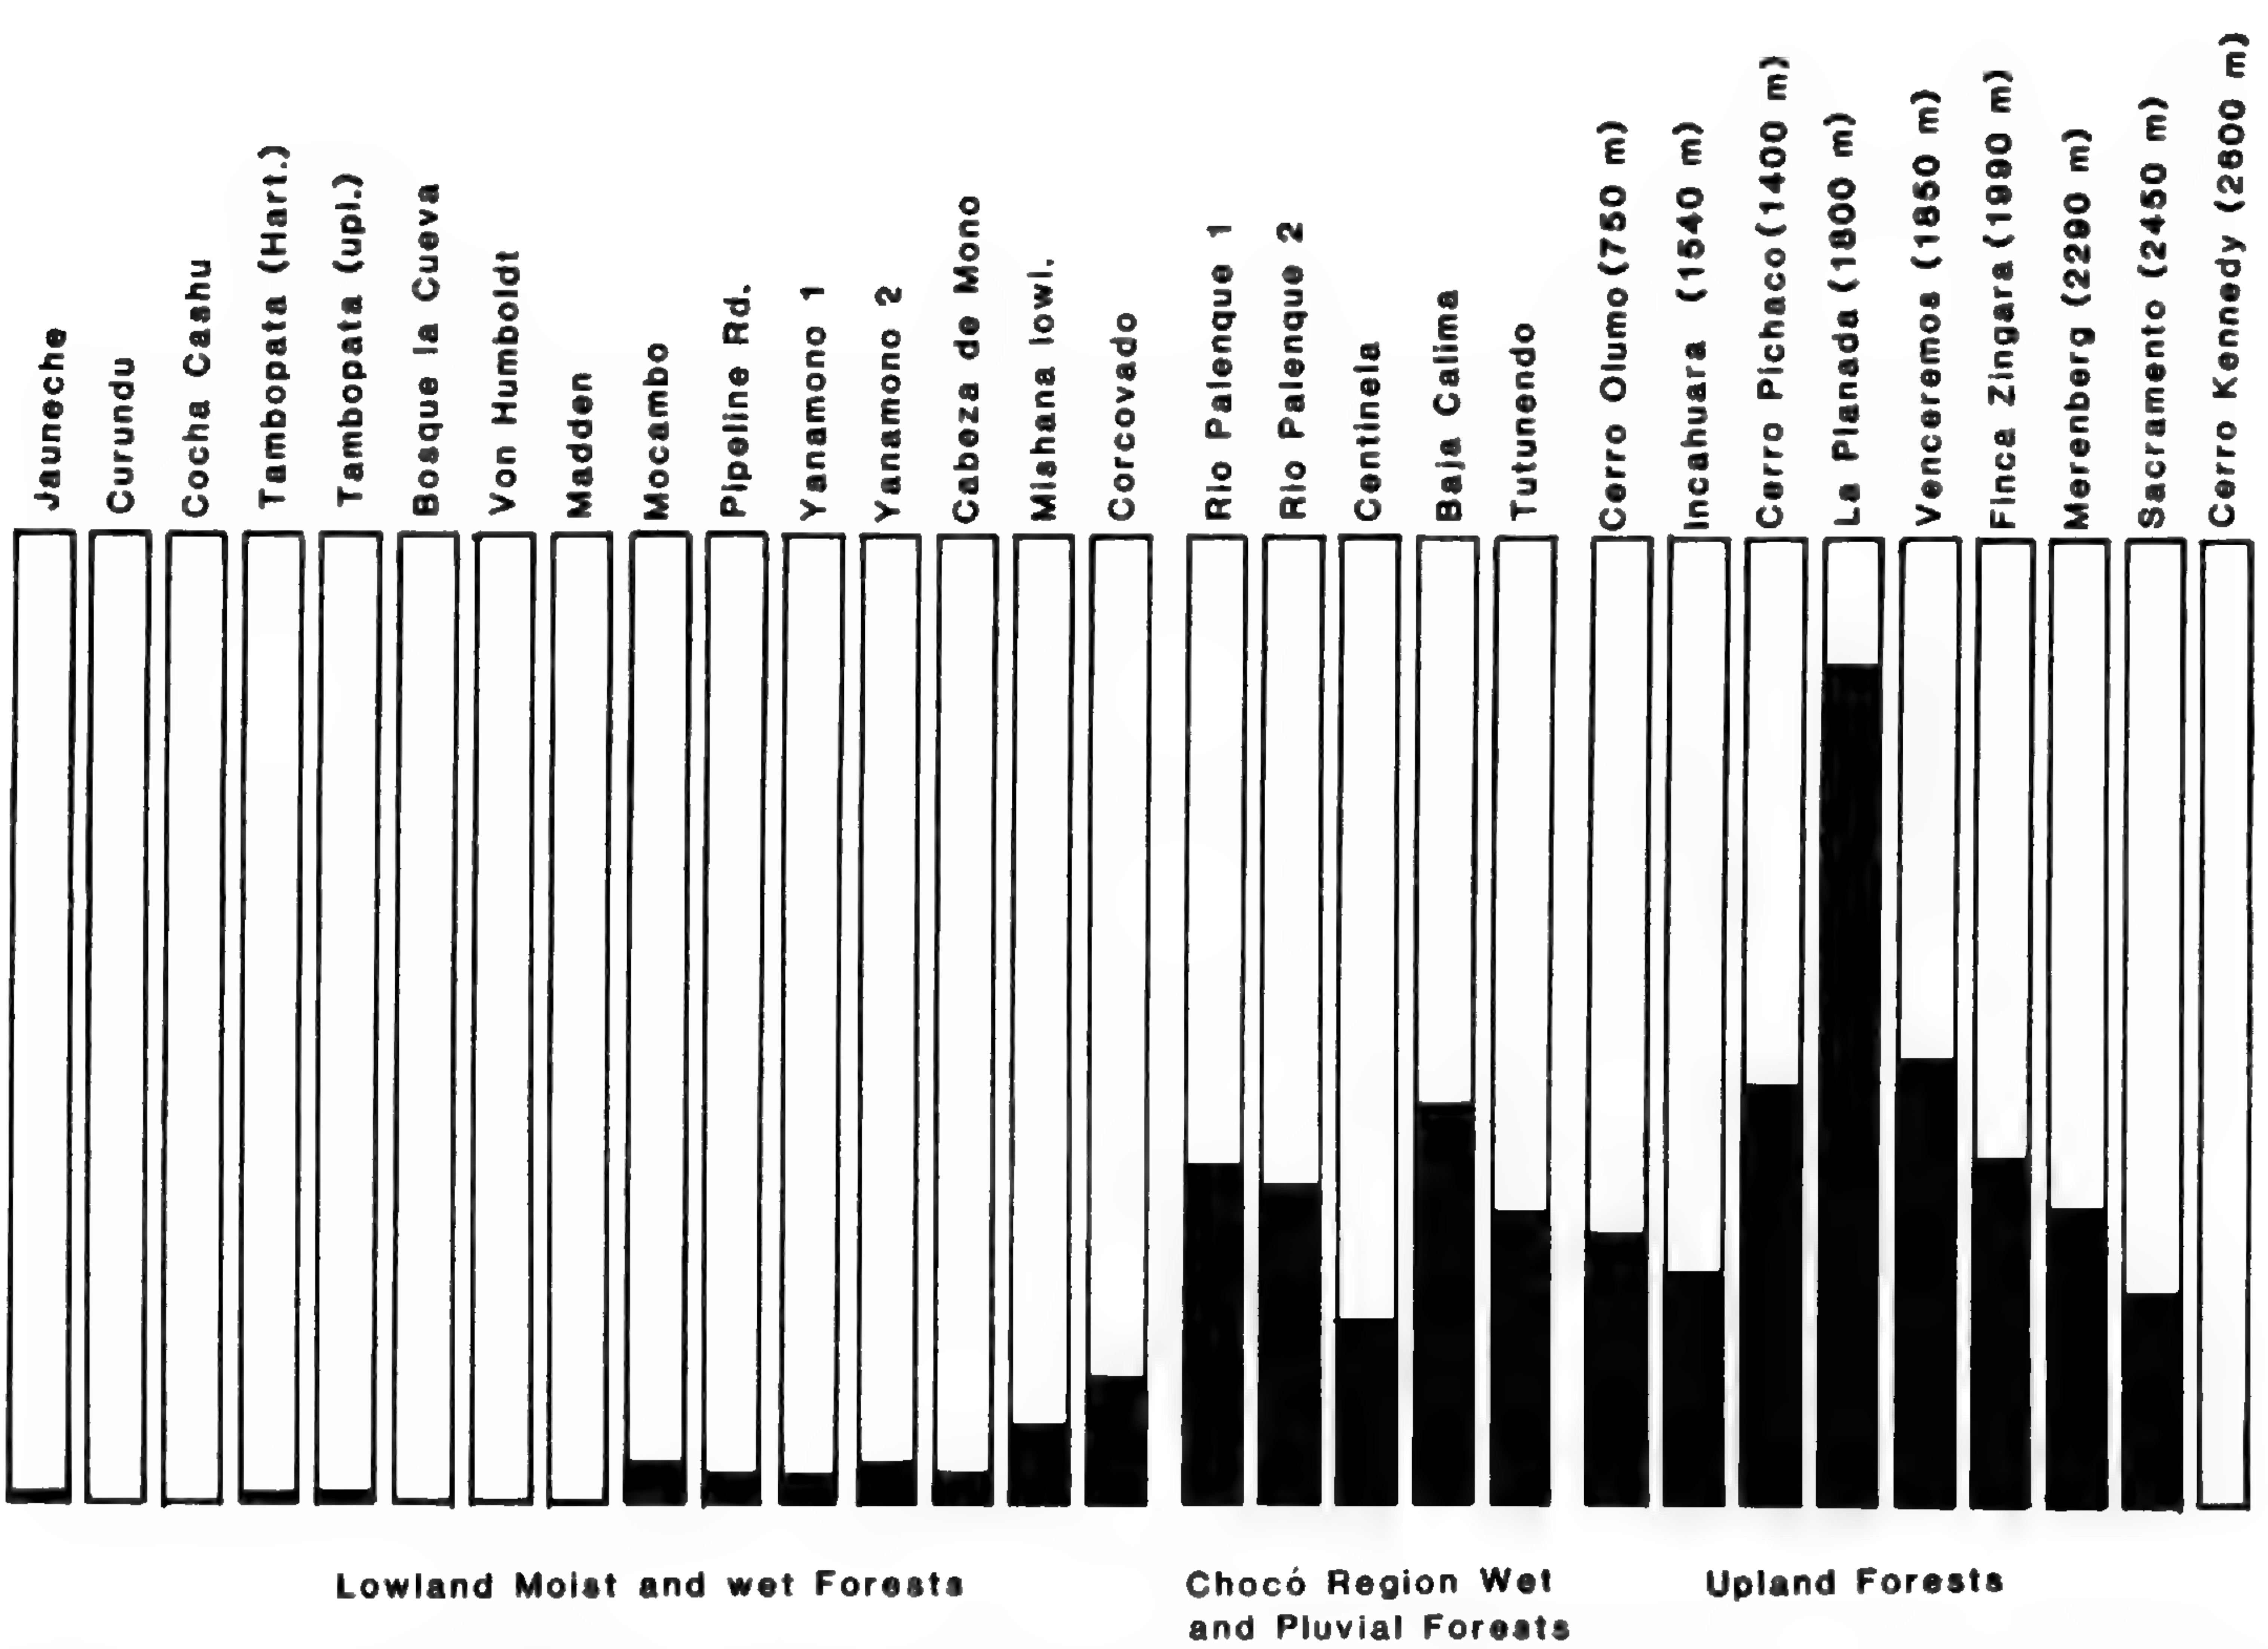

FIGURE 11. *Percent of hemiepiphytes (black portion of bar) in sampled climbers for 0.1-ha samples of upland forests (in altitudinal sequence) compared with lowland Chocó area and non-Chocó area samples. Note apparent peak in hemiepiphytes at 1,800 m.*

speculation in the literature about a "mid-altitude bulge" in diversity (Janzen, 1973; Janzen et al., 1976; Scott, 1976; Gentry & Dodson, 1987b), there is no hint of such a phenomenon in the data of Figure 10. Instead, there seems to be a constant rate of decreasing species richness in moist Andean forests from the lowland tropics to near tree line. Unfortunately, no sites have been sampled from the Andean foothill region between 600 and 1,500 m, making it difficult to judge at what altitude the decrease in diversity begins. Clearly there is no altitudinal effect up to at least 500 m (Cocha Cashu, Peru; see Gentry, 1985a). Since samples from sites at 1,700 m would be near the average value for lowland wet- and moist-forest sites (Fig. 10), we can assume that there is little or no decrease in diversity up to that altitude.

Although there is no increase in diversity at middle elevations, there are some noteworthy physiognomic changes. One of the most striking is the increase in sampled hemiepiphytes around 1,800 m (Fig. 11). However, since increased numbers of hemiepiphytic species (and individuals) are concomitant with decreased numbers of free-climbing liana species and individuals, there is no net change in community diversity. Also noteworthy is the relative abundance of hemiepiphytic climbers in wet lowland sites in the Chocó area, a typical example of the tendency of the forests of this region to have features and taxa more characteristic of upland forests (Fig. 11; Gentry, 1986b). At higher altitudes free-climbing lianas take over again, so that at 2,500 m and above, hemiepiphytes have completely dropped out.

Even near the tree line above 3,000 m, Andean forests are more species rich than are temperate forests. Our highest-altitude sample, from 3,010 m at Pasochoa in the Ecuadorian Andes, has 25 species compared with only 21–30 species in the richest 5% of

SOME INTERCONTINENTAL DIVERSITY TRENDS

At a continental level, the Neotropics have many more species of plants than do either the Asian or Australasian tropics (Raven, 1976; Prance, 1977; Gentry, 1982a). Elsewhere, I have suggested that the "excess" neotropical species are mostly in herbaceous, epiphytic, and shrub taxa that have speciated explosively along the lower slope of the Andes and in southern Central America. To what extent, if any, does higher α-diversity of neotropical forests contribute to the continental pattern?

While I have relatively few comparable paleotropical data sets, a few general trends seem evident. One surprising indication from the available African data is that Central African forests ($\bar{X}$ = 127 spp., N = 5) may be as diverse in species ≥ 2.5 cm dbh as their neotropical equivalents ($\bar{X}$ = 105 spp., N = 9) for sites with 1,600–2,000 mm of precipitation. Even though the two high-rainfall sites in Cameroon do not show the increases in species richness that might be expected in the Neotropics, they are still very diverse, and the drier Gabon samples actually have more species than would be expected for similar rainfall values in the Neotropics. Moreover, one of the high rainfall sites with anomalously low diversity (Mt. Cameroon) is on the slopes of an active volcano, and the other (Korup) is on an unusually poor, highly leached skeletal soil (Thomas, pers. comm.).

West African forests, including Nigeria's Omo Forest in my data set and the Ghana forests studied by Hall & Swaine (1981), may be poorer in species for historical reasons since there are suggestions that most West African forests may have been extensively altered by Bantu populations prior to the first European colonization (Keay, 1953; Jones, 1956). Even though my anomalously low diversity Omo Forest site was in a plot of protected forest considered to be climax (though surrounded by a mosaic of other plots subjected to varying degrees of degradation historically) (G. Pilz, pers. comm.), a number of its constituent species, such as *Pausinystalia macroceras*, *Spathodea campanulata*, *Markhamia lutea*, and *Musanga cecropioides*, seem more characteristic of late secondary than of primary forest.

Nor is the high diversity of Central African forests restricted to woody plants. Data comparable to a complete local florula are available for one African forest site at Makokou, Gabon (Hladik & Halle, 1973; Florence & Hladik, 1980; Hladik & Gentry, in prep.). Comparison of these data with local florulas from the Neotropics indicates that Makokou is not only as species rich as equivalent neotropical local florulas, but it also has a similar habit composition (Table 4; Gentry & Dodson, 1987b). Similarly, data from 1-ha tree plots indicate that African forests may be almost as rich in tree species as comparable neotropical and Southeast Asian forests (Gartlan et al., 1986; Thomas, pers. comm.: 138

TABLE 4. *Continued.*

Río Palenque		La Selva[a]		Makokou	
Number	%	Number	%	Number	%
238	23	368	25	66+	6+

165	16	310	21	389	34
475	45	622	42	418	37
1,055		1,490		1,140	

spp. in 0.64 ha on transect S, Korup National Park, Cameroon; Gentry, in press).

On the other hand, it is noteworthy that my single Madagascar site is richer in species than any of the continental African sites, which might be anticipated from the now widely accepted hypothesis that Africa's low continent-wide plant (and bird) species richness stems largely from extinctions associated with climatic deterioration during the Pleistocene or late Tertiary, whereas Madagascar was protected by being an island (Raven & Axelrod, 1974; Axelrod & Raven, 1978).

Quite the opposite of Africa, Asian forests have been widely thought to have more tree species than neotropical forests (e.g., Ashton, 1977; Whitmore, 1984). This conclusion was based on comparison of extant neotropical data for 1-ha tree plots with similar Asian data sets. However, the previously available neotropical tree plots were all from areas that would be anticipated on biogeographical or ecological grounds to have species-poor forests (Gentry, 1988). Hectare plots in upper Amazonia consistently have more tree species than in most Asian forests (Gentry, 1988), and the most species-rich 1-ha plots are in upper Amazonia. Indeed, these plots are so diverse—up to 300 species out of 606 individuals ≥ 10 cm diameter at Yanamono, Peru—that it is hard to imagine how a forest could be much more diverse.

I conclude that plant community diversity, at least of woody plants in plots of 1 ha or

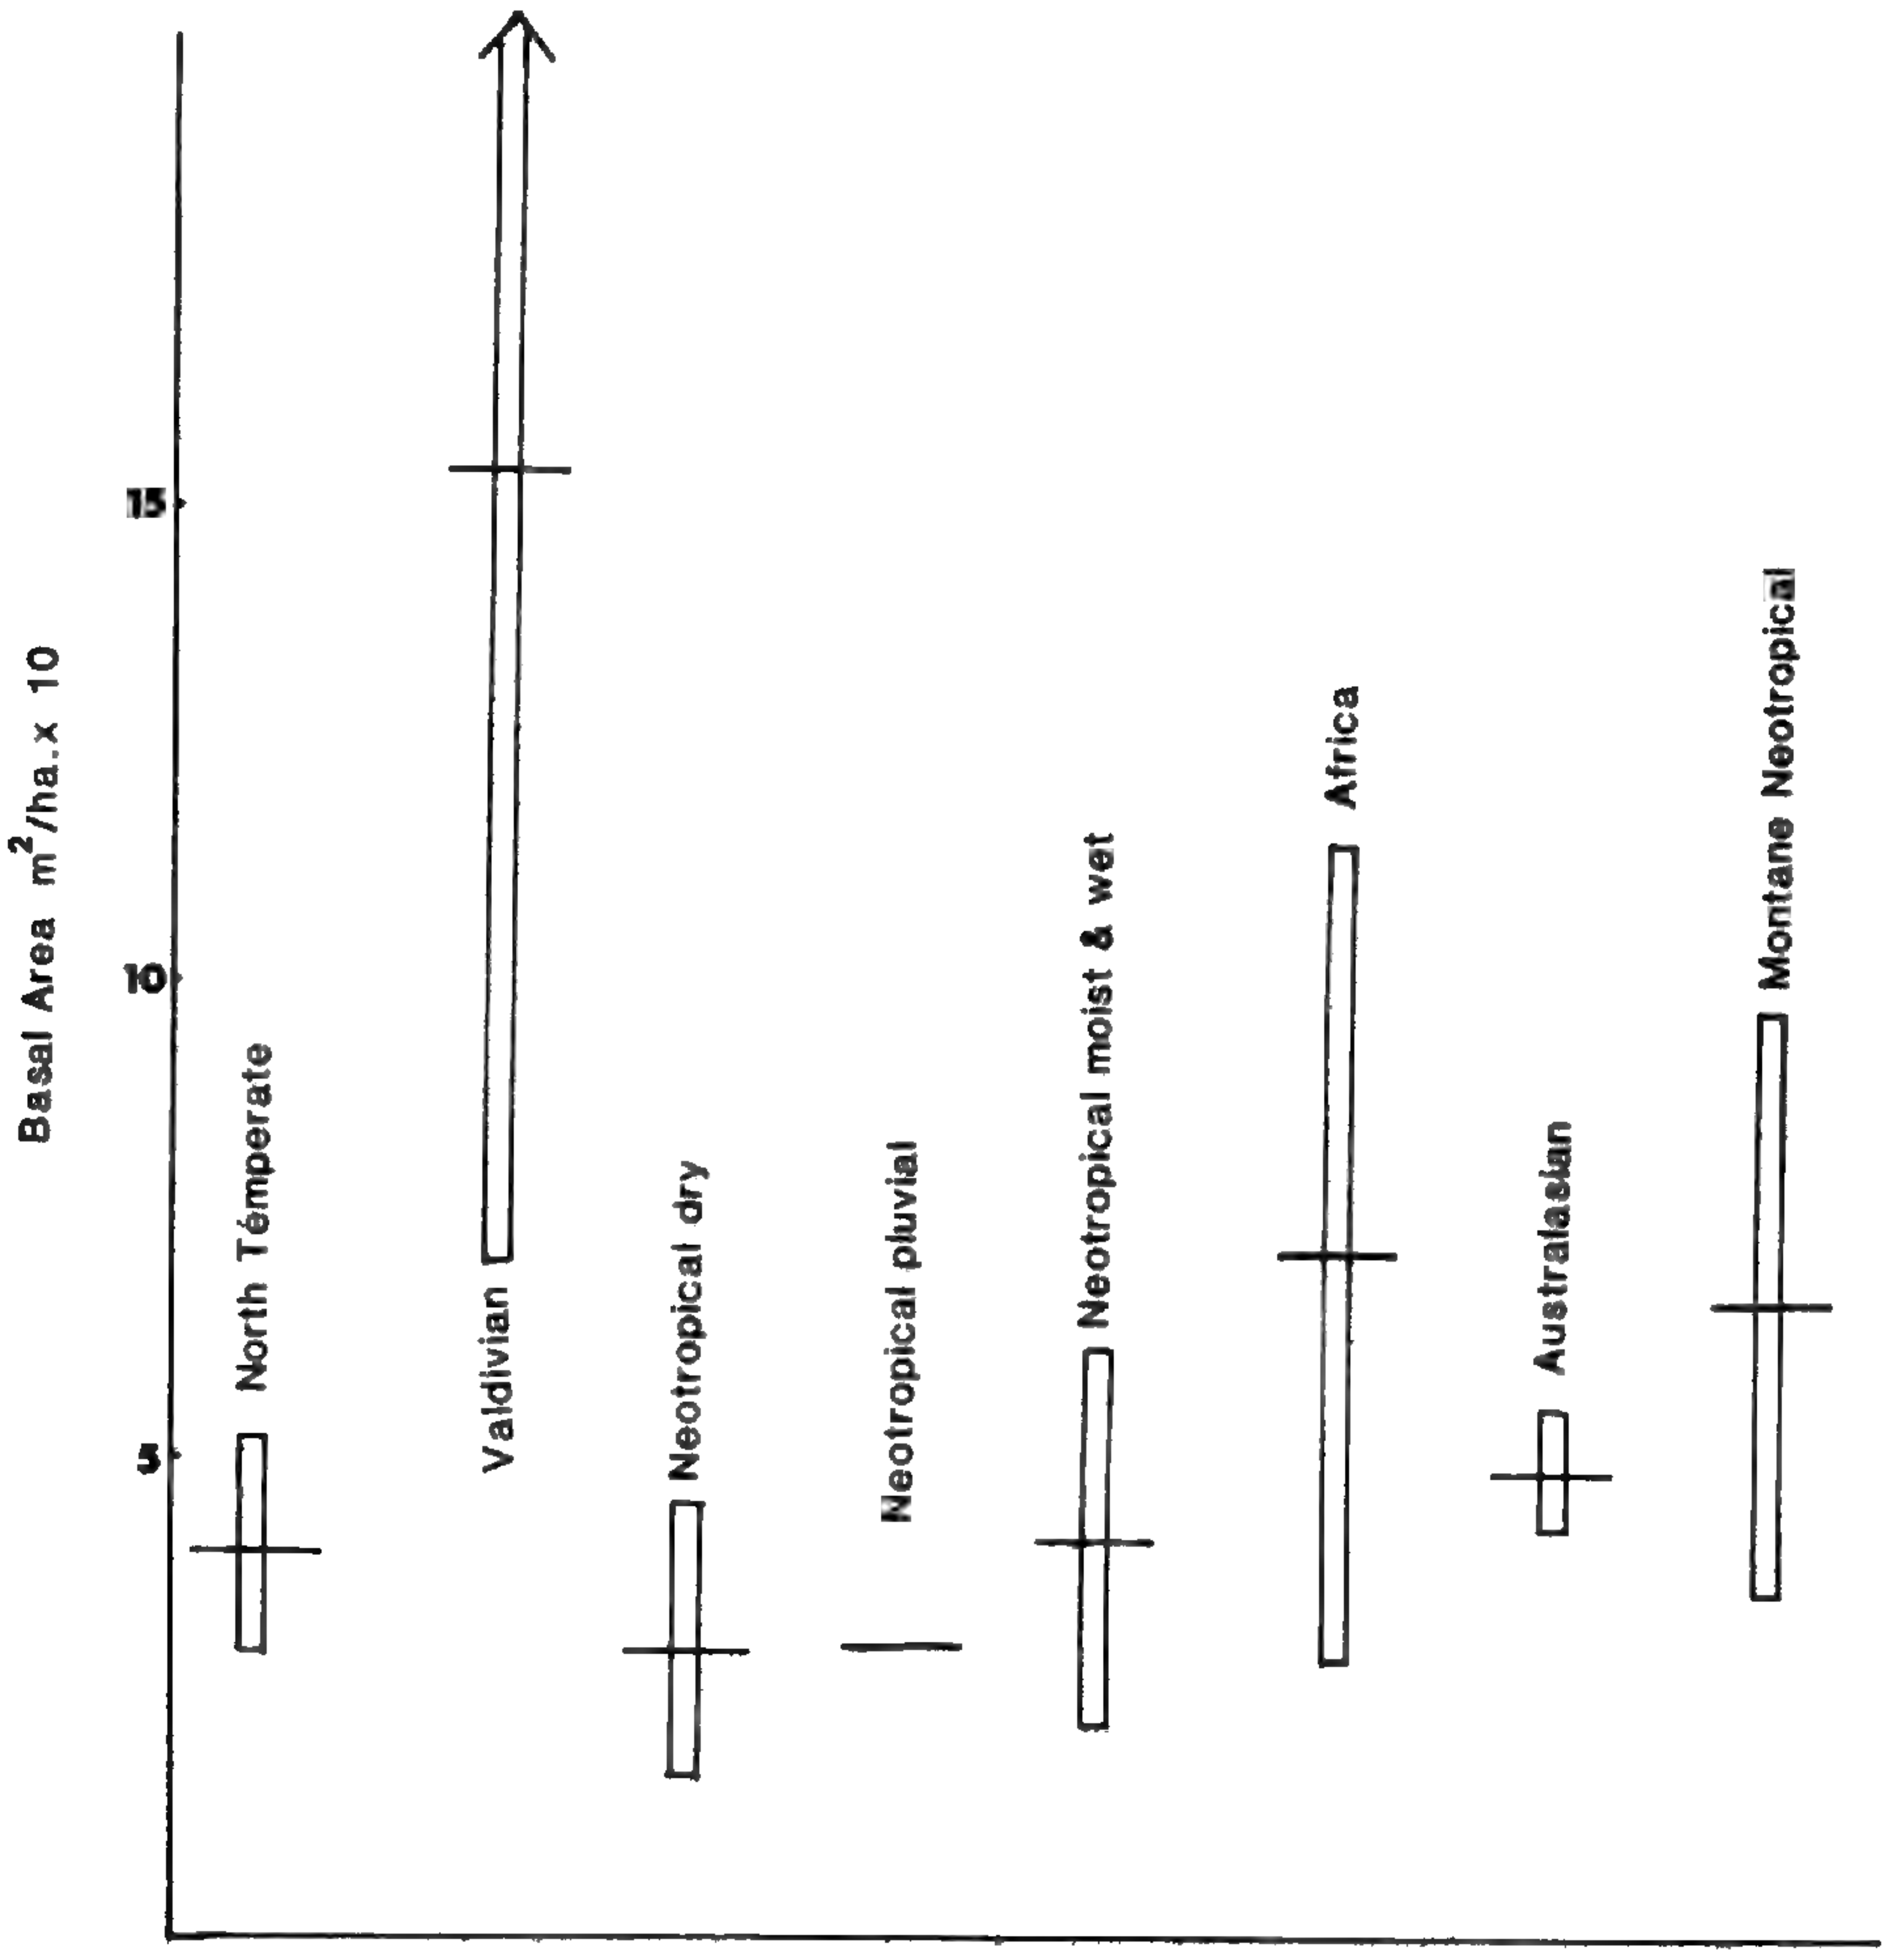

FIGURE 12. *Basal areas for 0.1-ha samples of some different forest types. Line = average basal area for forest type; bar = ± 1 s.d.*

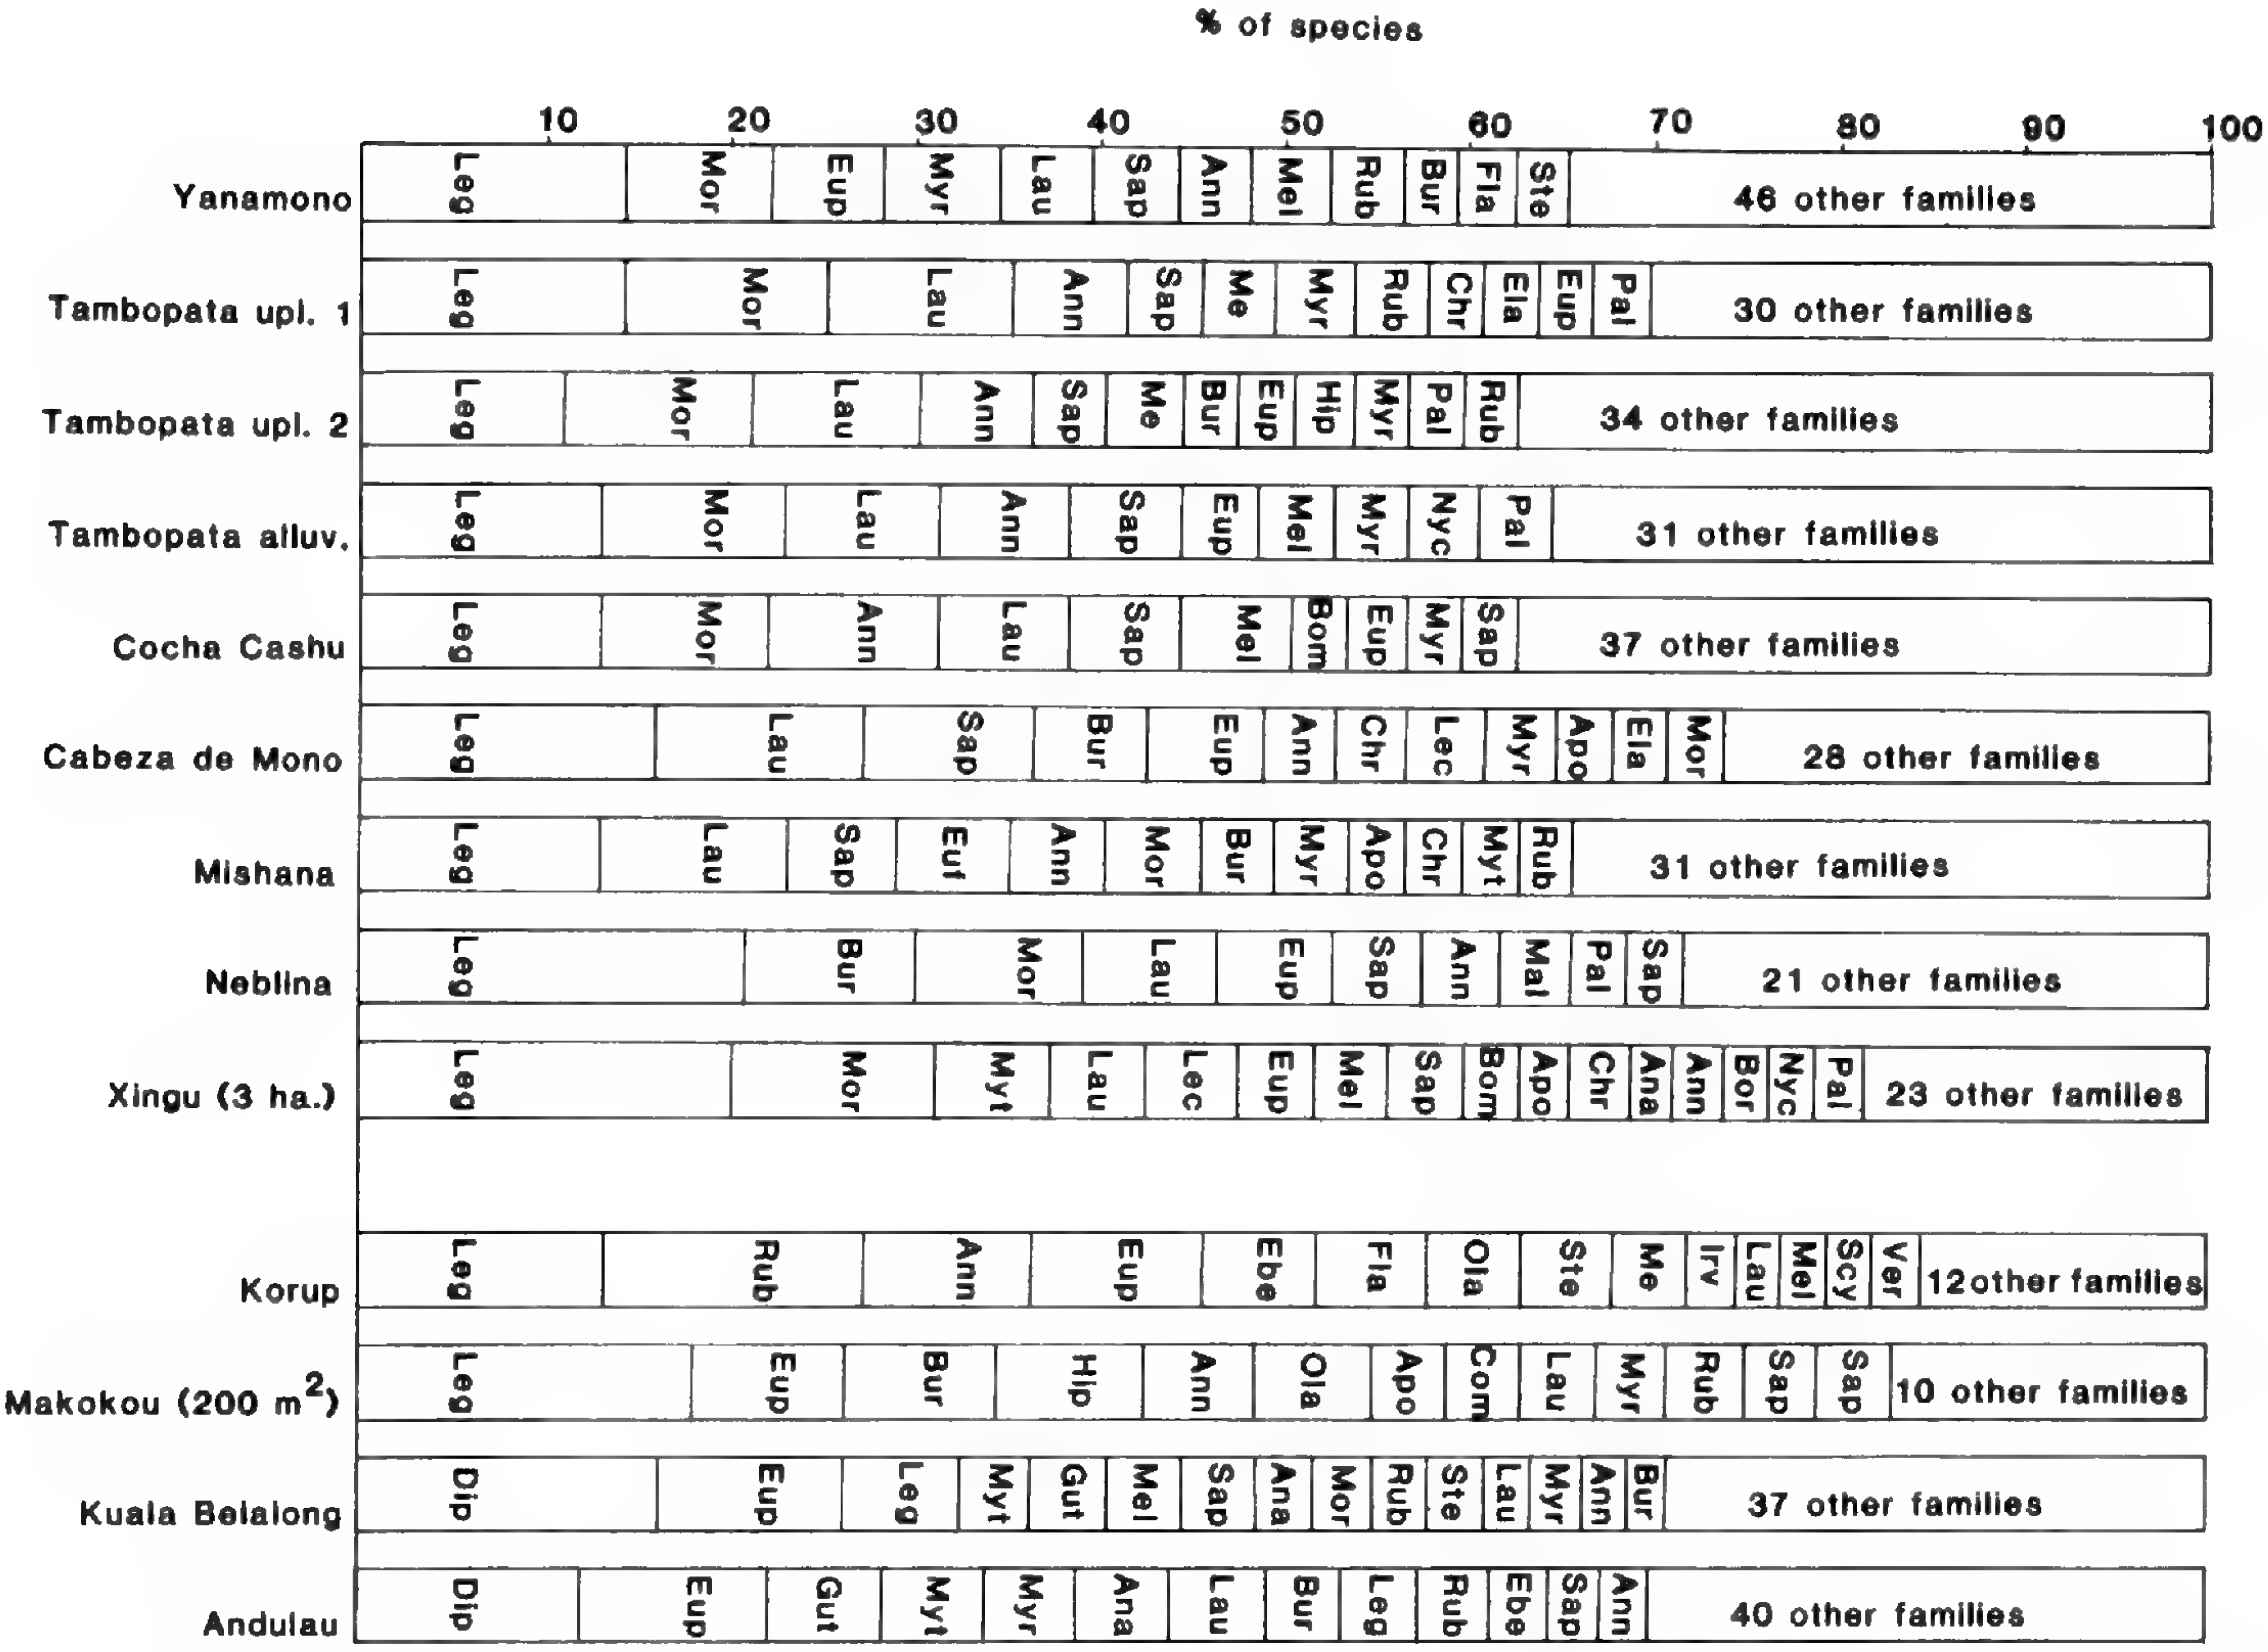

FIGURE 13. *Familial compositions of some tropical forest tree plots (plants ≥ 10 cm dbh) in Amazonia (Yanamono to Xingu), Central Africa (Korup and Makokou), and Southeast Asia (Kuala Belalong, Andulao). South American sites are from original data except Xingu (Campbell et al., 1986); Korup is from D. Thomas (pers. comm.); the Makokou data are the total for the ≥ 10 cm dbh subset for the two 0.1-ha plots listed in Table 1 combined. The two Asian sites are from Ashton (1964): the data are for a total sample area of 20 ha at each site, composited from 50 individual acre plots on different types of terrain. The other data are for 1-ha plots except as otherwise noted. Family codes are the first letters of the familial names, self-evident except me = Melastomataceae, mel = Meliaceae, sap = Sapotaceae (the second, if present, = Sapindaceae), myr = Myristicaceae, myt = Myrtaceae. Note that Leguminosae, the dominant family in all neotropical and African tree plots, is just as speciose as is Dipterocarpaceae in Southeast Asia. Also note that, except for dipterocarps, the forests on all three continents are mostly composed of species belonging to the same few woody families.*

less, has a similar range of variation according to local environmental conditions in all three of the world's main tropical regions; what happens at larger spatial scales remains an open question.

Although tropical forest α-diversity may be similar on different continents, its structure is not. For example, lowland neotropical forests have fewer lianas than African forests and more lianas than Asian forests (Emmons & Gentry, 1983). Large palms as a major and characteristic canopy element of lowland terra firme forest seem largely restricted to the Neotropics (Gentry & Emmons, 1987), Madagascar (20 palms ≥ 10 cm dbh/ha at Perinet), and a few other islands (e.g., New Caledonia: 20 palms ≥ 10 cm dbh/ha at Rivière des Pirogues). While stem densities of trees ≥ 10 cm dbh may be similar from continent to continent (Dawkins, 1959), tropical African forests tend to have more large trees and higher basal areas (and presumably biomasses) (70.7 m^2/ha vs. 34.9 m^2/ha) than do neotropical or Australasian forests (Fig. 12). On the other hand, Asian dipterocarp forests may have uniquely high densities of small polelike trees. Such structural differences, only beginning to be discovered, may be critical to forest organisms. For example, the intercontinental difference in liana density

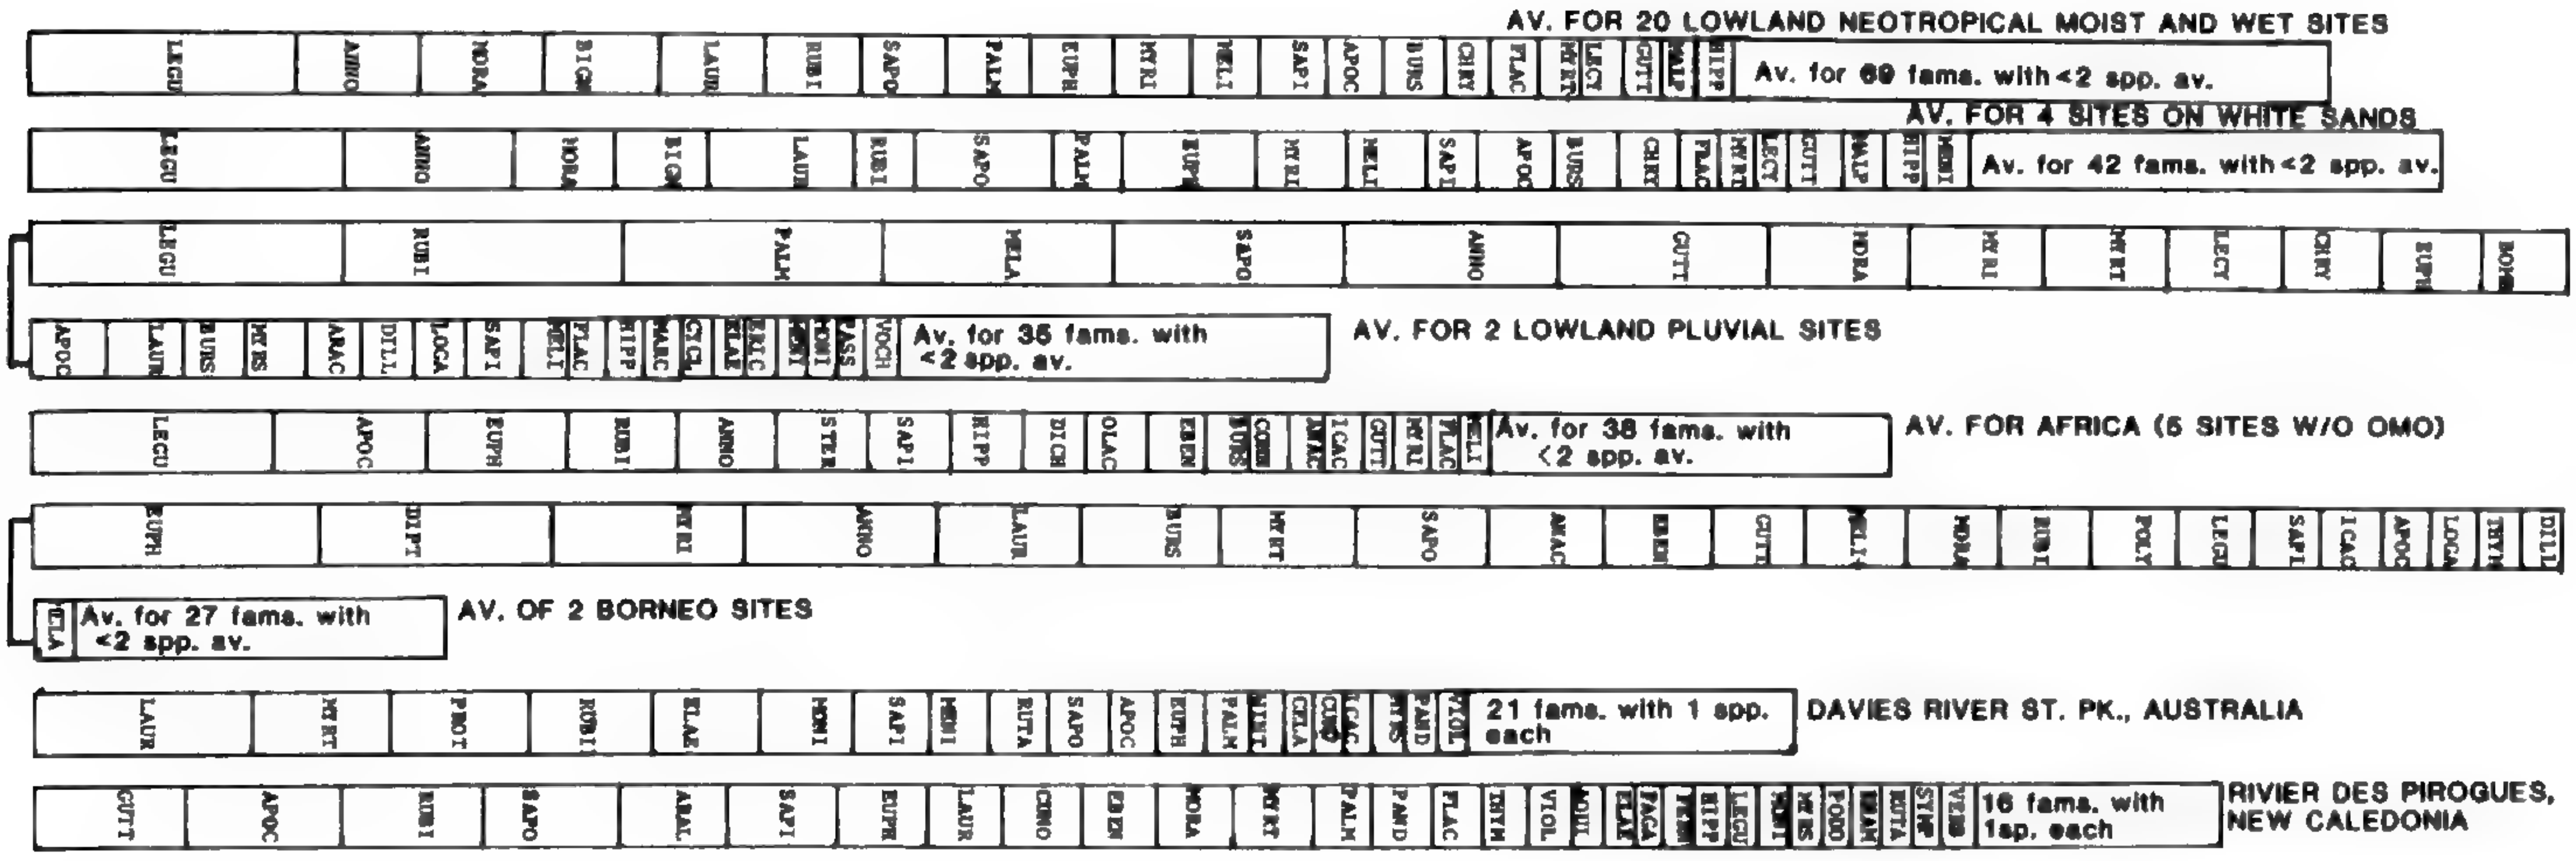

FIGURE 14. *Comparison of average number of species per family for 0.1-ha samples from subsets of different lowland neotropical forest types with equivalent paleotropical data. From top to bottom the columns represent: 1) average for 20 lowland neotropical moist and wet sites; 2) average for 4 neotropical sites on white sand; 3) average for 2 pluvial-forest sites in Chocó; 4) continuation of 3; 5) average for 5 central African sites (i.e., excluding Omo); 6) average for 2 Bornean sites; 7) continuation of 6; 8) Davies River State Park, Queensland, Australia; 9) Rivière des Pirogues, New Caledonia. Shortest column segments are two species tall.*

may have been the critical factor selecting for different locomotor adaptations among canopy vertebrates on the three continents (Emmons & Gentry, 1983).

FLORISTICS

Neotropical plant communities are put together in decidedly nonrandom ways. Thus community-level frequency of different seed dispersal and pollination syndromes is generally predictable from environmental parameters (Gentry, 1982b, 1983). Similarly, the floristic composition of different plant communities is remarkably consistent, at least at the familial level. Legumes are virtually always the dominant family in neotropical and African lowland primary forests. The only neotropical exceptions are on extremely rich soils where Moraceae become very diverse and are occasionally as species-rich as Leguminosae in 0.1-ha plots (Gentry, 1986b, c). Of the 43 continental neotropical lowland 0.1-ha samples between 23.5°N and S latitudes, 39 had Leguminosae as the most species-rich family. The dominance of legumes in the Neotropics and Africa is equally apparent when only trees ≥ 10 cm dbh are considered (Fig. 13). Indeed, legumes contribute almost exactly as much to the diversity of neotropical and African forests as dipterocarps do in Southeast Asia. Similarly, in Africa, on the rich volcanic soil of the Mt. Cameroon plot, several families, especially Rubiaceae, Apocynaceae, and Euphorbiaceae have more species than legumes, but this forest, on the lower slopes of an active volcano, may not be strictly primary.

The other families that contribute most to species richness of different plant communities are also predictable. In the Neotropics the same 11 families—Leguminosae, Lauraceae, Annonaceae, Rubiaceae, Moraceae, Myristicaceae, Sapotaceae, Meliaceae, Palmae, Euphorbiaceae, and Bignoniaceae—contribute about half (38%–73%; $\bar{X} = 52\%$) of the species richness to 0.1-ha samples of any lowland forest. At least eight of these families are always among the ten most species-rich families in any lowland neotropical moist or wet forest (Fig. 14; Gentry, 1987b). Similarly, in 0.1-ha samples of lowland neotropical dry forests, Bignoniaceae, the preeminent liana family, is always second only to Leguminosae in its contribution to species richness (Fig. 15).

Somewhat surprisingly, the dominant families in neotropical forests also tend to be the most speciose on other continents. Rubiaceae, Annonaceae, and Euphorbiaceae are always among the ten most species-rich families in Africa and Asia, just as they are in the Neotropics. The rest of the 11 most species-rich neotropical families (Lauraceae, Moraceae,

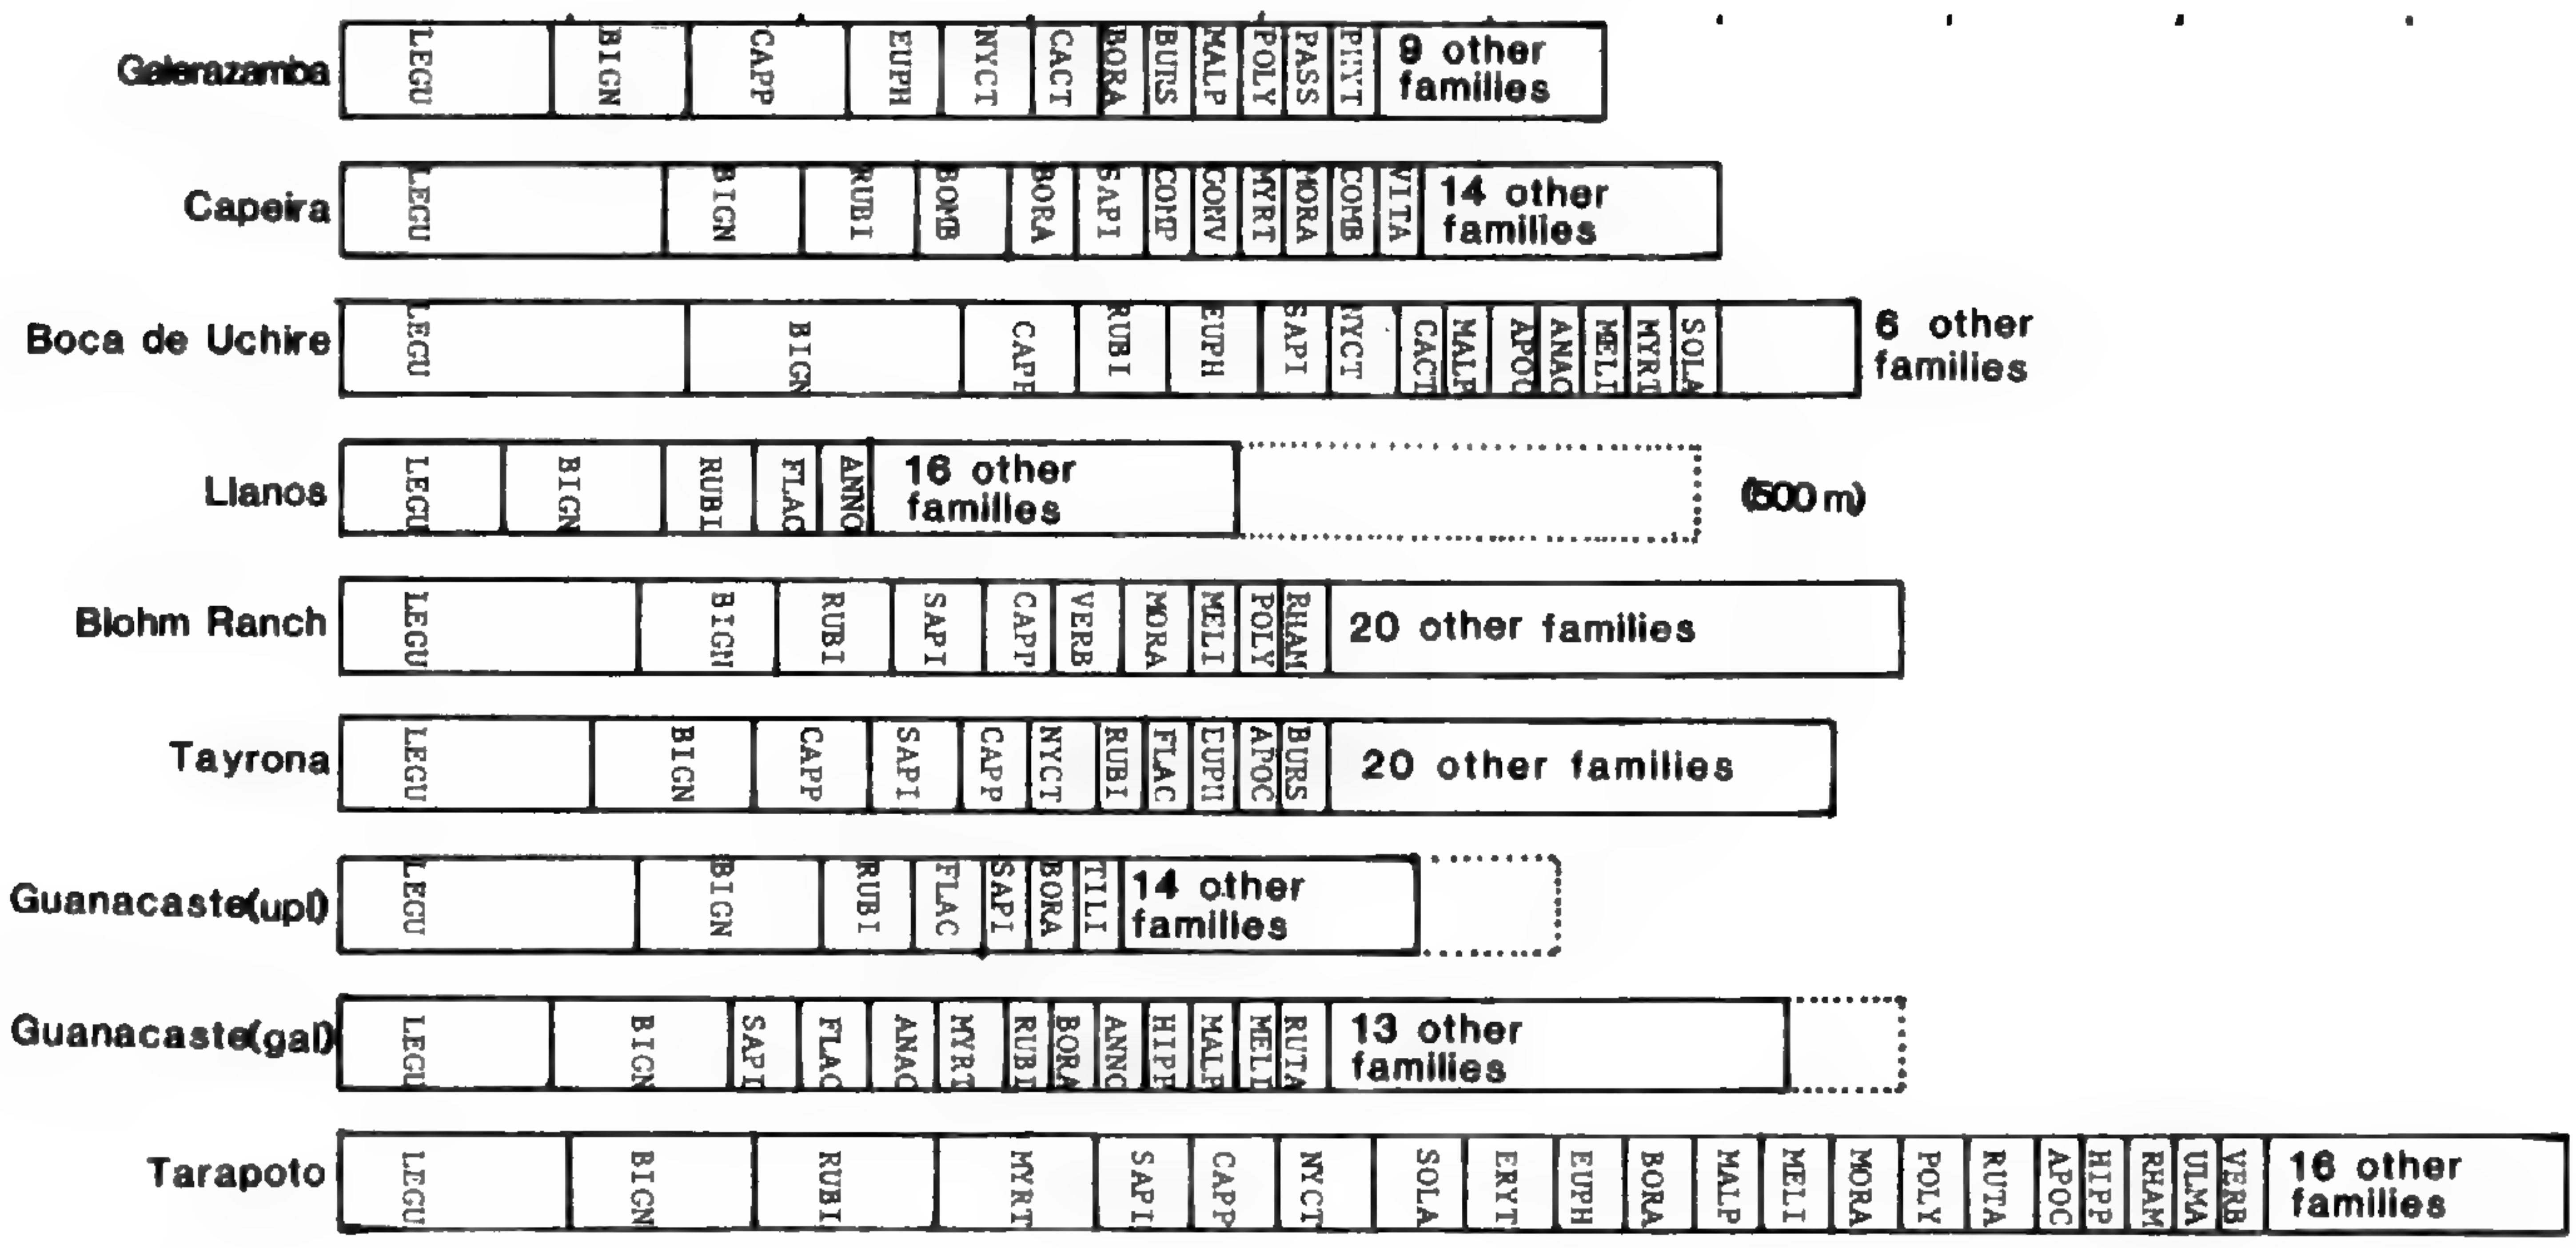

FIGURE 15. *Number of species per family for 0.1-ha samples of lowland neotropical dry forests. For three sites with sample areas of < 1,000 m²—Llanos, Guanacaste (upland) and Guanacaste (gallery), with 500 m², 700 m², and 800 m² of sample area, respectively—the actual values are inside the solid outlines with the anticipated number of species in 1,000 m² indicated by the dotted outline. Shortest column segments are two species tall.*

Sapotaceae, Palmae, Myristicaceae, Meliaceae, and Bignoniaceae) are all represented in at least some samples from both Africa and Asia and, except for Bignoniaceae and Palmae, are among the ten most species-rich families in at least one African or Asian sample. Thus, with the exception of the substitution of Dipterocarpaceae for Leguminosae as the most species-rich woody family in Southeast Asian forests, pantropical familial composition of lowland forests is remarkably similar.

Other minor differences include Ebenaceae (almost always present in Africa and Asia and among the ten most species-rich families in about half the samples from those continents but only occasionally represented in the neotropical samples, never by more than a single species), Olacaceae (usually represented on all continents but generally among the ten most species-rich families in Africa, never so in Asia or the Neotropics), and Sterculiaceae (always among the ten most species-rich families in Africa; represented by 1–3 species in almost all neotropical and Asian samples, although among the ten most species-rich families only in Cocha Cashu, Peru). Dichapetalaceae are almost always among the ten most species-rich families in African samples but are only occasionally represented by one or two species in the Neotropics and are absent from my Asian samples. Apocynaceae and Sapindaceae almost always turn up in samples from any continent but are generally among the ten most species-rich families in Africa (always in the case of Apocynaceae) but only rarely elsewhere. Disproportionately represented in Asia, besides Dipterocarpaceae, are Myrtaceae (always among the most species-rich families vs. almost always present but only rarely among the most species-rich families in the Neotropics and represented by a single species in a single sample on continental Africa). Other noteworthy anomalies include 9 species of Proteaceae, 7 of Elaeocarpaceae, and 6 of Monimiaceae in the Queensland sample (these three families ranking 3rd, 5th, and 6th in diversity after Lauraceae, Myrtaceae, and Rubiaceae), 7 Araliaceae species and 5 of Cunoniaceae in the New Caledonia sample (ranking 5th and 8th, respectively, in familial diversity), and 8 and 3 species, respectively, of *Xanthophyllum* (Polygalaceae) at Semengoh and Bako, Borneo.

Put another way, all of the paleotropical forests sampled were constituted almost entirely of the same plant families encountered in equivalent samples of neotropical forests.

Although 13 families not represented in the Neotropics were included in the paleotropical samples, and although each African and Asian sample included 1–3 families not represented in the Neotropics, with two exceptions, the sum contribution of all of these to species richness of the Asian and African forests is negligible. The two exceptions are Dipterocarpaceae in tropical Asia and Pandanaceae in Madagascar (3 spp.), Queensland (2 spp.), and New Caledonia (4 spp.). Excluding these two families, an average of 2 species (and ca. 3 individuals) per sample was contributed to paleotropical community diversity by families not included in the equivalent neotropical samples. At this level New Caledonia was the most distinctive, with one species each of Balanopaceae, Epacridaceae, Oncothecaceae, and Pittosporaceae, plus 4 of Pandanaceae. The Madagascar sample included, besides 3 Pandanaceae, a species of Sarcolaenaceae and two of Pittosporaceae, the Queensland sample a species of Balanopaceae and 2 of Pandanaceae (plus one of the sometimes Cunoniaceae segregate Davidsoniaceae). In Africa, Ancistrocladaceae was represented by one individual at one site, Medusandraceae by one individual at one site, and Scytopetalaceae by two species at one site. Only in the latter case did an endemic family contribute significantly to a site's diversity, with *Ouabangia alata* the 5th most common species (13 individuals) at Korup and *Rhaptopetalum* cf. *coriaceum* represented by three individuals at the same site. It is perhaps worth noting that several of the endemic families included in the above total are somewhat dubious segregates—Pandaceae (from Euphorbiaceae), Irvingiaceae (from Simaroubaceae), and Ixonanthaceae (from Linaceae). Lowland tropical forests throughout the world are overwhelmingly made up of the same plant families, with the exception of the Dipterocarpaceae for Leguminosae substitution in Southeast Asia.

Even at the generic level, there are striking floristic similarities between the compositions of lowland tropical forests on different continents. The generic similarity is especially marked between Africa and South America. An average of 30% (with extremes of 25% at Korup to 34% at Belinga) of the genera at the six continental African sites are neotropical genera, nearly all also included in the neotropical samples. When complete local floras are compared, generic concordance between tropical Africa and the Neotropics remains equally high. Thus 30% of the genera represented at Makokou Gabon also occur in the Neotropics. Both sets of figures would be much higher if such tenuously differentiated genera as *Pycnanthus* and *Virola* (Myristicaceae) or *Macrolobium* and its segregates (Leguminosae) were considered to be congeneric.

Generic overlap between tropical Asia and the Neotropics is less, averaging 23%, and between Australasia and the Neotropics intermediate (25% neotropical genera in the Queensland sample, 26% in the New Caledonia one). These relationships might be predictable from Cretaceous and Tertiary plate tectonic history and the timetable of Gondwanan breakup. In this light, it is especially interesting that about 36% of the genera sampled at Perinet, Madagascar, are shared with the Neotropics, the highest value for any paleotropical site.

There are also consistent and predictable floristic changes along environmental gradients, at least in the Neotropics. On poorer soils families like Burseraceae, Lauraceae, and Sapotaceae become more prevalent, whereas on the richest soils palms and Moraceae are disproportionately speciose.

In neotropical areas with a strong dry season, floristic composition is likewise predictable. Leguminosae are always the most species-rich family, with Bignoniaceae, represented mostly by wind-dispersed lianas, always second (Fig. 15).

On an altitudinal gradient in the Andes, Lauraceae consistently replace Leguminosae as the most species-rich family at intermediate elevations (Fig. 16). Other families that contribute to the diversity of middle elevation forests are Rubiaceae, Melastomataceae, Euphorbiaceae, Moraceae, Guttiferae, tree ferns, (hemiepiphytic) Araceae, and Palmae. Fam-

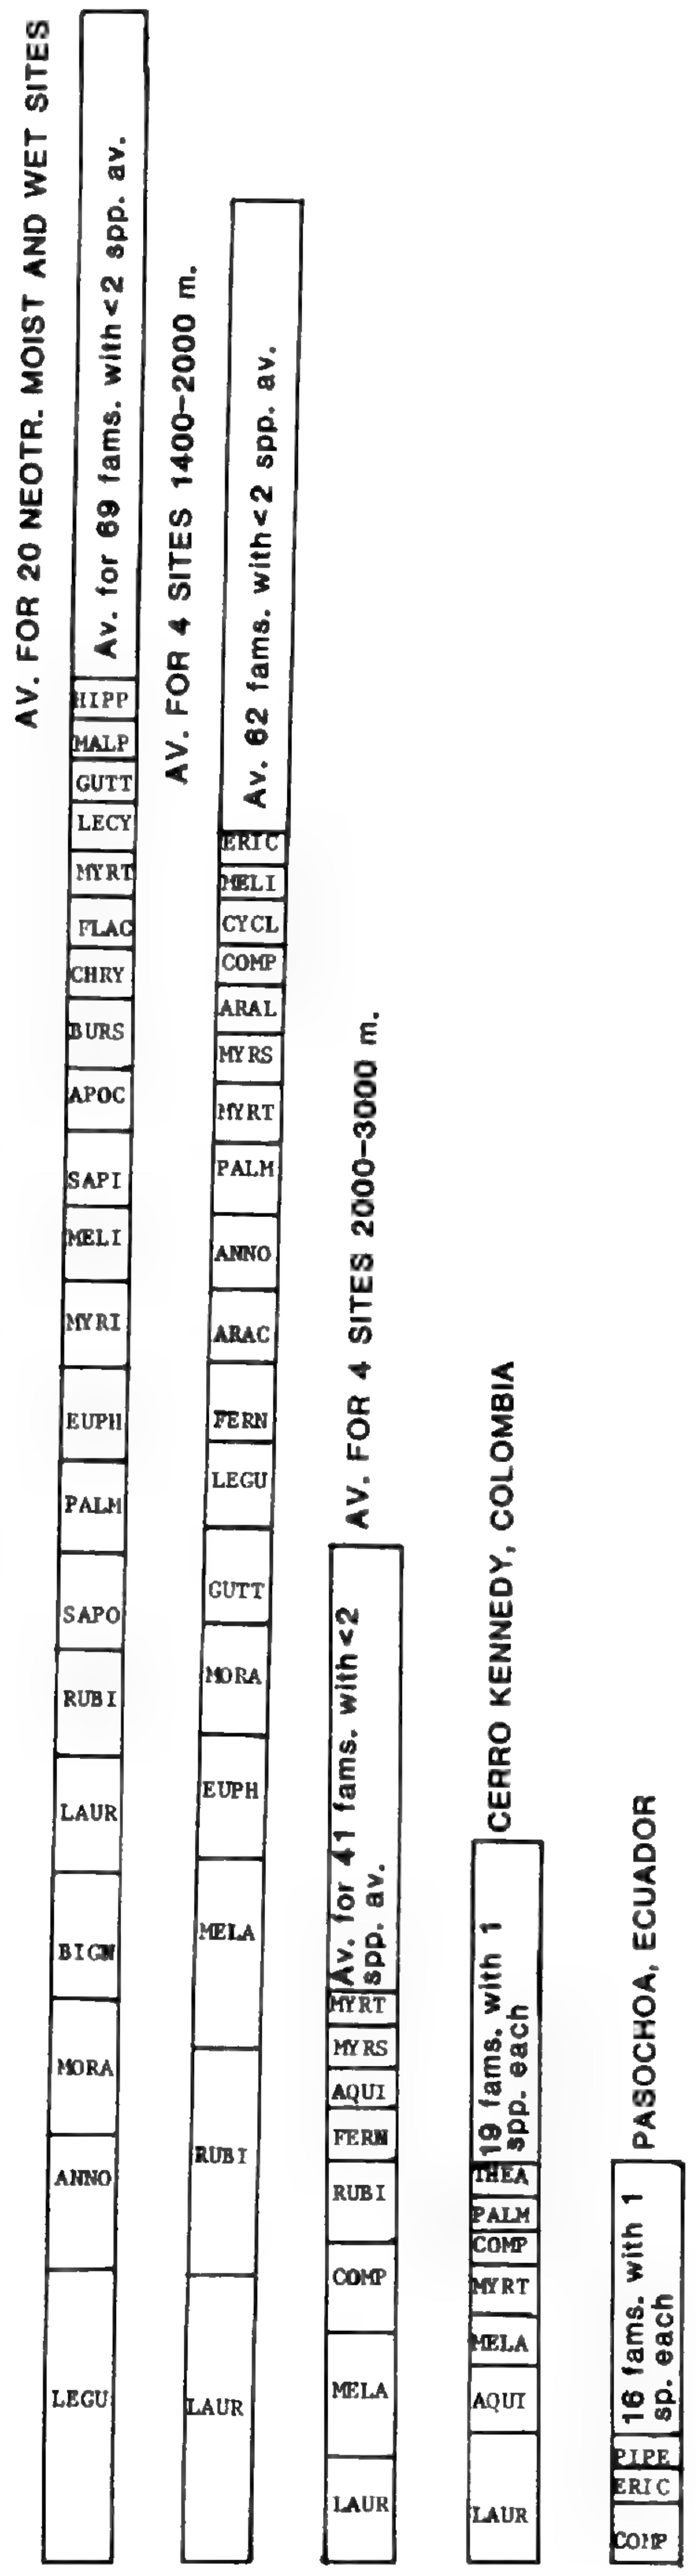

FIGURE 16. *Number of species per family for 0.1-ha samples at different altitudes in the Neotropics. From left to right columns are 1) average for 20 lowland neotropical moist- and wet-forest samples; 2) average for 4 sites between 1,400–2,000 m (Cerro Pichaco, Incahuara, Venceremos, Farrallones de Cali); 3) average for 4 sites at 2,000–3,000 m (Sacramento, Finca Mehrenberg, Cerro Kennedy, Finca Zungara); 4) Cerro Kennedy, Colombia (2,600 m, 500 m² of sample area);* ← *5) Pasochoa, Ecuador (3,010 m, 200 m² of sample area). Site data from Table 2. Shortest column segments are two species tall.*

ilies like Bignoniaceae, Sapotaceae, Myristicaceae, Meliaceae, Sapindaceae, Burseraceae, and Chrysobalanaceae are especially noteworthy as absent or much more poorly represented than in lowland forests. At higher elevations (> 2,000 m), Melastomataceae, Compositae, Rubiaceae, and tree ferns become more prevalent, although of these only Compositae increase in absolute number of species. At even higher altitudes, Aquifoliaceae, Myrtaceae, and Theaceae become relatively more important, while near timberline Compositae and Ericaceae predominate.

Curiously, the site at 1,000 m altitude at Perinet, Madagascar, had virtually an identical familial composition to the middle-elevation neotropical site; in addition to Lauraceae being the most speciose family, Rubiaceae, Euphorbiaceae, Moraceae, and Guttiferae followed in species richness; the only substantial differences are a transposition of the roles of Melastomataceae (more species in the Andes) and Myrtaceae (more species at Perinet), the presence of several species of Monimiaceae and Oleaceae in Madagascar, and the frequency of hemiepiphytic Araceae in the Neotropics (Fig. 17). A Queensland, Australia, site from 850 m was also rather similar in familial composition to the Andean middle-elevation sites, again with Lauraceae dominating, closely followed by Rubiaceae, though with greater prevalence of such southern families as Proteaceae, Elaeocarpaceae, and Myrtaceae. Such strikingly repeated patterns in parts of the world so widely separated today can hardly be due to chance.

Many of the major latitudinal changes in floristic composition are well known, with families such as Fagaceae and Juglandaceae replacing the tropical taxa in North America (Fig. 18). Perhaps less emphasized are how remarkably similar in familial composition different eastern North American forests are. While species, and to some extent genera, do change from place to place, from a world

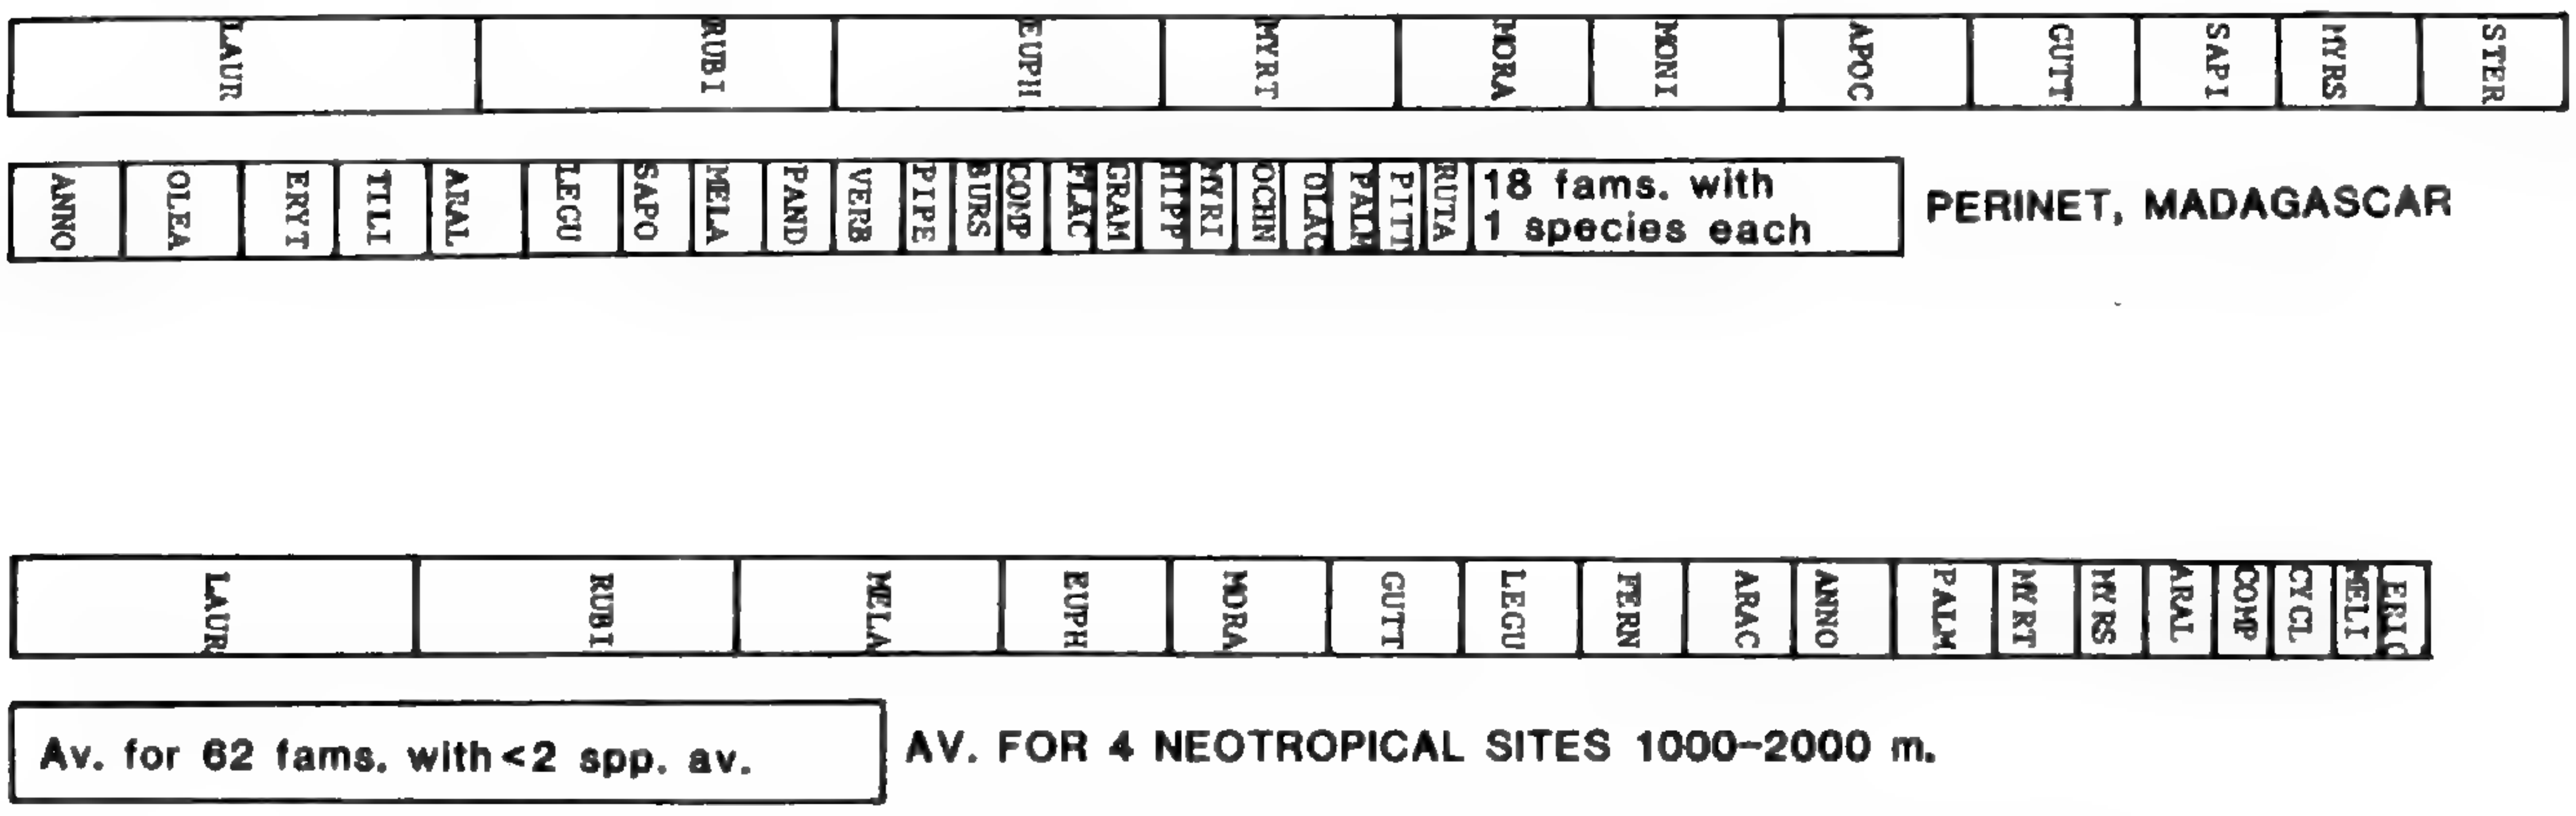

FIGURE 17. *Number of species per family for 0.1-ha sample at Perinet, Madagascar (950 m) (top two columns) compared with average for four mid-elevation neotropical sites (1,000–2,000 m) (bottom two columns). Note the remarkable similarity of familial composition. Perinet data based only on field identifications pending herbarium comparison of vouchers. Shortest column segments are two species tall.*

perspective the overall floristic composition of most of these forests is as similar as is their diversity. The contrastingly austral composition of the Valdivian flora is also well known. There are also floristic similarities between the austral and north temperate ones. For example, gymnosperms and Fagaceae become more prevalent in both north temperate and south temperate areas. One interesting and previously unremarked floristic difference between the Valdivian forests and their northern equivalents is that the former lack sympatric congeners. The difference in diversity between eastern North American and Valdivian forests (as well as between the North American forests and my two European samples) is almost entirely accounted for by this lack of sympatric species in genera like *Quercus* and *Carya*. Why Chilean *Nothofagus* species, unlike their northern cousins, should be almost entirely allopatric is unclear, but the effect of this pattern on the diversity of the south temperate forests is obvious.

DISCUSSION

To this point I have attempted to present a series of observations of changes in diversity and floristic composition on various gradients. I now focus briefly on some theoretical generalizations that would seem to derive from these data.

The overall message is that plant communities are put together in decidedly nonrandom ways. Diversity and floristic composition are highly predictable from environmental and geographical factors, with maximum plant community diversity occurring in full-tropical lowland areas with rich to intermediately infertile soils and high annual precipitation and/or little dry-season stress. Such patterns are often taken as evidence of niche saturation and community equilibrium (MacArthur, 1965, 1969; Cody, 1975; see also Whittaker, 1977).

Much of the controversy about equilibrium vs. nonequilibrium communities has focused on the role of niche specificity vs. stochastic generation or maintenance of diversity (e.g., Hubbell, 1984; Hubbell & Foster, 1986; Ashton, 1969; Connell, 1978). My data suggest that even though tropical forests contain many different plant species, they are far from random assemblages. Can these data and conclusions be reconciled with the very different ones of Hubbell (1979; Hubbell & Foster, 1986, 1987)? Below I will focus on several points that may be relevant to this debate.

From a somewhat different perspective, some authors (e.g., Federov, 1966) have argued that the exceedingly high diversity of tropical forests is too great to be accounted for by niche specificity; therefore, some kind of nonselective or stochastic mechanism must be invoked. However, it seems to me that it is stochastically most unlikely that the extreme species richness of forests like that at Yanamono, Peru, with 300 species out of 606 individuals in a hectare, would result

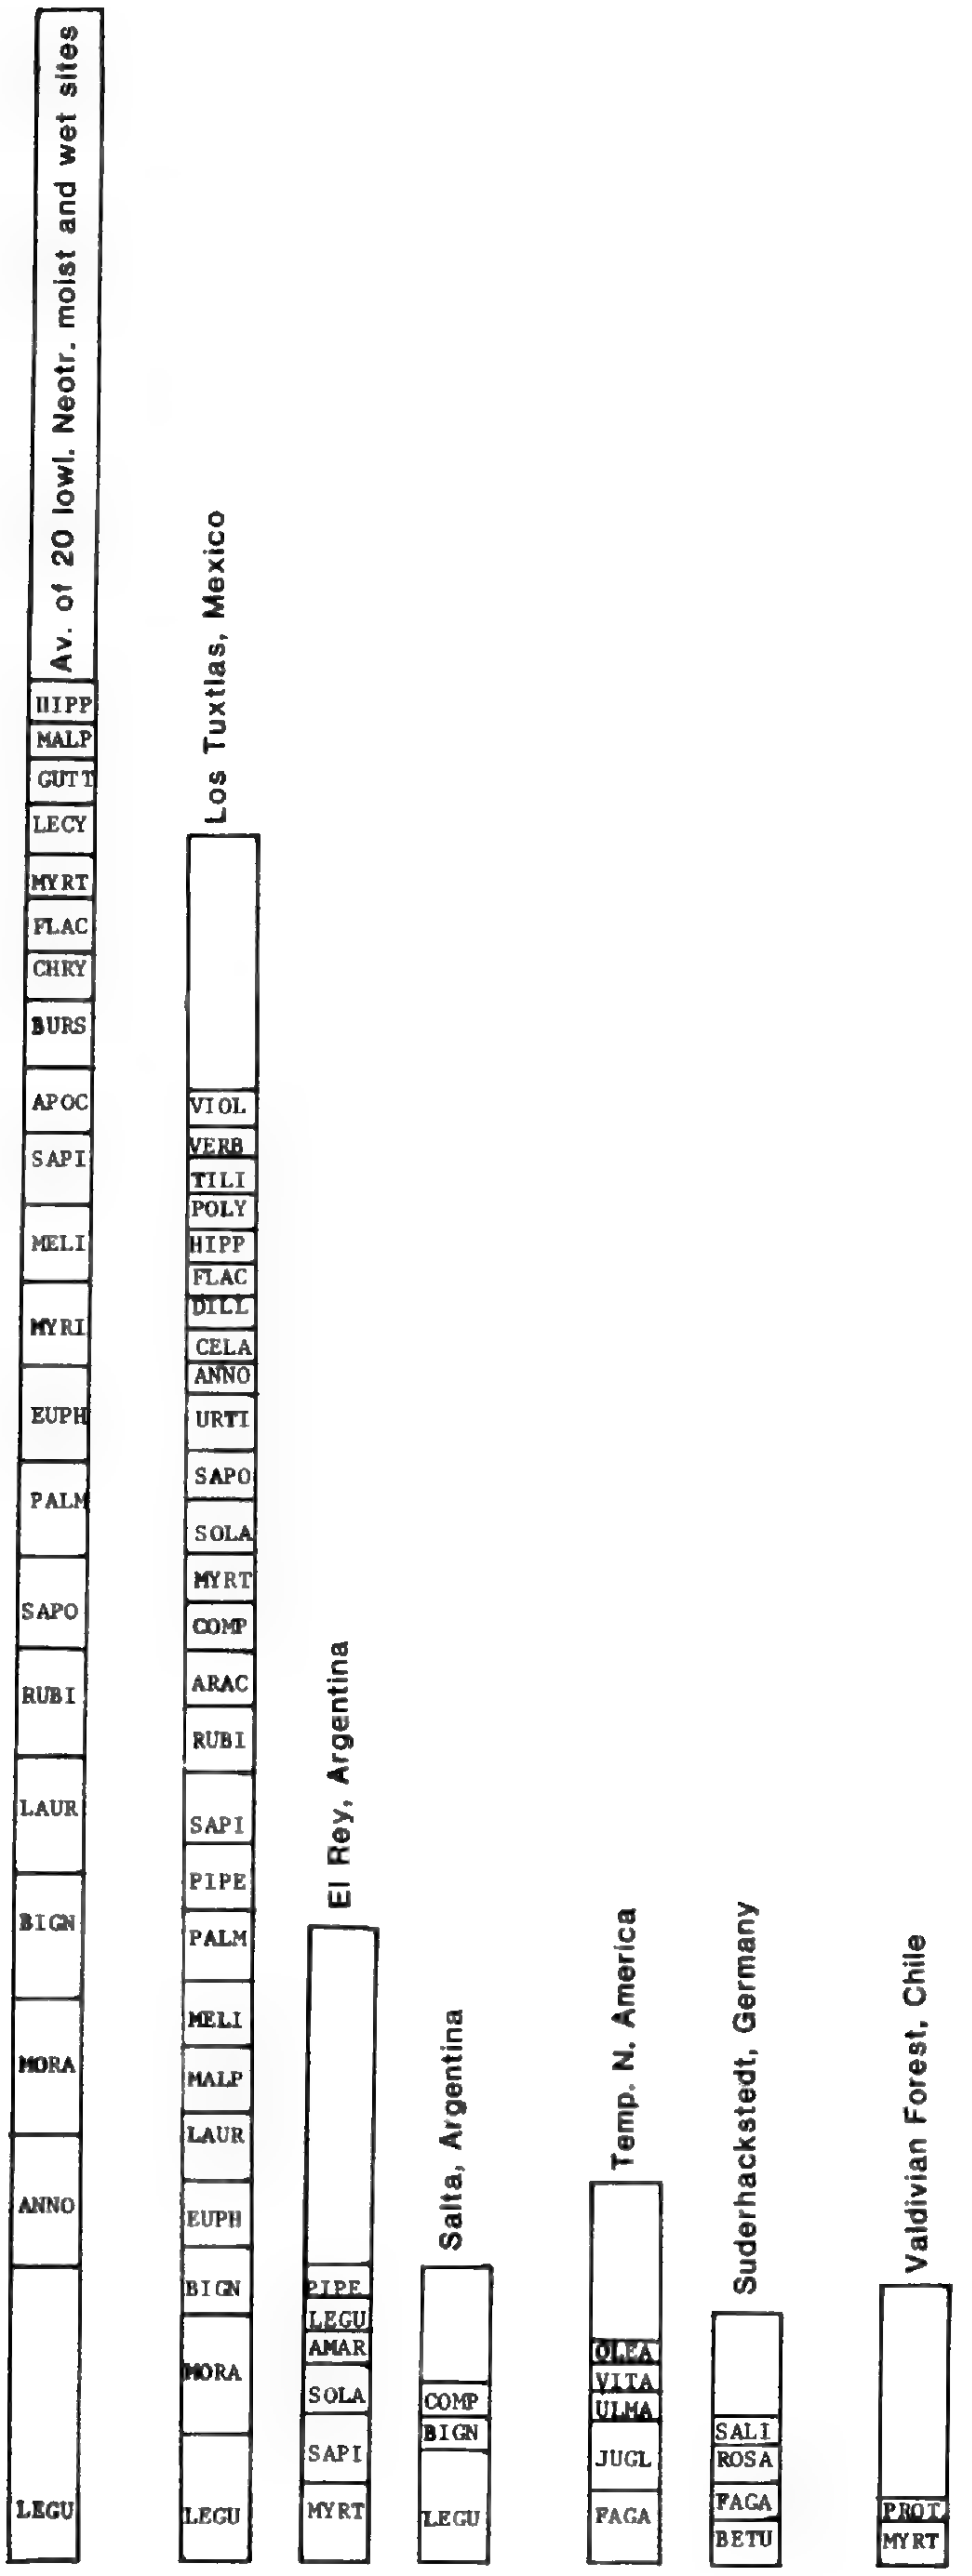

FIGURE 18. *Number of species per family for some 0.1-ha samples at different latitudes. From left to right, columns are: 1) average for 20 lowland neotropical moist- and wet-forest samples; 2) Los Tuxtlas, Mexico (wet forest, 18°35′N, 200 m alt.); 3) Parque El Rey, Argentina (moist forest, 24°45′S, 1,000 m alt.); 4) Salta, Argentina (dry forest, 24°40′S, 1,300 m); 5) average for seven temperate North American sites (28°15′N–39°2′N); 6) Suderhackstedt, Germany* ← *(54°N); 7) average for three Valdivian, Chile, sites (39°30′S–40°43′S).*

from random processes, unless there is a potential sample universe of many thousands of tree species. Forty-eight species are represented in the first 50 individuals sampled at Yanamono, and the 65 individuals in the first Yanamono 0.1-ha subplot constitute 58 species. Such high levels of diversity, far from indicating stochasticity, would seem to indicate very strong ecological pressures resulting in phenomenally low densities of the individual species (and high community diversity).

The striking regularities in the patterns discussed above clearly indicate that at some levels both community composition and diversity are highly predictable. How this relates to community equilibrium remains clouded, however, in part because of definitional problems. Hubbell & Foster (1986) defined an equilibrium community as one in which a particular combination of *species* maintains itself against outside perturbations, whereas the predictable diversities of different tropical forests with similar environments but different assemblages of species is more akin to the "equilibrium" theory of island biogeography (MacArthur & Wilson, 1967), considered by Hubbell as a nonequilibrium theory because of the taxonomic randomness involved. Many Amazonian forests are clearly richer in tree species than equivalent Central American forests (Gentry, 1988). They also have much greater habitat differentiation and β-diversity (Gentry, 1986a). Thus some of the higher diversity of the Amazonian forests may be due to the "mass effect" phenomenon of Shmida & Wilson (1985), with accidental immigrants adapted to other environments contributing significantly to the α-diversity of an individual Amazonian forest. Arguing along similar lines from the nonequilibrium viewpoint, Hubbell & Foster (1986) suggested that biogeographical pattern plays a major role in tropical forest α-diversity: if the regional diversity is greater, as it certainly is in Amazonia, more species, on the average, should occur in individual forests due purely to phenomena associated with patch dynamics and local immigrations. But there are also problems with such interpretations. That the families and genera represented in these different samples are so predictable strongly suggests that at least some kind of familial-specific niches may be involved. Moreover, the apparent partitioning of the species of each family into different sets of species specialized for different substrates in Amazonia seems strong circumstantial support for selectionist interpretations (Gentry, 1985b).

Data from several 1-ha tree plots in the Tambopata Reserve, Madre de Dios, Peru, can be used to document the effect of substrate specificity on species composition. Data are available from two completely identified 1-ha samples from similar poor-soil terra firme forest separated by about 1.5 km, a completely identified plot in mature forest on rich alluvial soil, and from as yet incompletely identified plots in young riverside secondary forest, in swamp forest, and in forest in a transitional area between the rich floodplain and poor-soil uplands (see Fig. 8). As is usually the case in species-rich tropical forests, most of the species sampled were represented by one or two individuals on a single plot and are inadequately sampled to draw any conclusions about habitat specificity. Table 5 lists the species that occur in all three completely sampled plots plus all species that are common (i.e., > 10 individuals) in at least one of the plots plus a few other selected species.

At one extreme are 13 species that occur both in the two poor-soil plots and in the fertile-soil alluvial plot. These might be classed as ecologically insensitive; none of them occurs in the secondary forest, six of them (and possibly more) in the swamp plot, and most (perhaps all) of them on the intermediate plot. All of these are essentially uniformly dispersed with similar numbers of individuals in each hectare. *Bertholettia excelsa*, which has 1–2 large emergent trees per hectare throughout the Tambopata Reserve (except in secondary forest), is a good example of this pattern. Other good examples include the subcanopy tree *Leonia glycicarpa*, which has 6–19 individuals per hectare, and the canopy tree *Symphonia globulifera* with 1–4 individuals per hectare, again excluding the second growth plot.

At the opposite extreme are the 21 habitat specialists listed in Table 5, locally common, but occurring in only a single habitat: good soil, poor soil, swamp, or second growth. The extreme case is *Lueheopsis hoehnei*, the absolute dominant in the swamp plot with 265 trees, but completely absent elsewhere; that this is only the second record of such a locally common species from Peru is instructive as to the state of Amazonian Peruvian floristic knowledge. Another example worth mentioning is *Sparrea schippii*, previously unreported from Peru (or indeed from Amazonia), which is the fourth most common species in the alluvial plot. The large number of species that are completely faithful to a single habitat (presumably also including many additional less common species not listed in Table 5) is a good example of the importance of niche specificity in maintaining overall Amazonian species diversity. Each community is rich in large part because it has many species uniquely adapted to a specific substrate.

Perhaps more interesting from the viewpoint of ecological theory are the other two distributional categories indicated in Table 5. The first are species that are common in one habitat but also have a few individuals in one or more of the other habitats. Some of these may represent cases of "mass effect" (Shmida & Wilson, 1985), with an occasional individual surviving but not reproducing outside its normal ecological range. The second pattern is species of the poor soil forest that are common in one of the two sample plots but absent from the other. These may be examples of "ecological equivalents" (Shmida & Wilson, 1985), where due to some accident of dispersal or establishment, a given species occurs at one site but not at another where it would be equally well adapted. The ecological equivalent hypothesis seems especially germane to *Cordia*, where *Cordia mexiana* and *C. panamensis* occur in one upland plot while *C.*

TABLE 5. *Differences in occurrence and abundance in different 1-ha tree plots of some common Tambopata species (all species occurring in all three complete plots or with 10 or more individuals in any one plot plus a few others). Plot 1 is relatively fertile terra firme; plot 2 is swamp forest; plots 3 and 6 are on poor sandy, upland terra firme; plot 4 is on rich alluvial soil; and plot 5 is in young riverside secondary forest.*

toqueve and *C. ucayaliensis* occur in the other. Both of the latter situations represent the pattern thought to be prevalent on Barro Colorado Island (Hubbell & Foster, 1986), with high diversity of a given community due in large part to nonequilibrium fluctuations in its species.

At a different level, my data on plant community composition also seem much less predictable and much more in accordance with the nondeterministic, nonequilibrium viewpoint. In the nine 1-ha tree plots that have been analyzed, there was not a single repetition of a most-dominant species. Although one (or a few) species is always much more common, there is a different "dominant" species in each plot. Even if the several most-dominant species in each plot are compared, there is little overlap. Considering only those species with 10 or more individuals per hectare in at least one tree plot generates a list of 54 species documented to be relatively common locally somewhere in upper Amazonia. But of these, only five species are abundant on two different plots. The shared abundant species include *Astrocaryum murumura*, common on all three rich-soil plots (Yanamono, Cocha Cashu, Tambopata alluvial), and *Hevea guianensis*, common on three poor-soil plots. The other shared abundant species are *Otoba parviflora* on two of the three rich-soil sites (Yanamono and Cocha Cashu) and *Iriartea deltoidea* on a different pair of rich-soil sites (Cocha Cashu and Tambopata alluvial). But even though the same species are generally not abundant at different sites with similar ecology, they are usually *present*. If we take the three rich-soil tree plots as an example, all the abundant Tambopata alluvial-plot species are present in the Yanamono plot, and all the abundant Yanamono species, except *Otoba glycicarpa* and *Carapa guianensis*, are present at Tambopata. All of the abundant Cocha Cashu species are at Yanamono, and all but four of the abundant Yanamono species are at Cocha Cashu. If we compare the sandy-soil plots from Mishana and Cabeza de Mono, there is only one species abundant at both sites (*Hevea guianensis*), but all the common Cabeza de Mono species are present at Mishana, and most of the common Mishana species are at Cabeza de Mono. In contrast, only four species that are abundant at any poor-soil site are present at all in any rich-soil site, all at Yanamono, which has an intermediate level of soil fertility. The relevant point is that although the species present at a site may be predictable, the frequency of a particular species in different forests seems entirely unpredictable and is likely determined stochastically. This is similar to the concept that Shmida & Wilson (1985) have termed "ecological equivalency," i.e., the coexistence of species with effectively identical niche and habitat requirements for largely stochastic reasons. It is also the pattern that would be predicted by Hubbell's (1979; Hubbell & Foster, 1986) community drift theory. Indeed, Grubb (1986) generalized that the relatively sparse or rare species that of necessity constitute the bulk of the species of species-rich communities should interact so infrequently with each other that niche differentiation becomes largely irrelevant.

The same conclusion arises from the 0.1-ha samples. There are almost always a few very common species in any sample. One of these is usually much more common than all the others; at 11 sites the most common species was between two and seven times more common than the second most common species. Yet the only repeat of a "most dominant" species among 25 moist- and wet-forest sites is *Catoblastus velutinus*, shared between Rio Palenque and immediately adjacent Centinela in western Ecuador. For 12 dry-forest sites there was not a single repeat of a "most dominant" species.

Even if all 213 species that are dominant or subdominant in any of these samples (i.e., among the most common 5–10 species) are considered, only 38 are repeated in two or more different samples; ten of these repeated common species (13 if Rio Palenque and Centinela are considered part of the same site) are in repeat samples of the same forest. Thus, only 24 species are abundant at more than one site. One species, *Socratea exorrhiza*, is abundant at four sites, and three species—*Jessenia bataua*, *Arrabidaea oxycarpa*, and *Arrabidaea pubescens*—are abundant at three sites. Ten of the 24 species abundant at more than one site are shared between different dry forests, twelve are shared between different moist forests (typically between Central America and Amazonia), and one (*Mansoa verrucifera*) is abundant in one dry-forest and in one moist-forest site.

A major part of the debate on whether tropical-forest ecosystems are at equilibrium or nonequilibrium may be a by-product of the scale of a particular study or the focus of a particular author. The "rare" species that "random walk" through a 50-ha plot on Barro Colorado Island are mostly common understory or second growth species that would be regarded as permanent and continuous members of the more comprehensive moist-forest plant community that a biogeographer might define. The numerous microhabitat specialists suggested by a casual glance at a series of the Hubbell-Foster Barro Colorado Island distribution maps become nonspecialists if the relatively few individuals that occur away from a favored habitat are emphasized. I suspect that differences in taxonomic focus may also relate to the interpretational differences. Hubbell focused entirely on a particular combination of *species* in addressing the question of community equilibrium. My data suggest that while the species that make up different communities may be very inconstant from place to place, at the same time the different families (and perhaps genera) that contribute to community floristic diversity are very consistent. Perhaps the family is the basic unit on which selection for low population densities (and thus indirectly for high species richness) occurs. For example, many seed predators and leaf-eating insects are host-specific at the generic or familial, as well as the specific, level (Janzen, 1975, 1980, 1984). If family-specific predators and/or family-specific competition are added to the scenario of dynamic forests with some niche differentiation, an explanation pleasing to selectionists and nonselectionists alike could begin to take shape. As indicated in Table 1, the familial diversity of tropical moist and wet forests, unlike the species richness, is both high and remarkably constant. It is certainly within the realm of possibility that this is due to ca. 50 family-specific niches in a given forest, whereas the differing species richness of different forests could be largely stochastically generated by factors relating to higher turnover in the more species-rich sites on better soils and with higher productivities.

A different type of reconciliation, especially of the differences between upper Amazonian and Central American species richness, their causes, and the equilibrium status of the forests involved, might come from a different approach to the data. Hubbell & Foster (1986) emphasized that niche differentiation among Barro Colorado Island species seems to consist mostly of separation into about a dozen generalized multi-species guilds based on degree of shade tolerance and preference for edaphic or topographic microsites. Indeed they suggest that *lack* of niche differentiation might make possible the co-occurrence of many potential competitors which are forced to share the same generalized niche. But by and large the lowland forests of Central America are composed of the same species that in Amazonia would be regarded as the most widespread and weediest species of their respective families or genera (Gentry, 1982a, 1986c). A relatively depauperate Central American forest made up of species adapted for weedy generalized strategies might have little in common with an upper Amazonian forest composed mostly of narrow-habitat specialists. Given a few million more years of evolution, perhaps Central American forests might seem much closer to ecological equilibrium than they do today.

It is no accident that many tropical biologists who have considered the question of why tropical forests are so rich in plant species have greatly modified their original views, no matter on which side of the equilibrium/nonequilibrium question they began (Ashton, 1969 vs. 1984; Hubbell, 1979 vs. Hubbell & Foster, in press; Gentry, 1982b vs. 1982a and Gentry & Dodson, 1987b). We still know so little about tropical forests that generalizations elude us. Almost certainly there are elements of truth on both sides of the question. Quite possibly different forests and the different taxa that make them up will often prove to be doing things quite differently. Although we have not yet reached anything like a consensus on how different factors, or even which factors, interact to determine diversity, it seems abundantly clear from the data presented here that there are discernible and surely deterministic patterns in the species richness of different plant communities. I conclude that which families, how many species, and possibly what individual species make up a tropical plant community are to a large extent deterministic and predictable from simple environmental parameters; how common the species are and how they are put together into different communities may be completely random.

PATTERNS OF VASCULAR PLANT DIVERSIFICATION IN THE FOSSIL RECORD: PROOF AND CONJECTURE

Karl J. Niklas[1]

ABSTRACT

An analysis of historical trends in diversification can suffer from a variety of defects and limitations. Among these is the potential failure of genus and family compilations to yield sufficient information on biological events, such as mass species extinctions. Another is the inadequacy of taxonomically based estimates of diversification to reveal patterns in changing community structure and morphology, which are important in evaluating adaptive evolution. These deficiencies are examined for the plant fossil record and by means of computer simulations of mass extinction events. Comparisons among species, genus, and family diversification patterns reveal qualitative differences sufficient to warrant caution in the use of taxonomic ranks above the species level. However, genus tabulations appear to be an adequate surrogate database for inferring patterns of species origination. Computer simulations revealing patterns of family extinctions may be inadequate for evaluating mass species extinction events since peaks in species and family extinctions rarely, if ever, coincide. A pluralistic approach to evaluating diversification is advocated involving the examination of biotic changes within assemblages and trends in morphological, anatomical, and reproductive evolution.

The notion of *diversity* in paleontology differs little from its use in ecological studies (Raup & Stanley, 1971; Whittaker, 1977). Diversity can be defined as the number of taxa in a community or as the synthetic characteristic of taxonomic richness and equitability, i.e., the relative evenness of the importance values of taxa within a sample (Lloyd & Ghelardi, 1964). However, the nature of the fossil record precludes a direct comparison of diversity between past and present biotas (Krassilov, 1975; Padian & Clemens, 1985). In ecology, taxonomic richness reflects the number of species in a sample of standard size, while measures of equitability involve some gauge of the abundance or productivity of one species divided by the importance values of all other species within the sample (Pielou, 1977). By contrast, fossil assemblages usually reflect time-averaged samples of a geographically ill-defined area. Further, terrestrial organisms are preserved where they were buried, not generally where they lived, and most often after significant periods of decomposition (cf. Niklas et al., 1980; Padian & Clemens, 1985). Frequently, transport to sites of burial results in the disarticulation of land plants and animals, and in deposition of parts in sedimentologically different microenvironments (cf. Kidwell, 1986). Consequently, there is great difficulty (1) in recognizing a species from its parts, (2) reassembling the components of a community, and thereby (3) arriving at a measure of diversity that is comparable to contemporary ecological studies (Raup, 1976, 1979; Niklas et al., 1980; Knoll, 1984; Benton, 1985).

Despite its limitations, the fossil record provides a potentially valuable perspective on a number of evolutionary issues. The paleontologist can compare patterns of diversification over billions of years of Earth's history and can track the origin, radiation, and eventual taxonomic diminution of organisms that no longer exist or are rare in present biotas. Although the nature of paleontological data defines the temporal and taxonomic resolution with which evolutionary issues can be ad-

ANN. MISSOURI BOT. GARD. 75: 35–54. 1988.

dressed, recognition of large-scale patterns that develop, change, and disappear over long intervals of time confers a perspective that augments neontological studies.

This paper is concerned with changes in tracheophyte diversity over the last 400 million years of the Phanerozoic. The fossil record of terrestrial vascular plants is reviewed and discussed within the context of large-scale patterns in composition and taxonomic richness of assemblages through time. The bulk of the data to be discussed has been presented elsewhere in a variety of forms (Niklas et al., 1980, 1985; Tiffney, 1981; Knoll, 1984, 1986; Knoll et al., 1984). Consequently, many facets of tracheophyte diversification will be referenced but not discussed in detail. The principal focus of this paper will be on the limitations of the data and on the qualitative statements about plant evolution that can be made from an inherently imperfect fossil record.

LARGE-SCALE CHANGES AND TAXONOMIC LEVEL

The species is the taxonomic level of choice for determining changes in diversity through geologic time. However, species-level compilations present a variety of procedural difficulties, the most significant of which involve sampling errors (Signor & Lipps, 1982; see also Pease, 1985). Comparisons of global patterns in species diversification with higher taxonomic levels are desirable, because they provide insights into the information to be gained or lost by each type of compilation.

The upper panel of Figure 1 shows a plot of the total species-richness of vascular plants through the Phanerozoic. The data are taken from primary paleobotanical citations tabulated by Niklas et al. (1985) and are segregated into three major categories of tracheophytes: pteridophytes, gymnosperms, and angiosperms. The plot shows a Silurian to mid-Devonian radiation of primitive pteridophytes followed by a Carboniferous proliferation of more advanced or derived pteridophytes and early gymnosperms. A Permo-Triassic decrease in overall diversity precedes a more or less constant level of species number until the middle of the Cretaceous when angiosperms begin to radiate. Diversity of pteridophytes decreased during the Permo-Triassic and reached a relatively constant level throughout much of the Mesozoic and Cenozoic. With the advent and proliferation of angiosperms, the number of gymnosperm species decreased significantly through much of the late Cenozoic.

The lower panel in Figure 1 shows large-scale temporal patterns in diversity at the family level. These data (from Knoll, 1984) were compiled independently from the data on species from Niklas et al. (1980). Data for pteridophytes and gymnosperms are not segregated, thus providing for direct comparisons between species- and family-level diversity for nonangiosperms and for angiosperms. Differences in the diversity between Devonian and Carboniferous families are less pronounced than those seen in the top panel. As Knoll (1984) noted, the number of species in late Paleozoic families is higher than in early Paleozoic families, presumably due to the appearance of more complex or numerous morphological and anatomical features upon which species can be based. Ordinal changes in plant diversity compiled by Knoll (1984) conform in large measure to the trends seen in the family diversity plot.

Despite the differences between species and family diversity, it is evident that the number of vascular plant taxa increased throughout much of the Paleozoic and has accelerated during the Cenozoic with the advent of angiospermy.

The value of comparing diversity among different taxonomic levels can be further illustrated by examining data for a specific group rather than the entire domain of tracheophytes. The selected group ought to have a fossil history that spans the Phanerozoic and thus obviates any idiosyncratic feature of a geologic period. Three major groups of vascular plants have a virtually continuous fossil record since the Upper Devonian: lycopods, sphenopsids, and ferns (Stewart, 1983). Of these three groups, the ferns are the most abundant through time. Hence, they

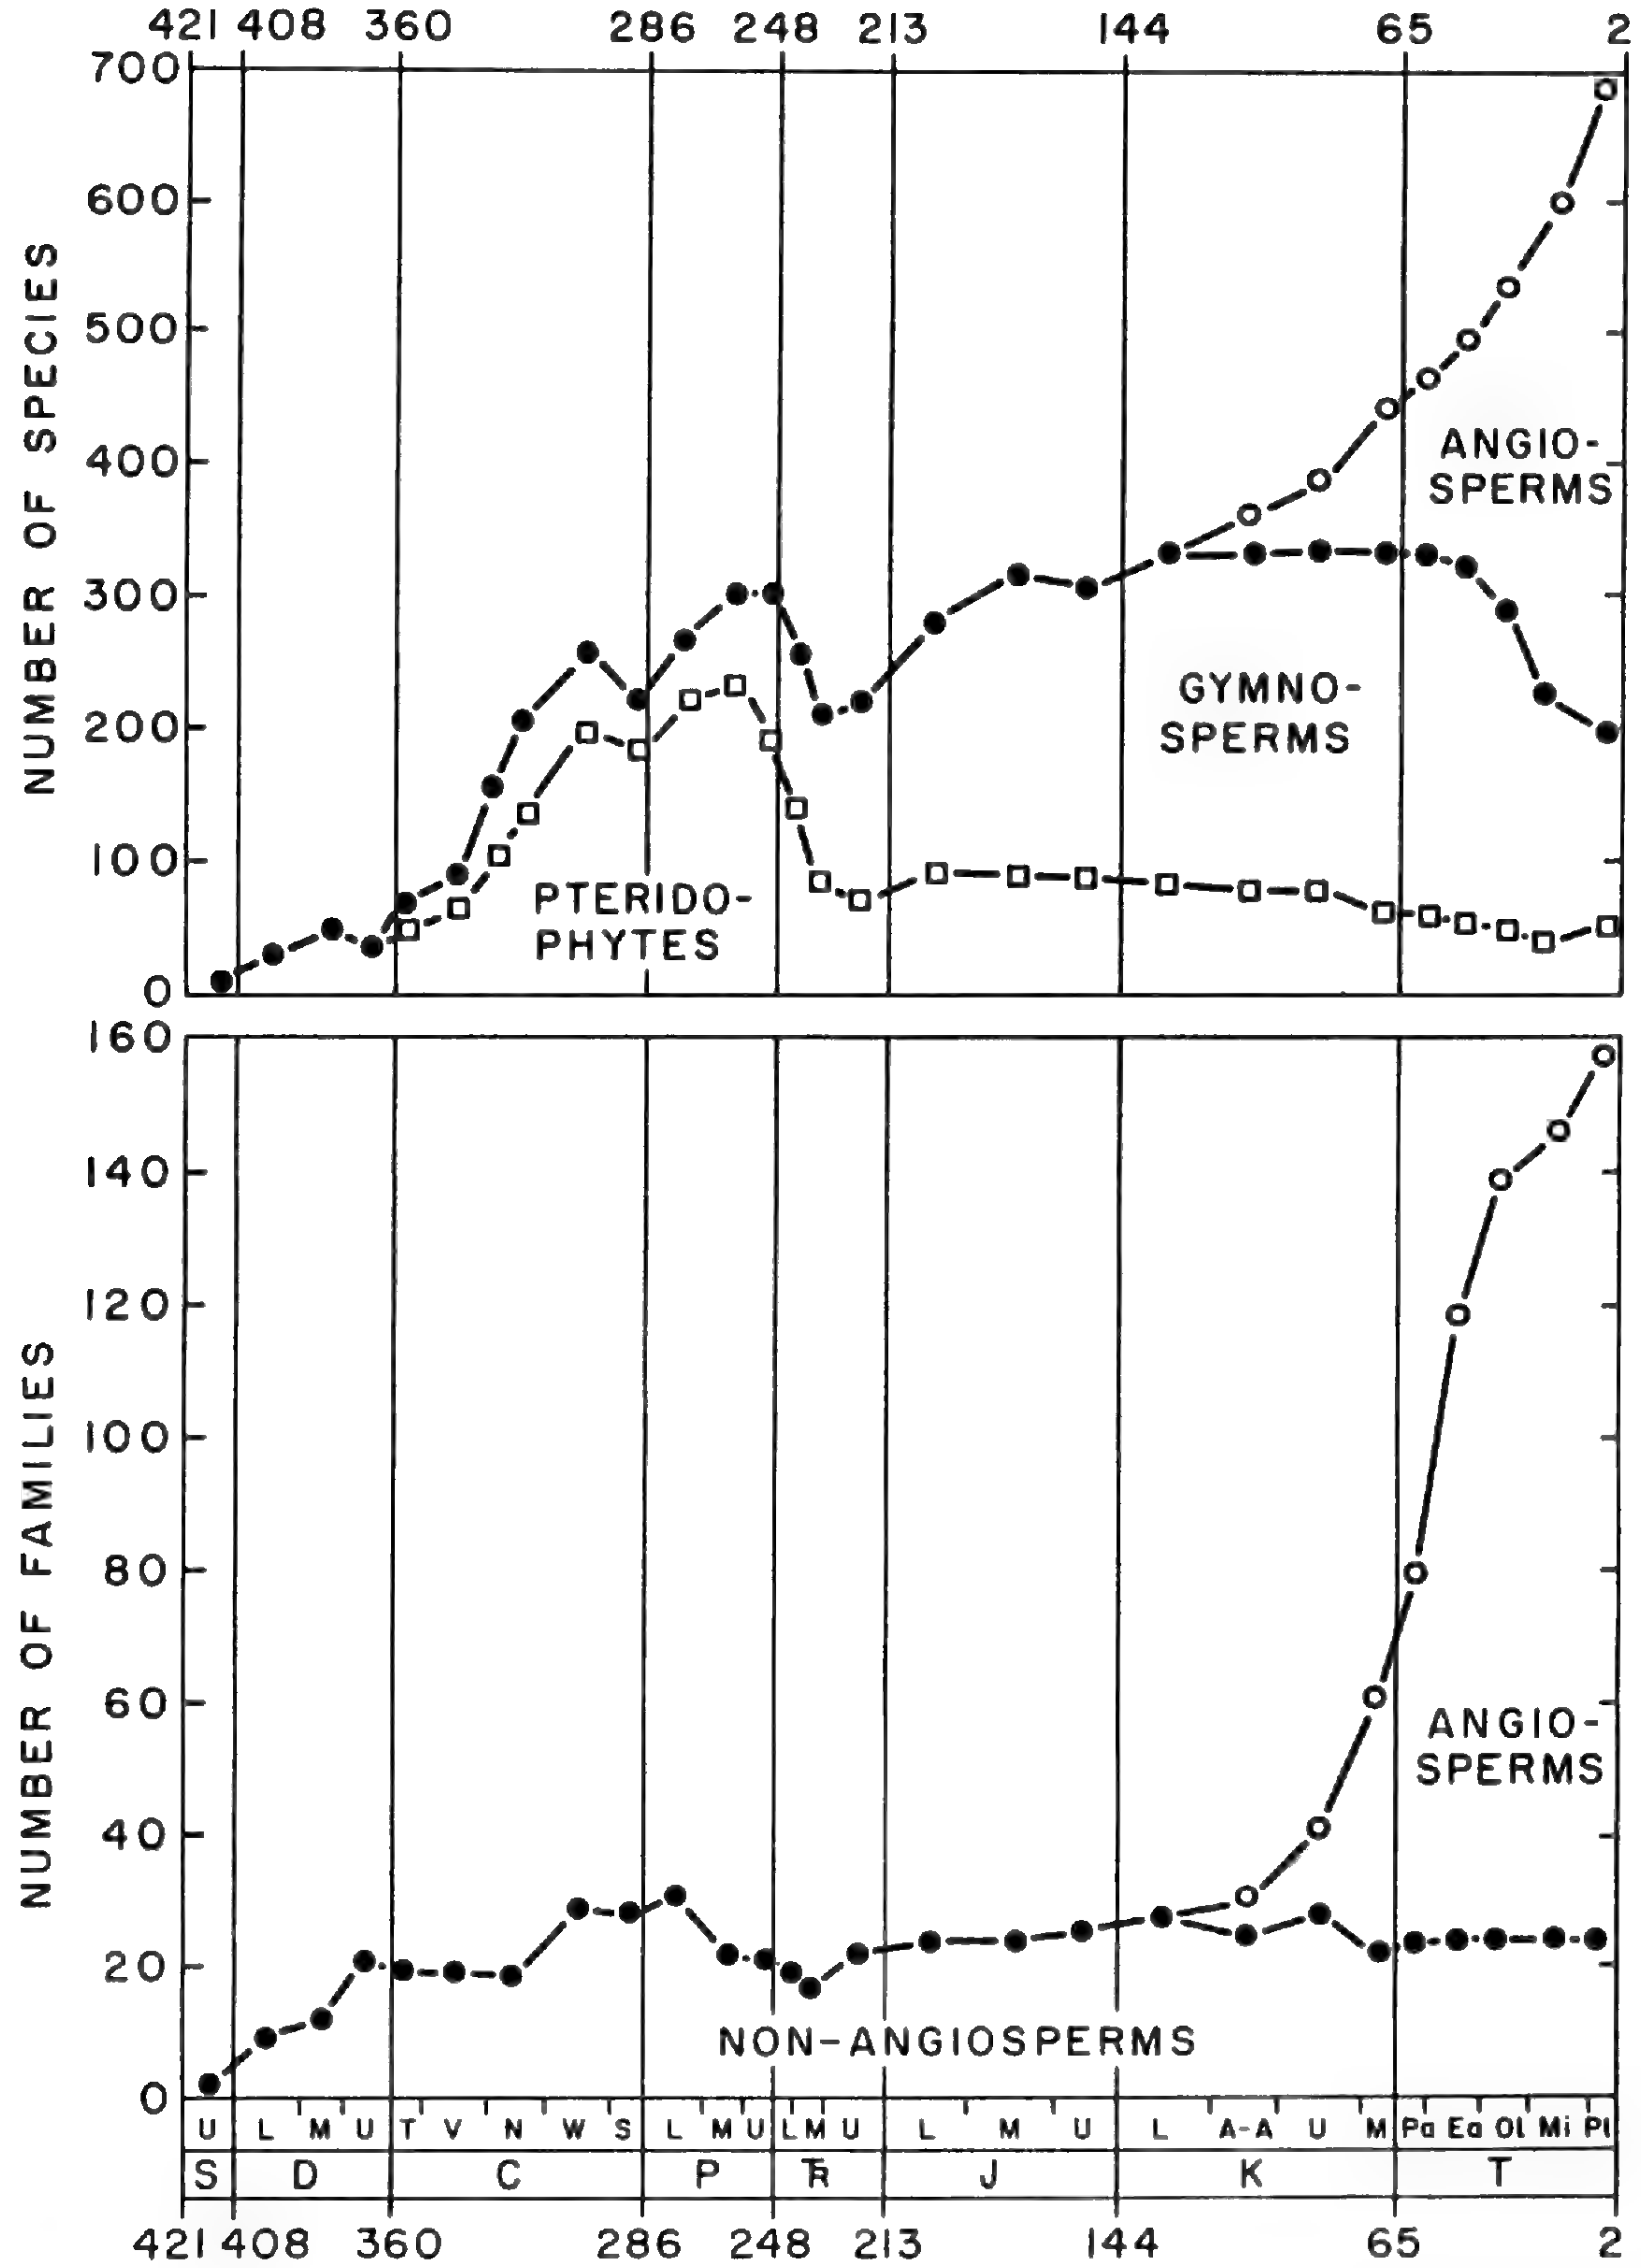

FIGURE 1. *Large-scale changes in diversity of tracheophytes at the species- and family-level (upper and lower panels, respectively) recorded per epoch through the Phanerozoic. Species global diversity data were taken from Niklas et al. (1980, 1985); family diversity data are redrawn from Knoll (1984). The time-scale is that of Harland et al. (1982): For the Carboniferous (C), T = Tournaisian, V = Visean, N = Namurian, W = Westphalian, S = Stephanian; for the Cretaceous (K), L = Berriasian-Barremian, A-A = Aptian-Albian, U = Cenomanian-Campanian, and M = Maastrichtian.*

are convenient for comparing differences in diversity based on compilations of species, genera, and families. The most complete treatment of fossil ferns is that of Boureau (1970). Unfortunately, this does not reflect recent advances in taxonomy nor does it present a critical evaluation of stratigraphic occurrences (see for example Phillips, 1974; Stewart, 1983). Nonetheless, the data contained within this volume are useful because they are easily accessible and reflect the state of paleobotanical knowledge as compiled in a single reference. Accordingly, the data for fossil ferns are dealt with here solely for the

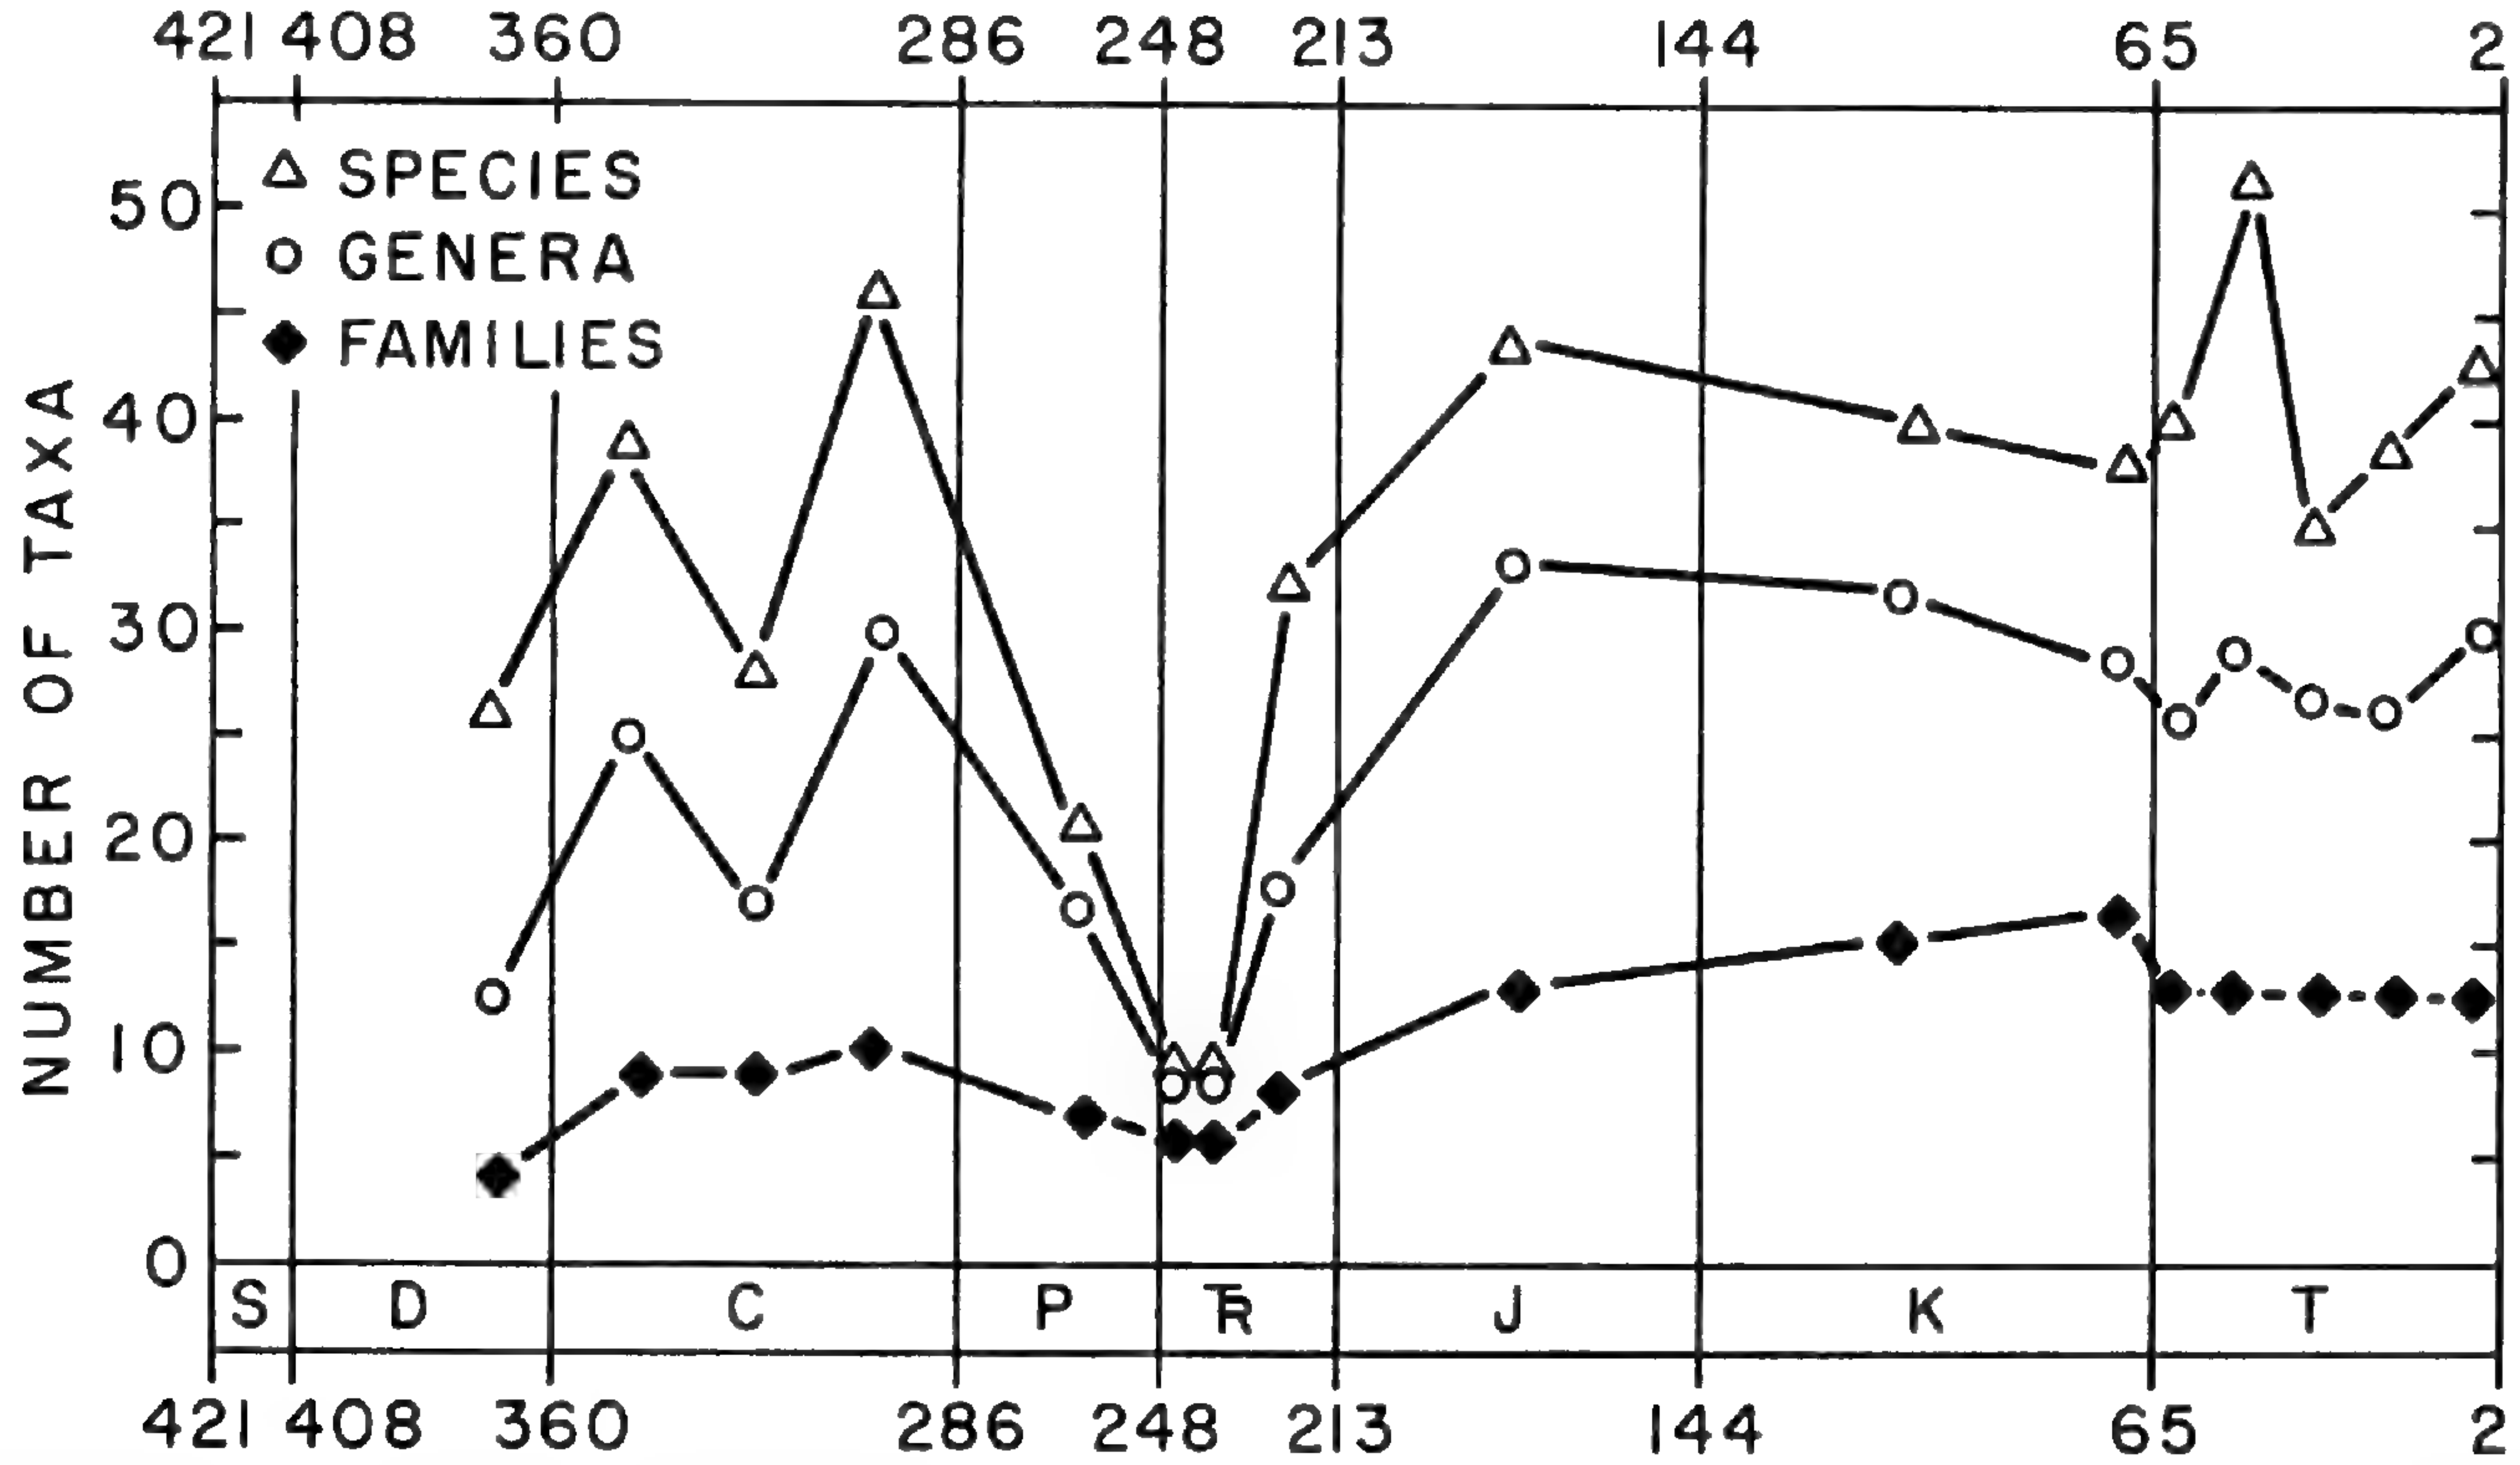

FIGURE 2. *Taxonomic diversification of ferns based on data compiled by Boureau (1970). Stratigraphic resolution of species, genus, and family occurrences from the source is coarser than that of species diversity plotted in Figure 1. Consequently, the time-scale of this figure is less precise than desirable.*

purpose of comparing the qualitative diversity measurements made at different taxonomic levels within a major plant group.

Figure 2 shows the total diversity of fossil ferns based on species, genus, and family compilations. Since the citations given in the data sets are rarely more specific with regard to stratigraphy than lower or upper, middle, and lower divisions of each period, the resolution of the geologic scale is necessarily more crude than desirable and not directly comparable to those given in Figure 1.

Peaks in the species diversity of ferns occur in the Lower and Upper Carboniferous, the Middle Jurassic, and in the Eocene. The maximum number of fossil fern species is recorded in the Eocene. Species numbers significantly decrease in the Middle Carboniferous, Lower and Middle Triassic, and in the Oligocene. Generic tabulations reveal similar peaks and valleys in diversity as those seen in the species data; however, the overall diversity maximum in the Lower Eocene is less pronounced in the generic data set than in the species compilation. Family diversification is muted throughout much of the Phanerozoic. Nonetheless, the Triassic decrease in diversity (from ten families in the Upper Carboniferous to six families in the Middle Triassic) occurs in both the species and generic plots.

What then is the appropriate taxonomic level for gauging long-term patterns in diversification? Large-scale changes in tracheophyte diversification at the species and family levels are poorly correlated (Fig. 1). This is not surprising given the diversity of lineages that comprise the tracheophytes. The diversification of tracheophyte species may show episodes of increase due to the radiation of a few families even if the majority of the remaining families dwindle in species numbers or go to extinction. Even for a particular group of plants, such as the ferns, there appears to be only a loose correlation between changes over geologic time in species or genus and family numbers, presumably for much the same reason—"taxonomic stacking."

The family may not be the appropriate taxonomic level for analysis for many types of evolutionary questions, as, for example, the identification of mass-extinction events (see next section). A family is eliminated from the fossil record with the extinction of its last surviving species. This terminal extinction event may occur well after the major period of species-attrition within a family. Thus, there is a double-edged effect in the use of higher taxa for determining unusual perturbations in overall diversity. A "mass-extinction event" may be due to the geologically synchronous elimination of the relic species of numerous, species-depauperate families. On the other hand, many species-rich families could undergo a geologically sudden and severe depauperation in species without the total disappearance of these families from the fossil record. A dramatic reduction in taxonomic diversity below the family level would reflect a significant event in the history of life that could go undetected in family tabulations of diversity. Similar arguments could be made concerning the effectiveness of genus tabulations in detecting intense episodes of species extinction.

Species compilations comprise the most biologically relevant database for paleontology. However, a paleospecies is not operationally defined or identified at the same level of taxonomic scrutiny or with the same body of information and experimental format as a species of living organism. This severely limits the application of conventional species concepts to fossil material.

Recognition of a fossil plant species is perhaps even more difficult than that of a fossil animal species. Plants are phenotypically more plastic than many major groups of animals (Cahn & Harper, 1976; Harper & Bell, 1979; Harper, 1985; White, 1979). The recognition of ecotypes or taxonomic varieties of living plants is notoriously difficult and requires detailed transplant experiments, cytological and electrophoretic examination, and field observations of population dynamics across environmental gradients (Harper, 1977, and references therein). Fossil plants are most frequently found as disarticulated organs which, for many plants, have been previously assigned to separate taxa (Knoll & Rothwell, 1981; Stewart, 1983). Only when found in organic connection can organ genera be placed in synonymy. Consequently, the recognition of genus as an "organ" can only be done on an ad hoc basis. Since whole plant reconstructions are still rare in the paleobotanical literature, the inflation of species richness due to the effects of dealing with fragmented parts is a serious limitation to assessing the true taxonomic diversity in a fossil assemblage.

Perhaps the only reasonable solution to the choice of taxonomic level is to deal with species and genus tabulations for each family. Correlations in the patterns of diversification among all three taxonomic levels for particular groups of plants could then be used to estimate long-term trends or geologically sudden changes in taxonomic richness. As yet this suggested type of multiple-level analysis has not been undertaken for any group of organisms.

MASS EXTINCTIONS: AN ARTIFACT OF HIERARCHY?

Measurements of diversity based on taxa above the species level have been used to determine large-scale evolutionary patterns. Perhaps the best example of this approach comes from the use of family-level data on marine animals to determine major diversification and extinction patterns (Sepkoski, 1980, 1981a, b, 1984; Raup & Sepkoski, 1982, 1984). Sepkoski (1981a, b, 1984, and elsewhere) has argued that family data represent a good proxy for estimating diversity of species (cf. Sepkoski et al., 1981). In addition, comprehensive data with good stratigraphic resolution do not exist for marine animal species or even genera (e.g., Sepkoski, 1984: 247–248). However, as will be shown in this section, the behavior of families as evolutionary "units," and in particular the pattern of family extinction rates, is dependent upon the frequency distribution of species within families.

Raup & Sepkoski (1982, 1984) identified five statistically significant "mass extinction" events in the Phanerozoic record of marine animal families: late Ordovician (Ashgillian), late Devonian (Frasnian), late Permian (Guadalupian-Dzhulfian), late Triassic (Norian), and late Cretaceous (Maastrichtian). Although the magnitudes of species-extinctions are hard to

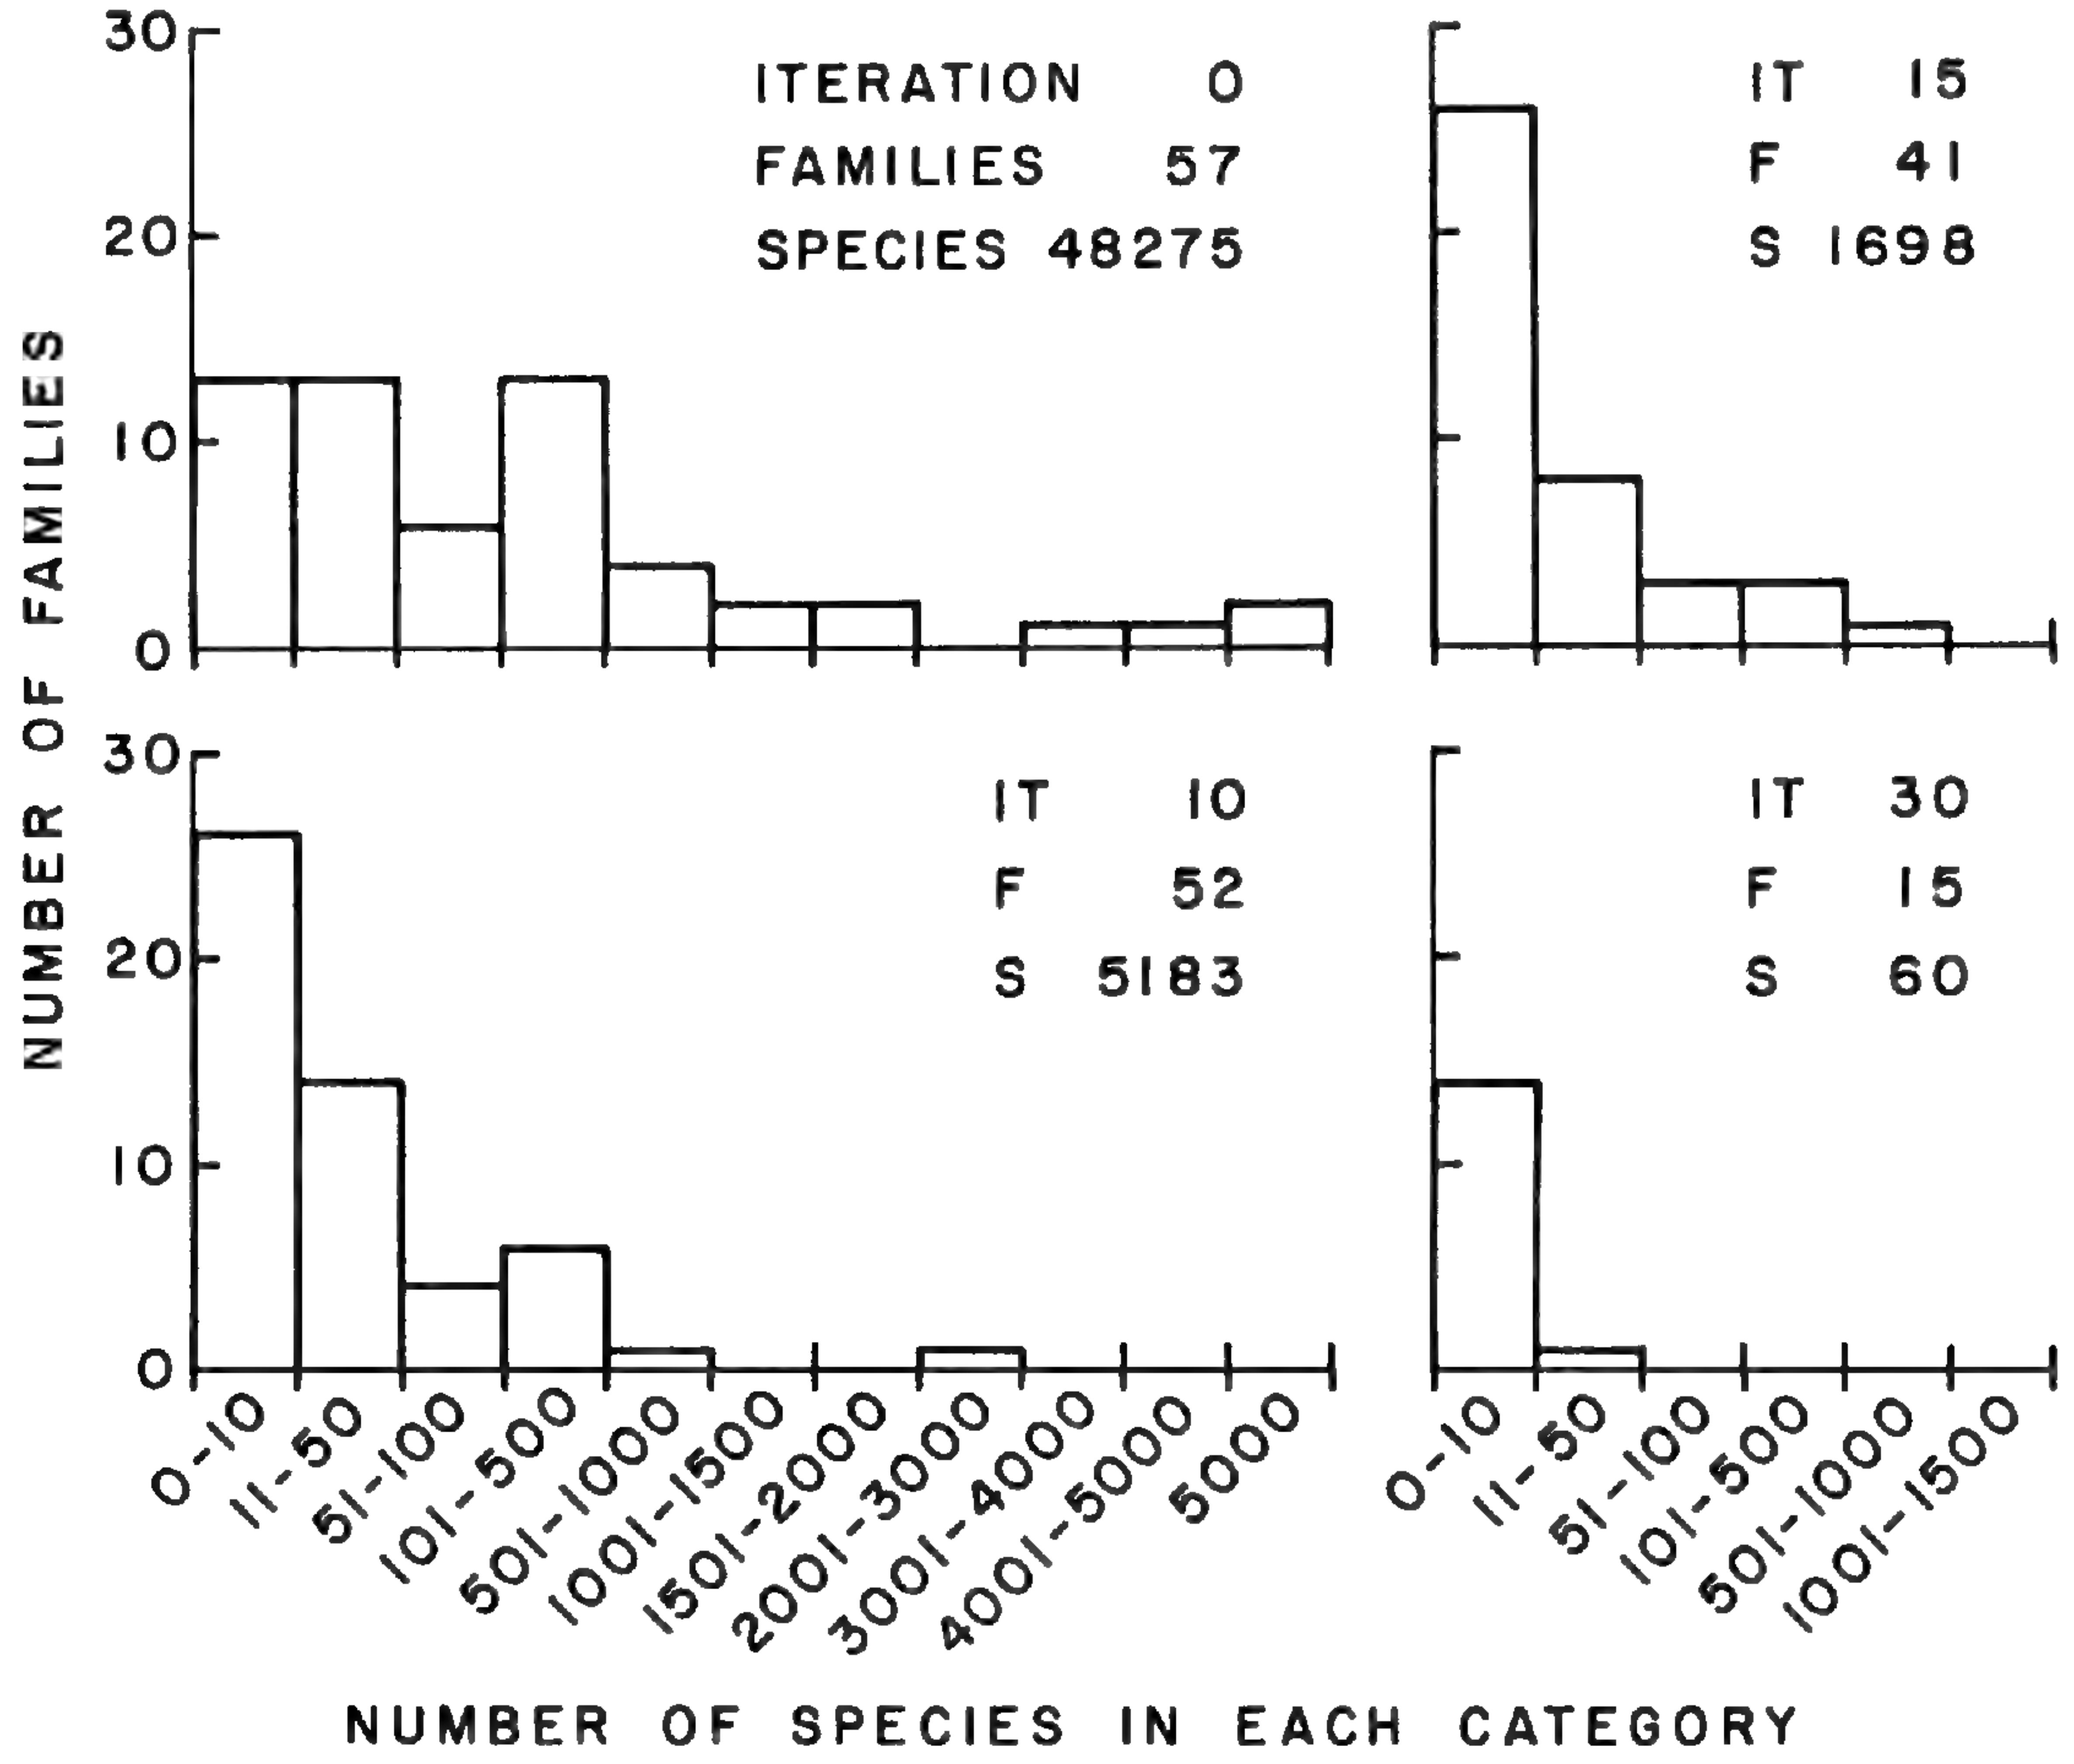

FIGURE 3. *Changes in the species frequency distribution of monocotyledon families predicted from a computer simulation of random species extinction. Data from Cronquist (1968, 1981) were used to construct an initial histogram (= iteration 0) representing 57 families and 48,275 species. Random species extinction (20% reduction of species number every iteration) results in a "mass species-extinction event" at iteration 1. Sequential extinction events (which withdraw fewer and fewer absolute numbers of species with each successive iteration) result in shifts of the histogram (cf. Figs. 5, 6).*

estimate from the family data, Raup (1979) suggested that the late Permian "mass extinction" event involved a reduction of as many as 96% of marine animal species. Significantly, Raup's regression of family background extinction rates against time yields a negative slope (a long-term decline in family extinction rates), which Raup & Sepkoski (1982) interpreted as reflecting a "fitness-optimization" in which surviving marine taxa become more resistant to extinction through geologic time (but see Kitchell & Pena, 1984). More recently, Sepkoski (1984) modeled the total rate of background extinction (with constant extinction parameters) and suggested that the decline in rates resulted from differential expansion and replacement of evolutionary faunas. Sepkoski's model involves lag phases in the evolutionary behavior of clades within each evolutionary fauna.

A continuous and constant rate of species extinction can produce discontinuous and abrupt increases in rates of family extinction provided blocks of species go to extinction. This can be illustrated by modeling family extinction rates based on the species frequency distributions of angiosperms.

Data on the approximate numbers of species per family in the major groups of angiosperms are provided by Cronquist (1968, 1981). Histograms of the species frequency distributions in the families of monocotyledons and dicotyledons are shown in Figures 3 and 4. In both cases, the majority of families have fewer than 500 species per family; however, both monocots and dicots have families with species numbers in excess of 5,000. (The Compositae with 19,000 species is not shown in the data set for dicotyledons.) These distributions are similar to those constructed by Clayton (1972, 1974) for the generic frequency distribution in angiosperm families, which conforms to a

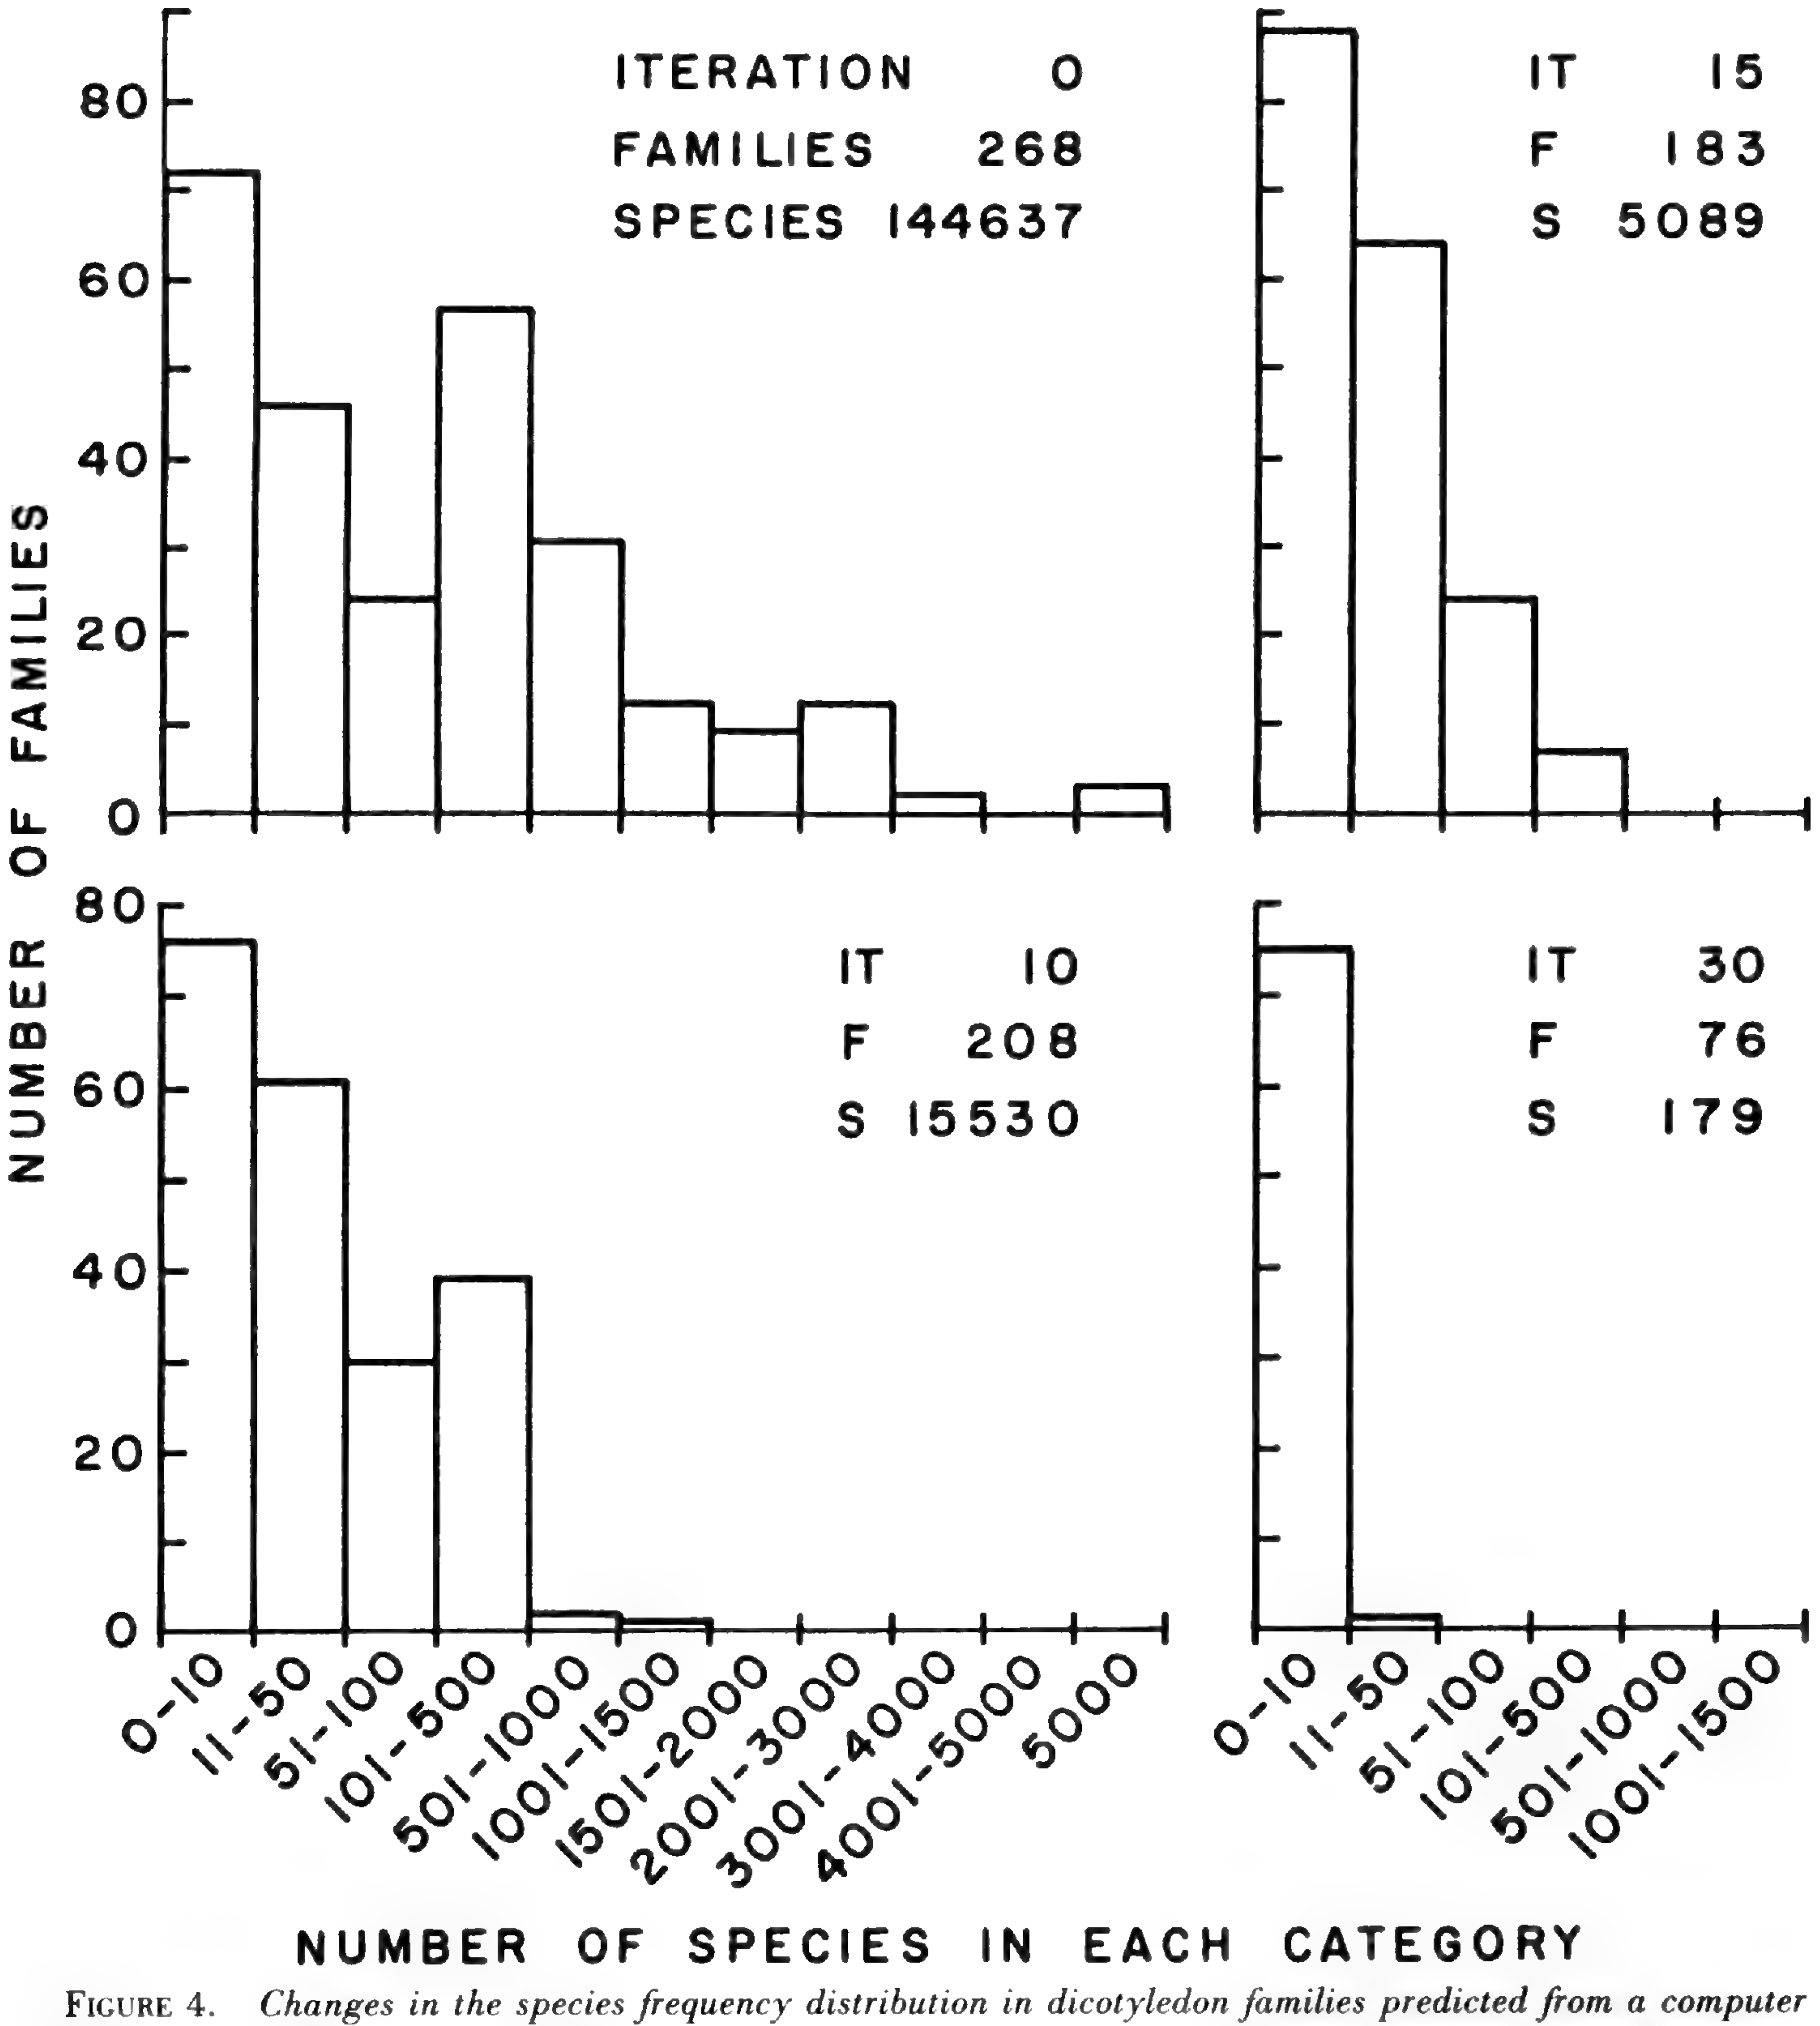

FIGURE 4. *Changes in the species frequency distribution in dicotyledon families predicted from a computer simulation of random species extinction. Data from Cronquist (1968) were used to construct the initial histogram (= iteration 0) representing 268 dicot families and 144,637 species (the Compositae are not included in this simulation). Random species extinction (20% reduction in number of species every iteration) results in a "mass species-extinction event" at iteration 1. Sequential extinction events result in the reduction of dicotyledon families (cf. Figs. 5, 6).*

logarithmic distribution. Consequently, the following arguments against the use of family compilations for determining mass extinction events can be extended to the use of genus tabulations.

A computer simulation technique was devised to track the family extinction rate as a constant percentage of species is reiteratively removed from each clade. The species undergoing extinction were selected randomly among all families by means of the standard linear congruent method, which does not bias

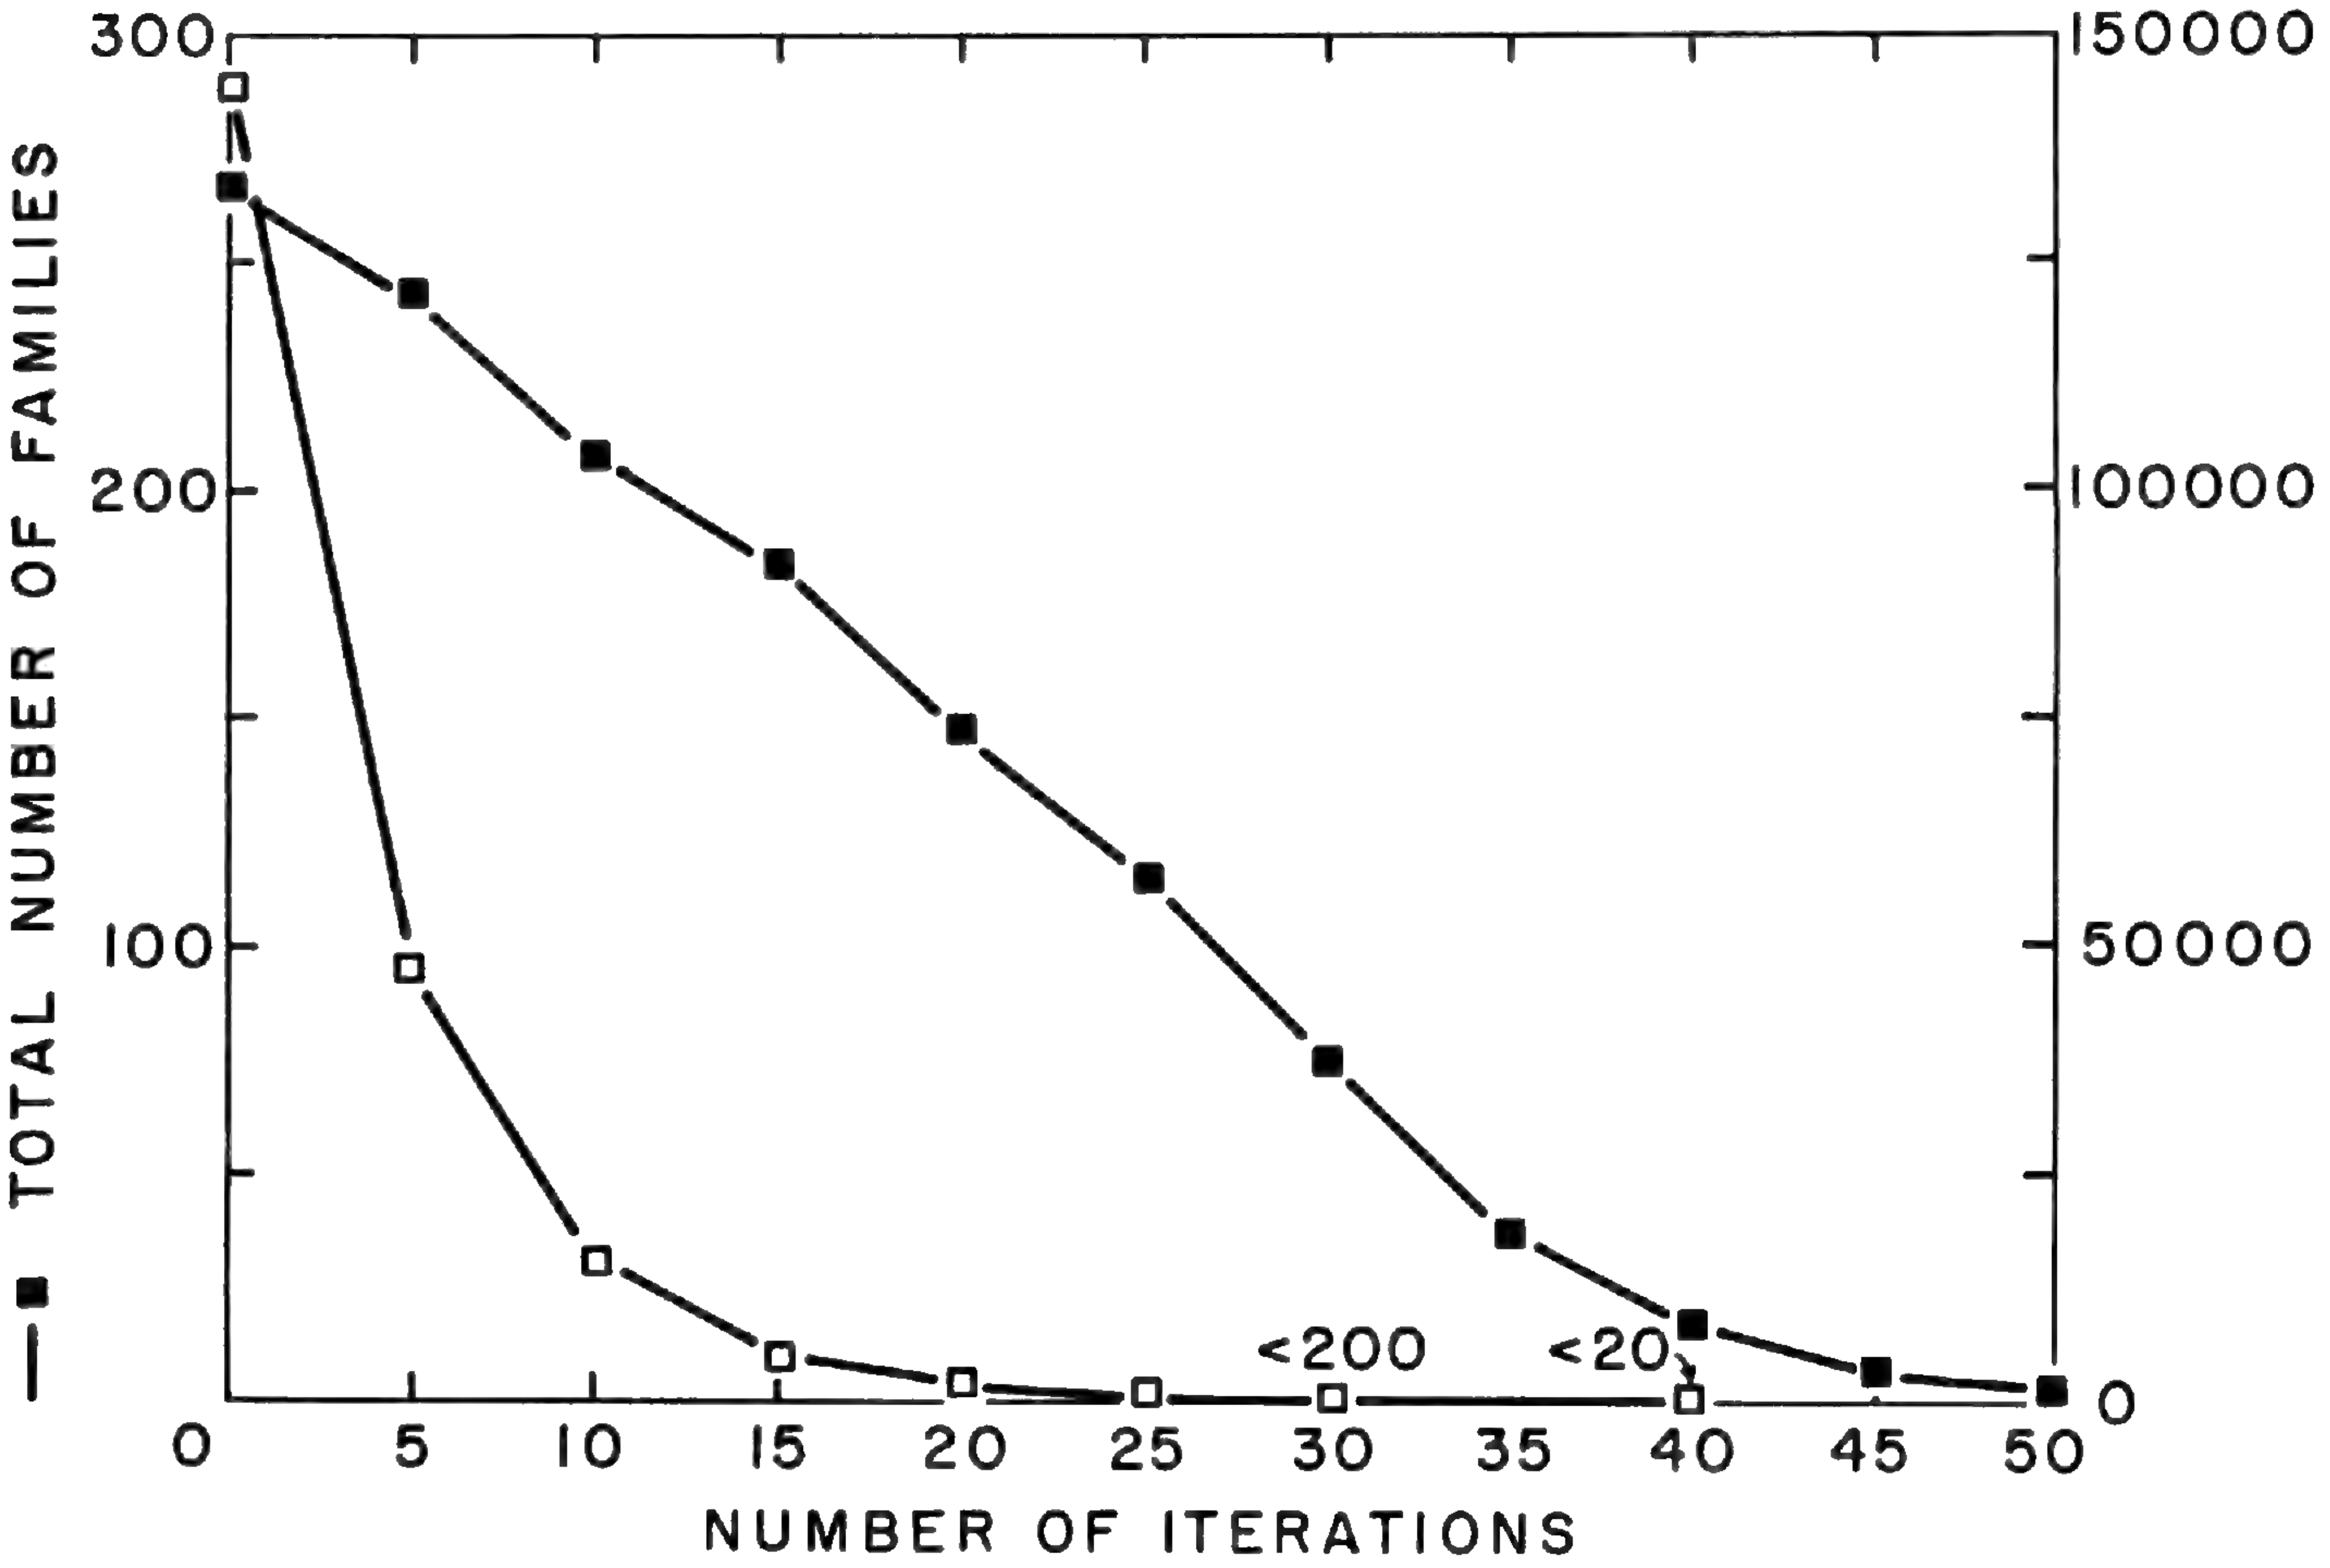

FIGURE 5. *Changes in the total number of dicotyledon species and families over 50 iterations of species extinction (20% reduction in number of species every iteration). Numbers of species decline exponentially; numbers of families decline in as near linear function until the 35th iteration.*

the probability of species extinction toward large or small families. Consequently, all species have an equal probability of going to extinction. If a constant percentage of species goes to extinction, then a "mass-species" extinction event occurs on the first iterative cycle of each simulation, i.e., each simulation starts out with the maximum number of species; therefore, the first cadre of species to go to extinction is the largest in absolute number. Successive extinction events result in a progressive decline in the absolute number of species undergoing extinction. The use of a constant percentage extinction rate provides an opportunity to look for possible correlations between mass-species and mass-family extinction events. Simulations in which a constant number of species go extinct ($ds/dt = k$) rather than a constant percentage of species yield similar patterns of family extinction but require extended reiterative cycles of species extinction. Each simulation based on a constant-percentage rate of species extinction was run for 50 reiterative cycles. At this point most families (99%) became extinct.

The consequences of successive iterative species extinctions on the frequency distributions of monocot and dicot families is shown in Figures 3–5. As expected, each histogram gradually shifts toward the left (= numerous species-poor families). Figure 5 shows that species numbers exponentially decrease and asymptotically approach the x-axis (which is a very crude analogue to time, since there is no a priori way to relate an iteration of species extinction to an interval of geologic time); decrease in the number of families with successive iterative species extinctions is nearly linear. Various species-extinction rates ranging from 10% to 50% yield comparable patterns. Significantly, however, total family-extinction rates (number of families going to extinction per iteration) are not constant. Comparisons between the dicot and monocot simulations are shown in Figure 6. The total family-extinction rate, E_F, for dicots increases

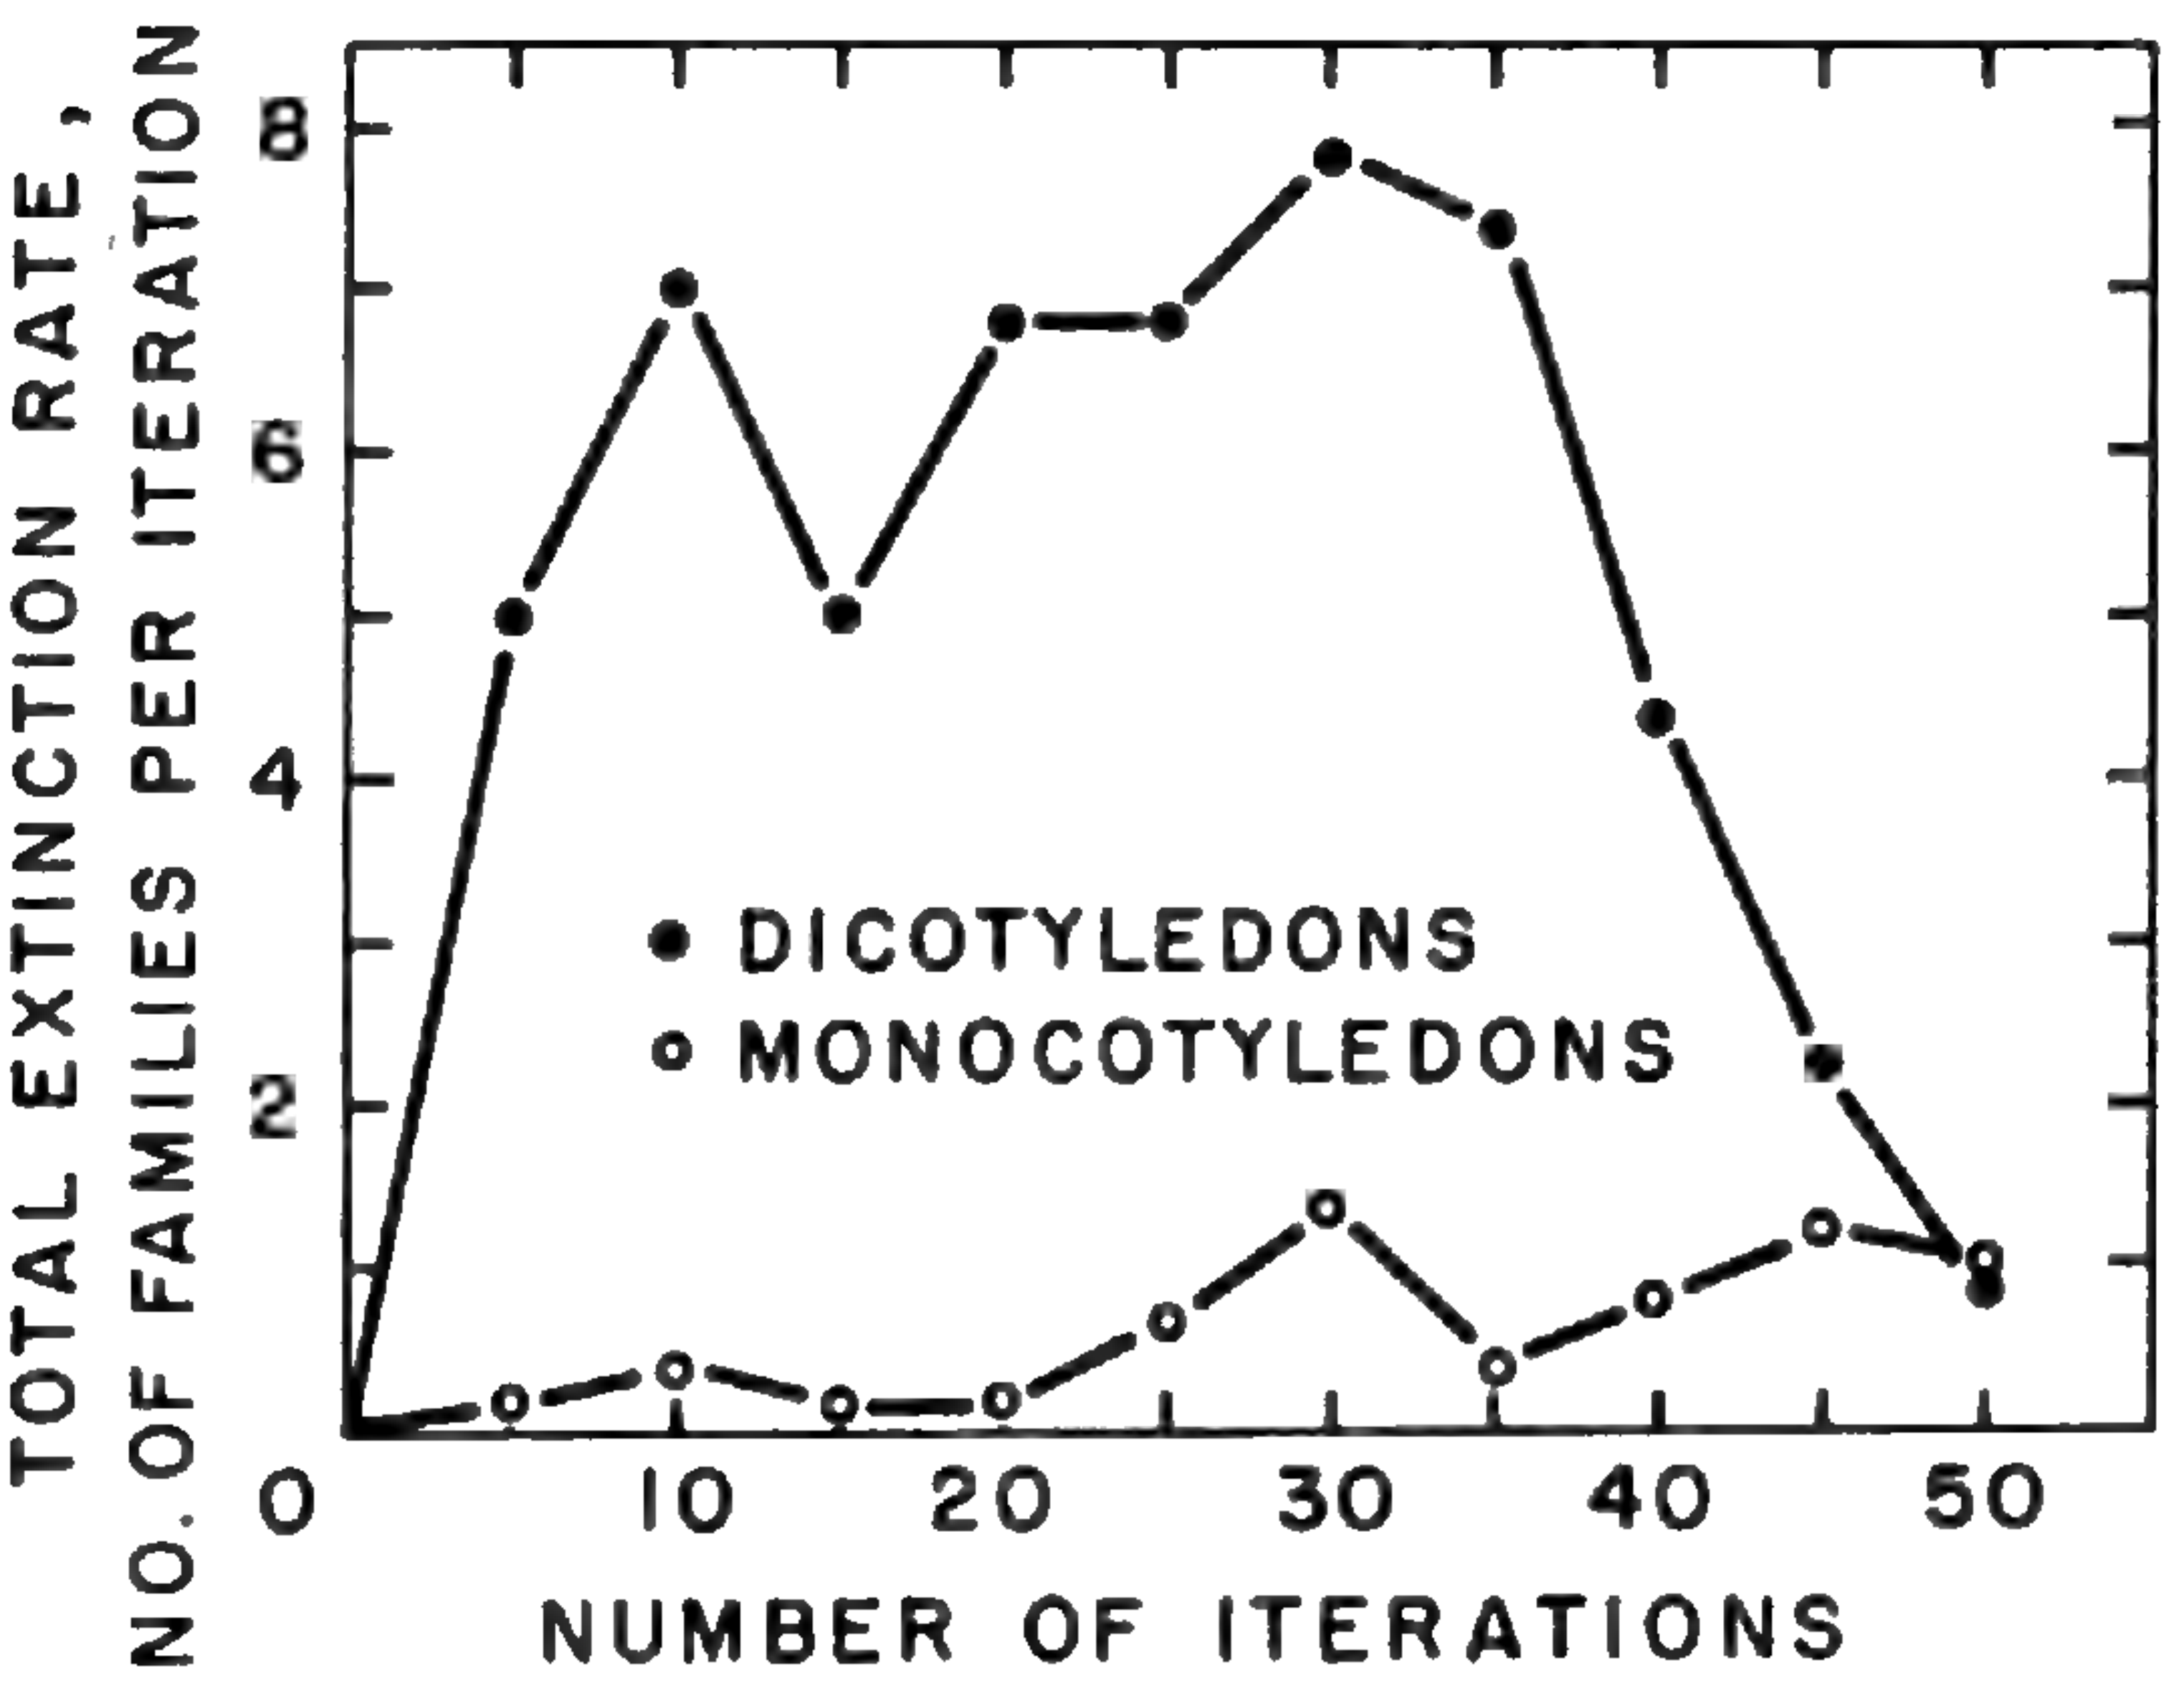

FIGURE 6. *Patterns of the total extinction rate of dicotyledon and monocotyledon families resulting from a 20% species-extinction rate. These values were computed on the basis of data shown in Figure 5.*

sharply to 7.0 (after 10 iterations), decreases to 5.0 (after 15 iterations), and then plateaus before it sharply declines after 35 iterations. A pattern that is qualitatively and quantitatively dissimilar to dicots is observed for the monocot simulation, e.g., E_F never exceeds 1.4 and increases only slightly over many iterations.

Differences between the patterns of family-extinction rates for monocots and dicots are due solely to differences in their respective initial species frequency distribution in families. To test the sensitivity of patterns of family-extinction rates to the frequency distribution of species among families, three artificial distributions were created: (1) one in which the majority of families contains many species (skewed to the right); (2) a distribution having an equal number of families in each category of species-richness (= horizontal distribution); and (3) one in which the majority of families contains few species (= the frequency distribution is skewed to the left). In each case, the total number of families was held constant (N = 111). Owing to the nature of the distributive functions, the total numbers of species and families in each distribution cannot be equal in each of the three cases. However, species-extinction rates are based on percentages, and family-extinction rates are the subject of concern. Therefore, the inequality of species numbers in the three frequency distributions does not appreciably influence comparisons among the three trends in family extinctions.

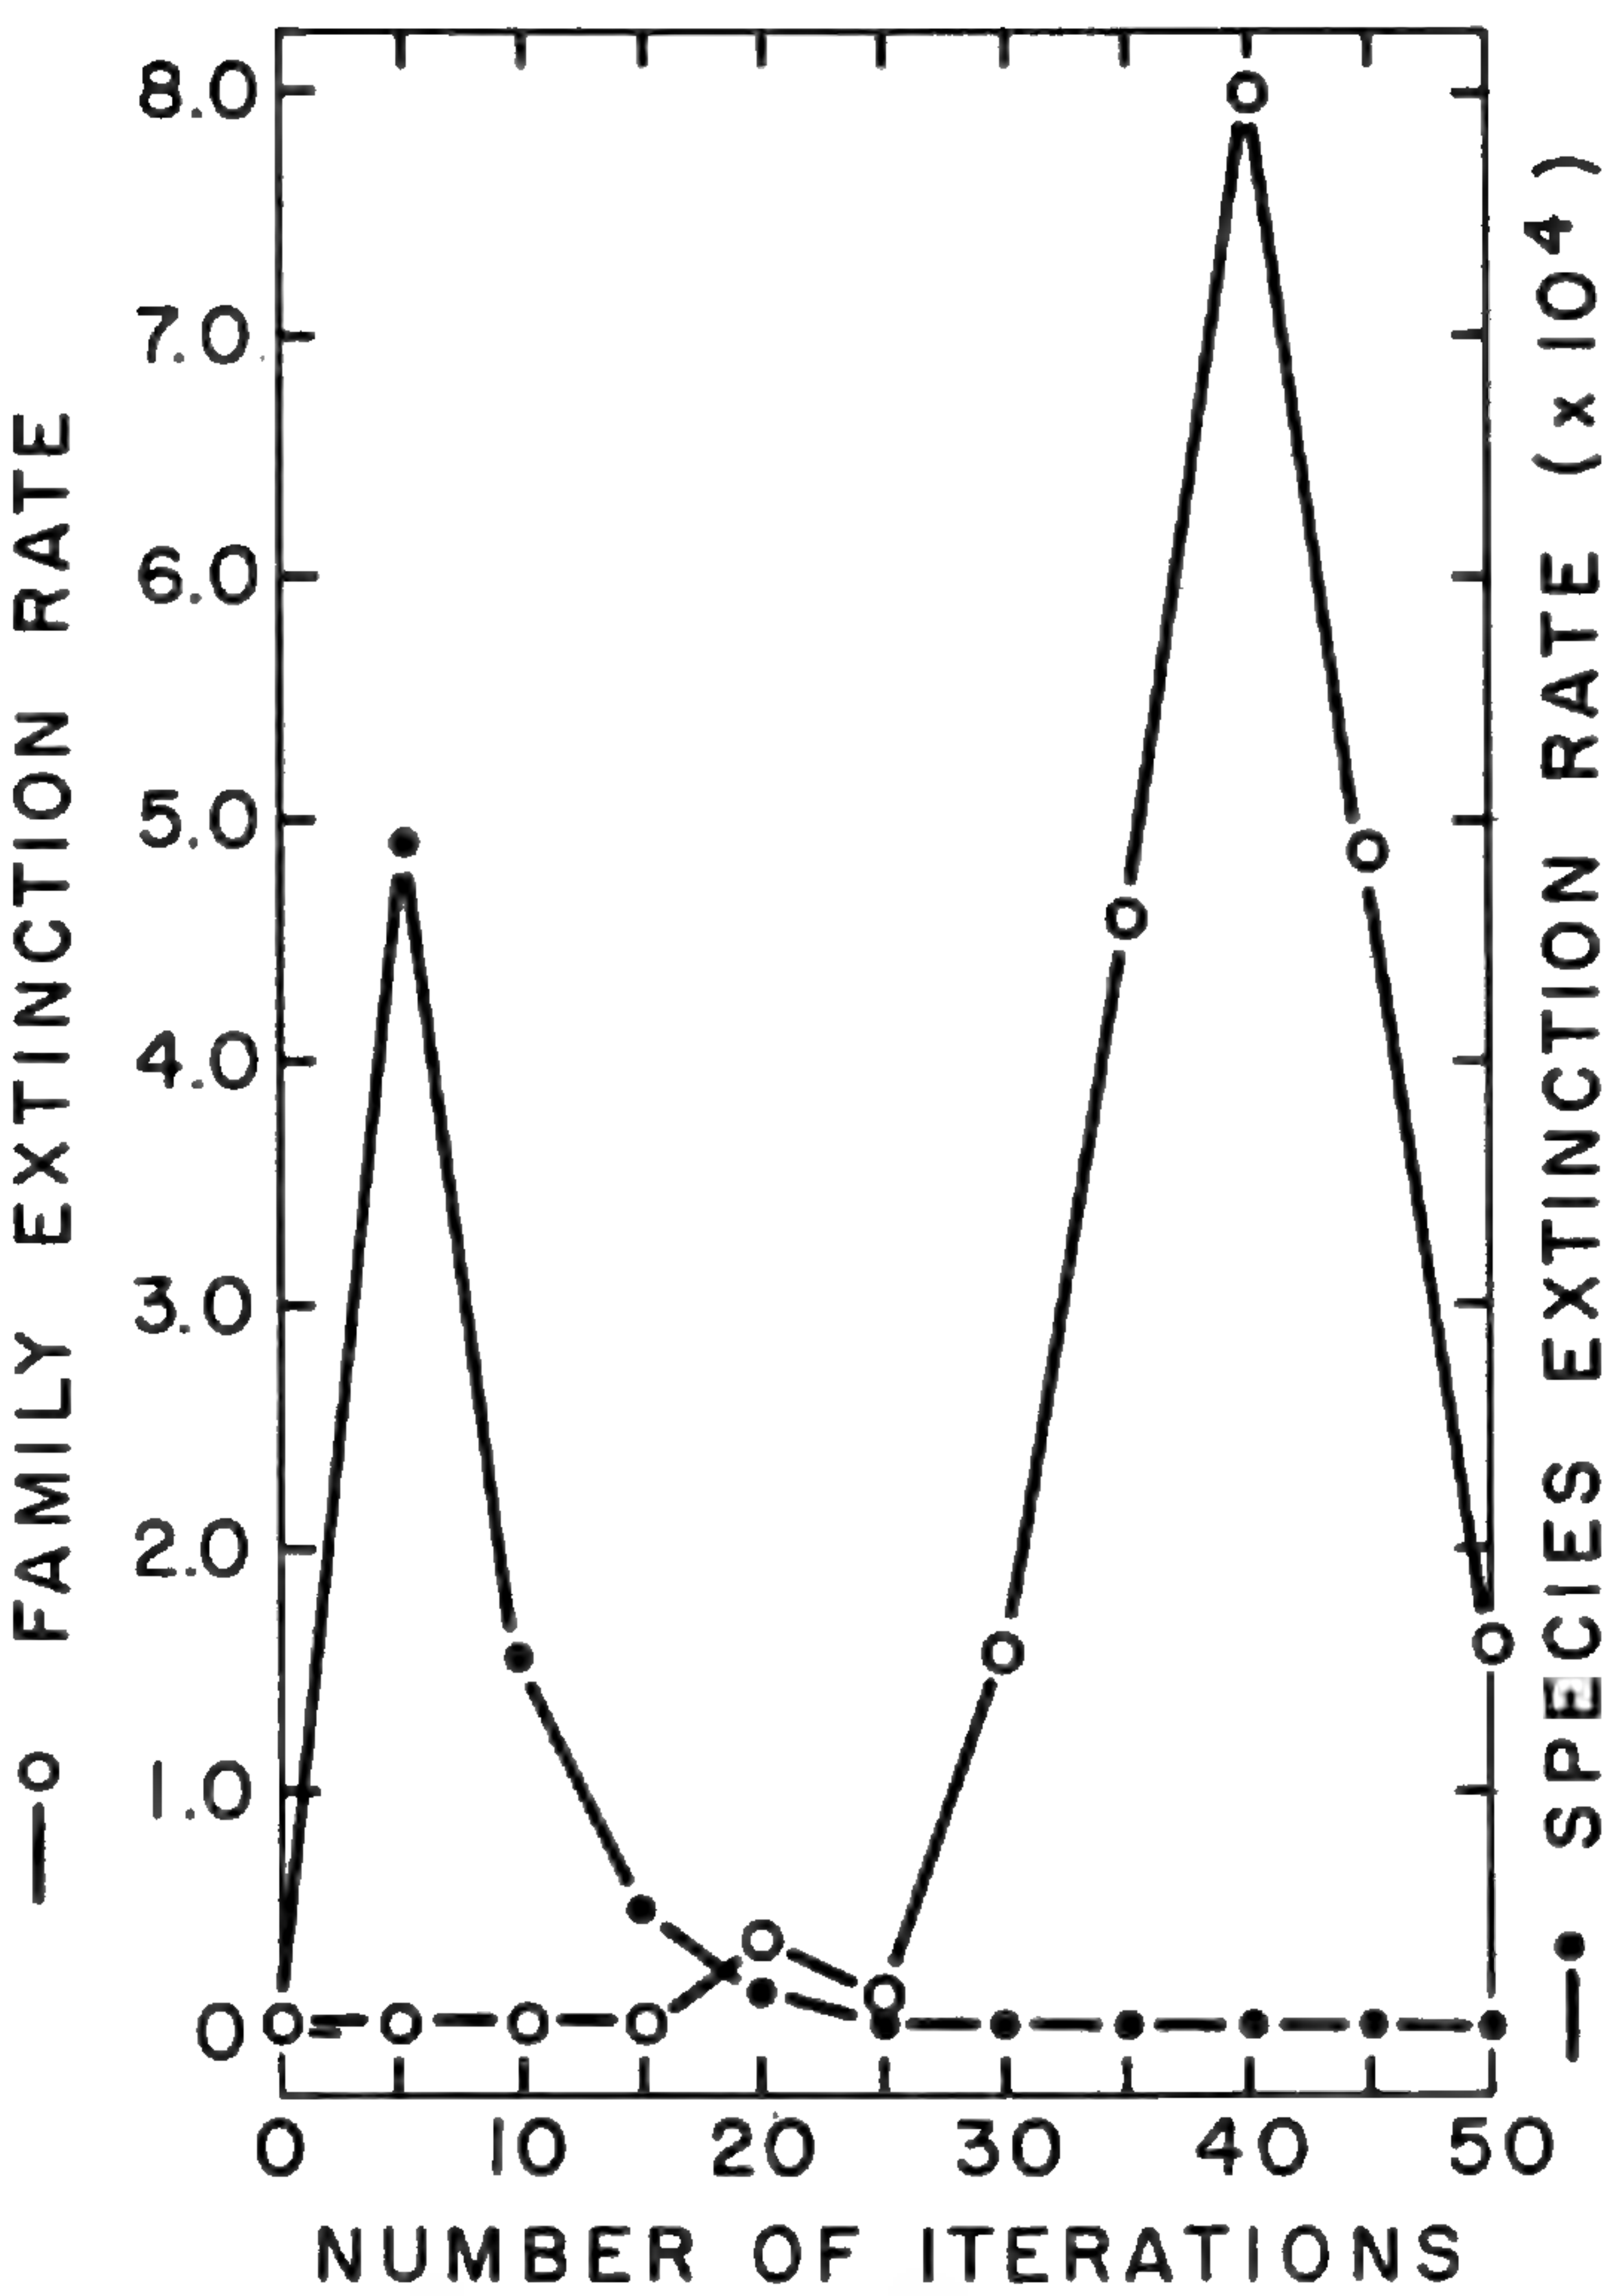

FIGURE 7. *Patterns of the total extinction rate computed for an artificially constructed species frequency distribution in which many families are species-rich and only a few families are species-poor. The total number of families in this simulation is 111; the total number of species is 360,871. A "mass species-extinction event" is apparent by the fifth iteration of 20% species extinction. The largest absolute number of species to go extinct occurs at the first iteration. However, data are graphed showing the summation of extinction events for intervals of five iterations. This is necessary because family extinction rates per iteration are very low. A "mass family-extinction event" is simulated at the 40th iteration.*

Figures 7–9 show the resulting patterns of total family-extinction rates for the three artificially created frequency distributions. A greater resolution of these peaks (in which family-extinction events are plotted every iteration) is possible. However, the number of families eliminated per iteration is very small (1–3 families); therefore, the magnitude of peaks in family-extinction rates would be small (1–3 families per iteration). By calculating family-extinction rates every five iterations,

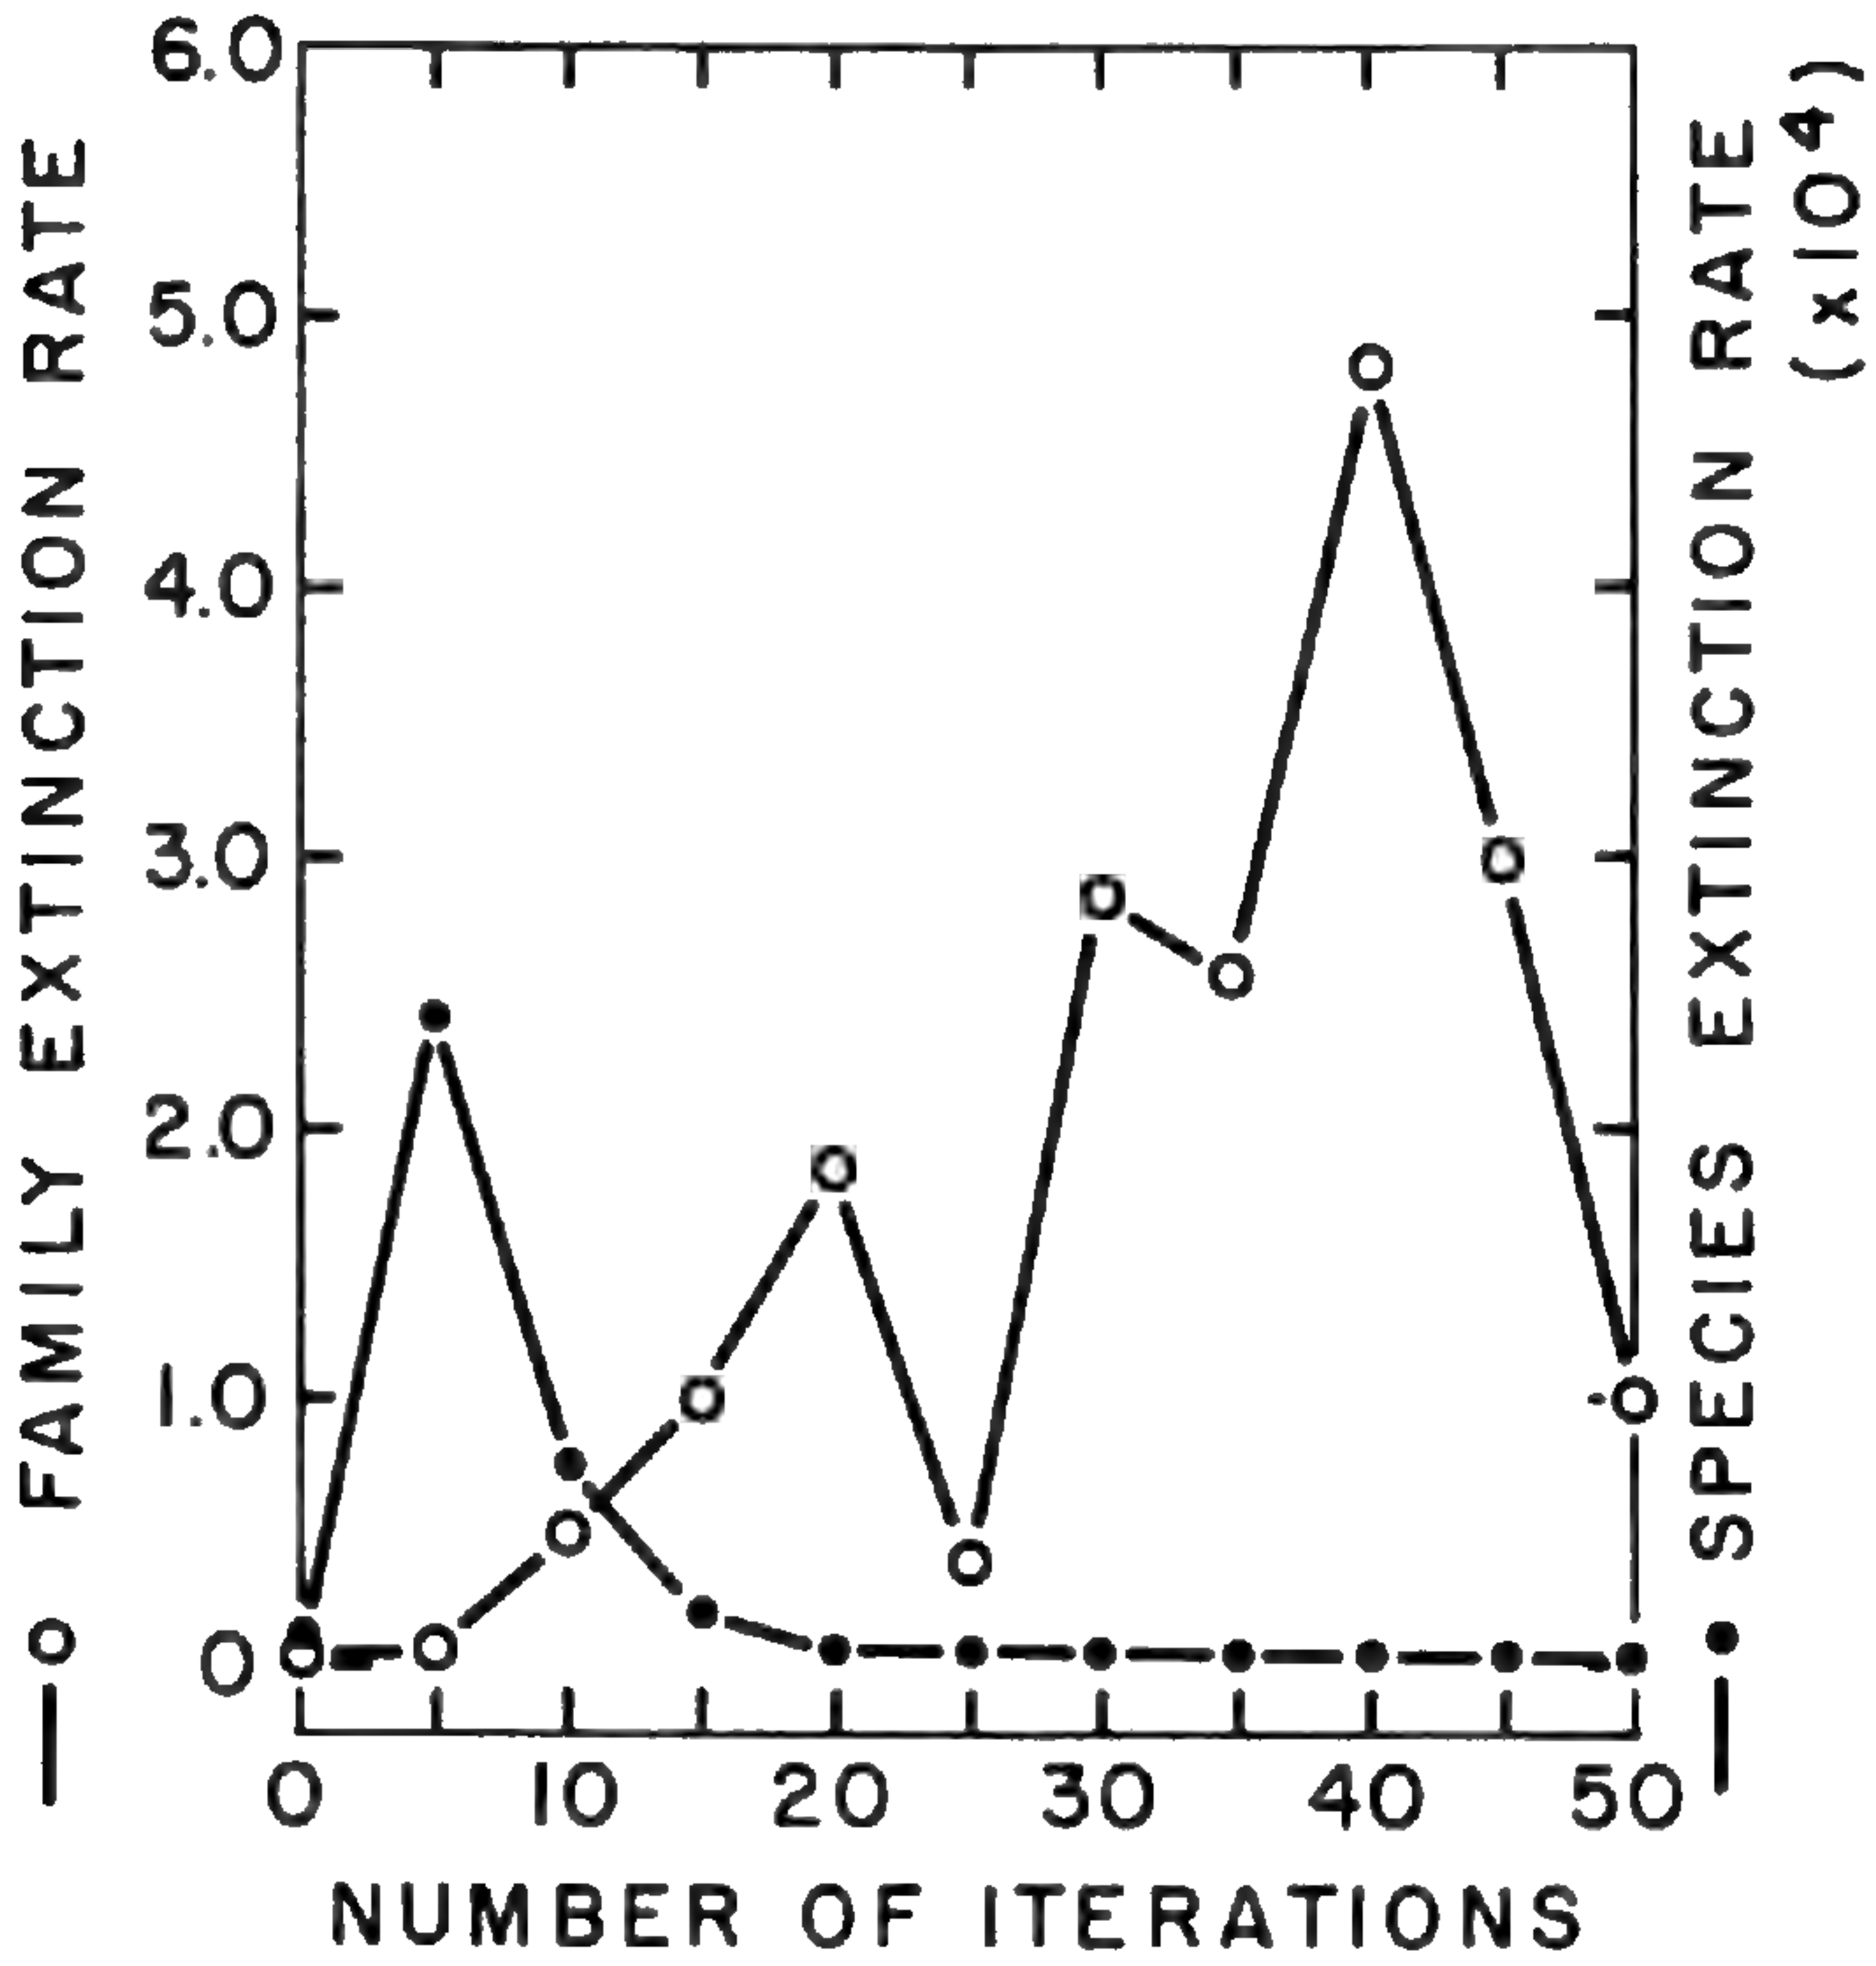

FIGURE 8. *Patterns of the total extinction rate computed for an artificially constructed species frequency distribution in which all categories of species richness are occupied by equivalent numbers of families (N = 111). The total number of species is 176,600. This species frequency distribution produces a "spiked" pattern of total family-extinction rate with a 20% species-extinction rate.*

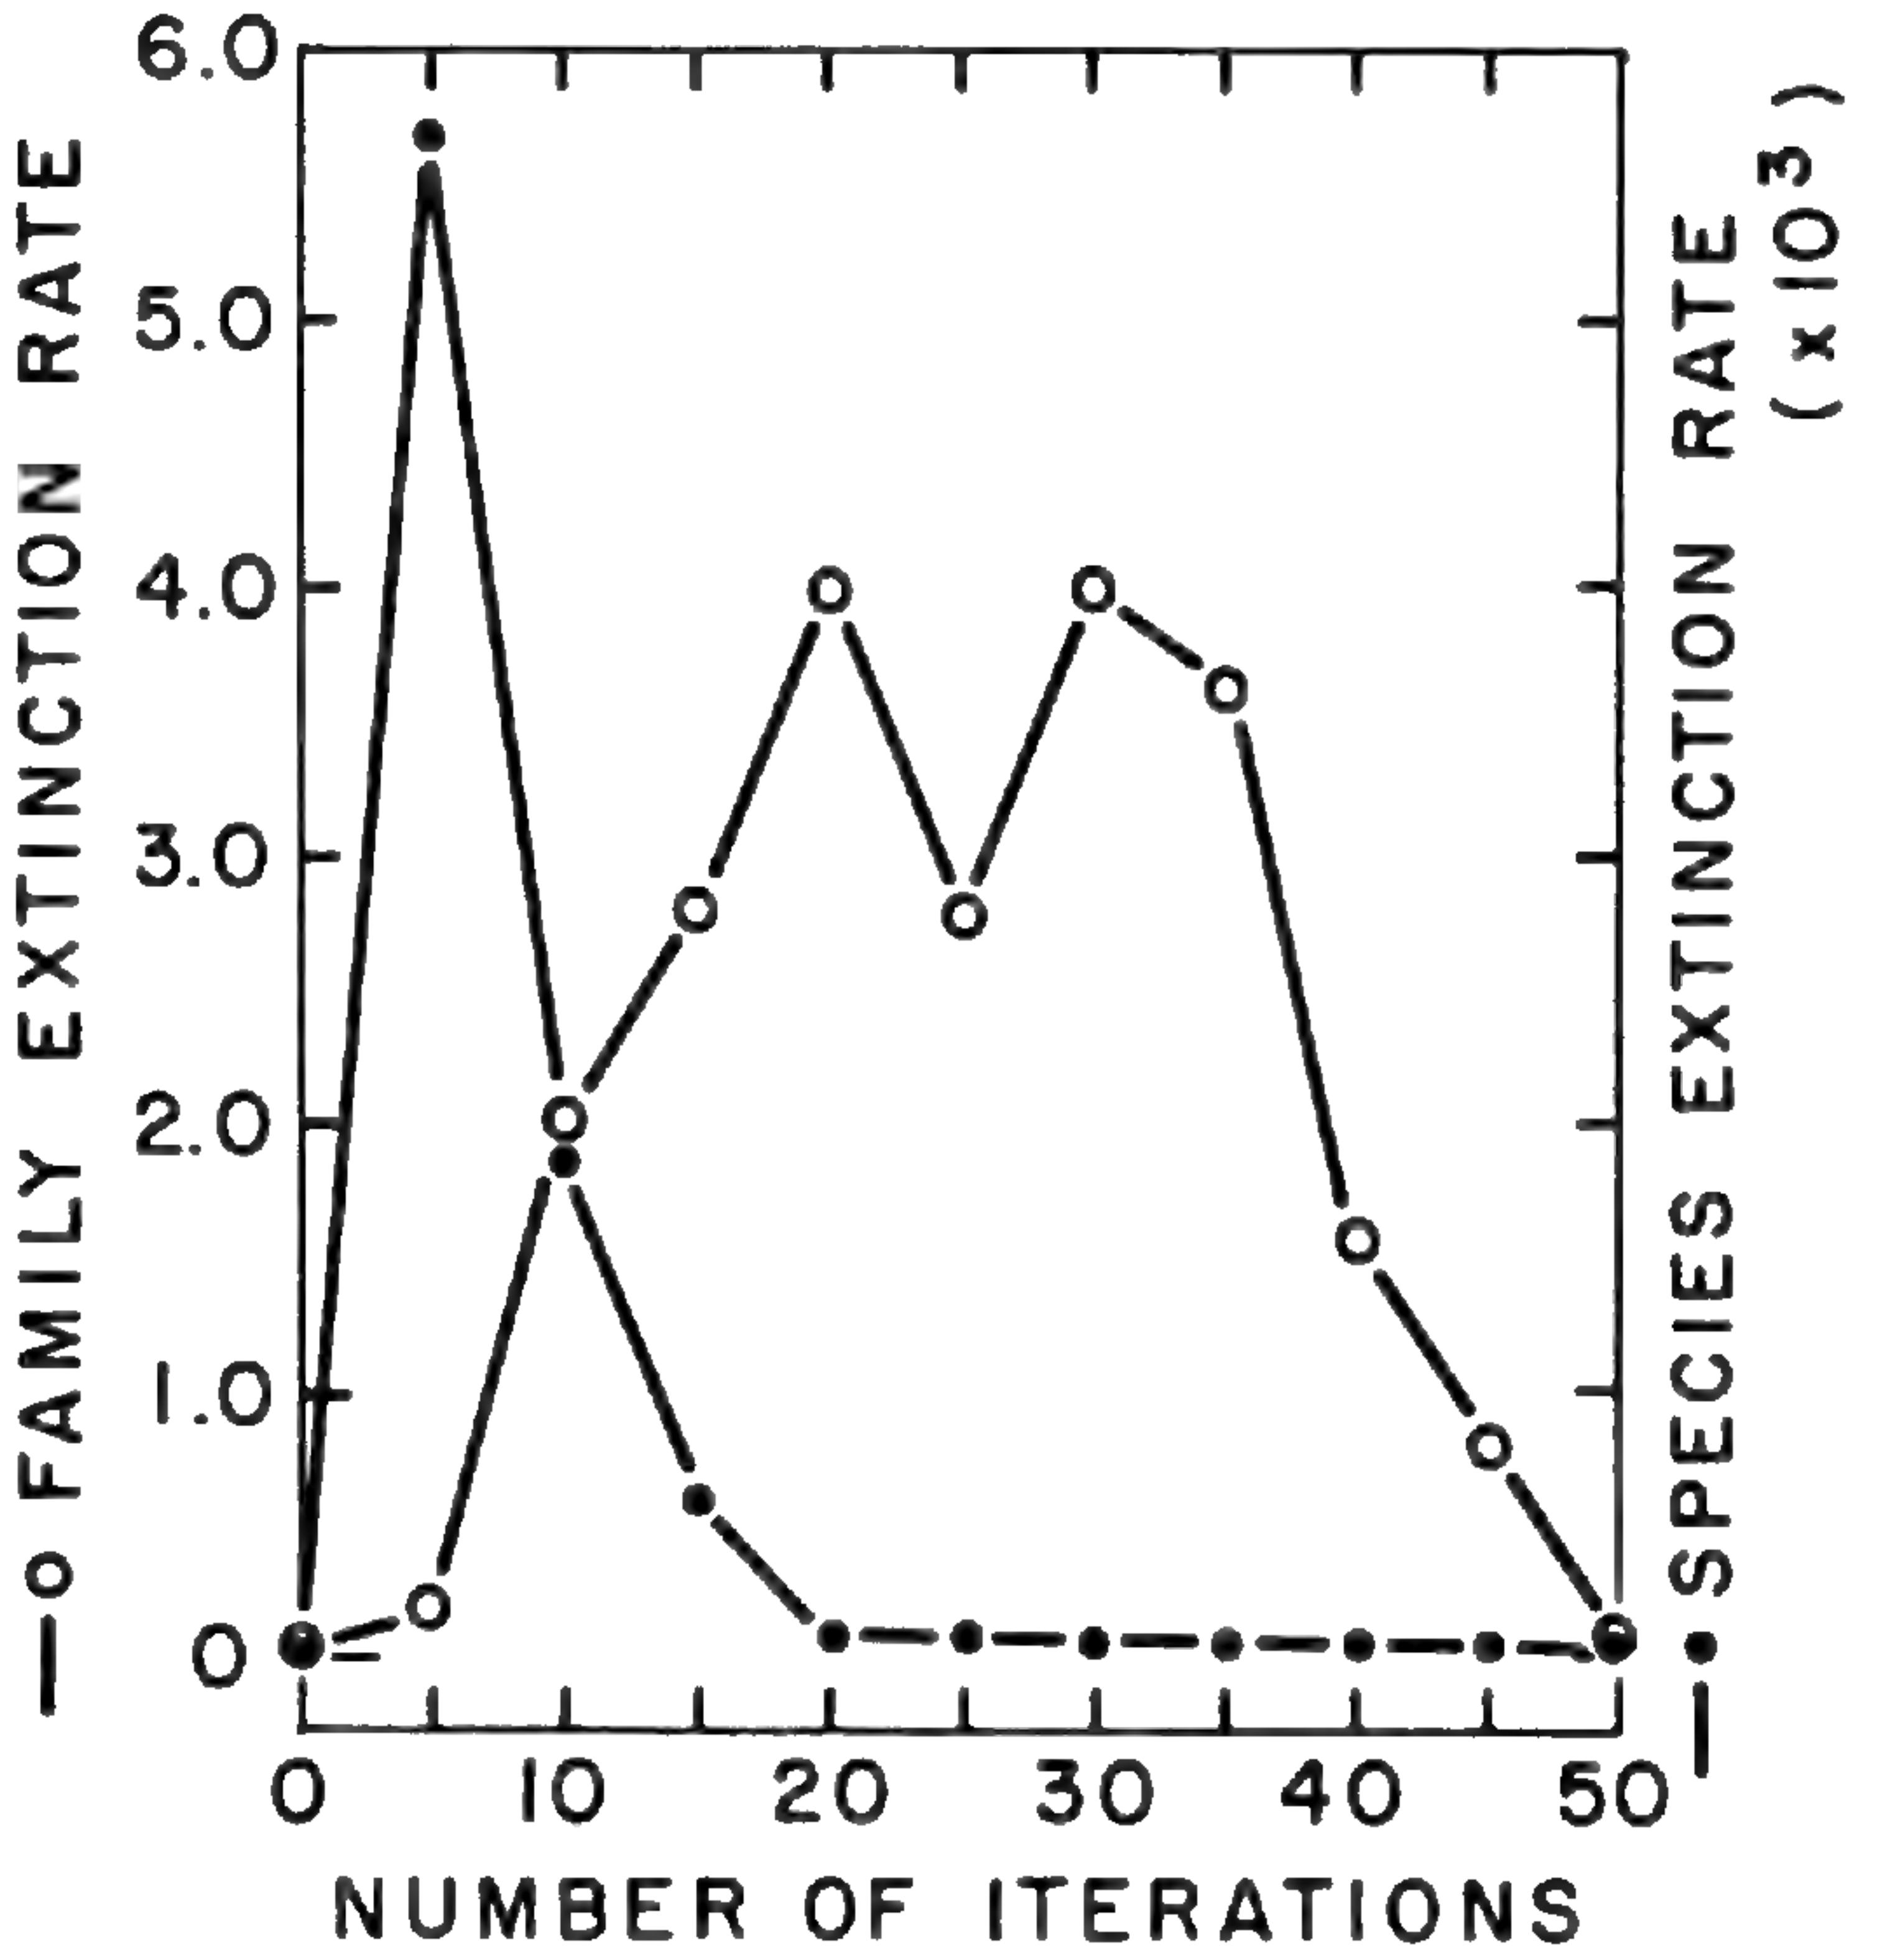

FIGURE 9. *Patterns of the total extinction rate computed for a species frequency distribution with many species-poor families and a few species-rich families (N = 111). A total of 43,070 species are represented in this artificially created distribution.*

the pattern of family extinctions is emphasized. The distribution skewed to the right (= most families with many species) shows a pattern vaguely reminiscent of a "mass extinction," in which the rate of family extinction varies little about a mean value of 0.12 through 25 iterations and then sharply increases to 8.0 after 40 iterations before declining to 1.6 at 50 iterations (Fig. 7). The pattern of extinction occurring up to 25 iterations results from the gradual and random extinction of a few species-depauperate families. With each successive iteration, however, species-rich families are reduced in numbers of species but, due to their large initial sizes, fail to go to extinction. After 25 iterations the "species buffering" experienced by these families is eroded and they become sufficiently depleted such that they collectively undergo a "mass family extinction." Only 2.7% of the total number of families are eliminated by the 25th iteration despite the extinction of over 99.5% of the original number of species. If this simulation reflected a real case from the fossil record, an abrupt increase in the rate of family extinction would not coincide with a mass species-extinction event: by the 15th iteration, over 96% of all species are eliminated, despite the survival of all families.

Similar incongruities between the extent to which family extinctions reflect or coincide with species extinctions are seen in the other two simulations. An even distribution in the number of families containing the various categories of species numbers produces an ascending but spiked pattern of family-extinction rates (Fig. 8). A distribution skewed toward many species-poor families yields a broad, irregularly plateaued pattern of family-extinction rates, which is somewhat similar to the pattern generated from the dicot data set (Fig. 9). These two frequency distributions are clearly artificial since neither is encountered in real species, genus, or family tabulations. Nonetheless, they are of interest because they indicate that no frequency distribution produces a correlation between species- and family-extinction patterns.

Computer simulations do not indicate that family-level compilations are necessarily inadequate to gauge "mass extinction" events. Clearly, there is no reason to assume that species extinctions are randomly distributed among all families. However, (1) "spikes" in the regression of family-extinction rates against geologic time can reflect the synchronous demise of many species-poor families belonging to a once robust taxonomic (or grade-level) cohort; (2) patterns in family-extinction rates are dependent upon the frequency distribution of species among the families considered; (3) mass species-extinction and mass family-extinction events may not coincide; indeed, the vast majority of species within a clade may disappear well before the event is noticeable at the family level (as in the case of *Ginkgo*); and (4) analyses of mass extinctions require information on the changing patterns of species distributions within suprageneric taxa. Similar arguments can be made for the use of generic tabulations to detect mass-extinction events (cf. Raup & Sepkoski, 1986; see also Hoffman, 1986). Similarly, diversity measured solely on the basis of species numbers ignores the relative abundance of individuals within taxa—an essential feature to understanding the ecological significance of an extinction event. The "mass extinction" of many species that contribute only a fraction of the biomass to a biota has a decidedly different effect than one involving species contributing many individuals to a biota.

NONTAXONOMIC MEASUREMENTS OF DIVERSITY

A treatment of diversity strictly from the perspective of changes in species numbers ignores many significant aspects of plant evolution. Qualitative changes in reproductive and vegetative morphology and quantitative changes in the numbers of individuals within a taxon are not reflected in patterns of changing species numbers. For example, the number of gymnosperm species during the Jurassic and Cretaceous remained relatively constant despite considerable taxonomic turnover within various lineages and significant alterations in morphology and anatomy of representative species. *Ginkgo biloba*, as a species, occurs from the Mesozoic to the present, yet the number of individuals significantly declined during the Cenozoic. Clearly, evaluations of diversity based on something other than species numbers are important in evaluating adaptive evolution and changes in community structure (Spicer & Hill, 1979; Phillips & DiMichele, 1981; DiMichele et al., 1985; Fisher, 1985).

Another reason for evaluating nontaxonomic measurements of diversity is that inferences on genomic (hence speciation) rates of evolution based on rates of morphological evolution may be faulty. Schopf et al. (1975) argued that differences in the number of species among lineages can be the consequence of dealing with taxa that differ in their degree of morphological complexity. If fossil species truly represent genomically distinct entities (sensu the biological species concept), then rates of morphological and genomic evolution would be highly correlated. These authors, however, assert that this direct correspondence can never be proven. Therefore, it is advisable to look at rates of morphological evolution and rates of paleospecies origination separately.

Fortunately, changes in species numbers and within-assemblage species composition, and morphological patterns of long-term evolution can be dealt with separately to visualize tracheophyte diversification. As in most cases with the use of paleontological data, however, quantitative analyses can only be used to construct qualitative comparisons or generalizations. Among these guarded generalizations are:

(1) The taxonomic composition of fossil plant assemblages is rarely, if ever, stable. It is altered most significantly by the substitution of taxa within related lineages during periods of relatively constant overall species numbers. These "intrataxonomic" alterations occur over extended geological time-scales and are generally discernable among lineages that share a common mode of sexual reproduction (Knoll, 1986).

TABLE 1. *Mean species numbers, x̄, of vascular plants in fossil assemblages for representative intervals.*

	Niklas et al., 1980 $\bar{x}$ (number of floras)	Knoll, 1986 $\bar{x}$ (number of floras)
Early Devonian	5 (7)	4.0 (8)
Late Devonian	8.2 (9)	10.7 (7)
Early Mississippian	10 (7)	11.9 (15)
Late Mississippian	22.5 (2)	23.3 (8)
Late Jurassic	27.5 (15)	30.8 (6)
Early Cretaceous	21.5 (15)	30.2 (22)
Late Cretaceous	43 (7)	54.4 (17)

(2) Global species numbers generally increase most significantly with the radiation of plants sharing a novel mode of sexual reproduction (Niklas et al., 1980, 1985).

(3) At least within the temporal resolution permitted by most paleontological studies, changes in taxonomic composition and large-scale species numbers are tightly linked to changes in vegetative morphology and the appearance of diverse growth habits (Niklas, 1987).

(4) The appearance of new reproductive modes and diverse morphologies within a clade or cohort of clades may not necessarily result in the ecological displacement of previously existing species. Throughout much of the Paleozoic and Mesozoic, taxonomic radiations are associated with the exploitation of environments not previously occupied (Tiffney, 1981; Knoll, 1986).

(5) The competitive advantages conferred upon a taxon by novel reproductive or vegetative capabilities are most pronounced early during its taxonomic radiation (Knoll et al., 1984; Knoll & Niklas, 1987).

Each of these generalities is not without exception or debatable inference, since each is based on a limited number of studies. It is more instructive to review the nature of the data upon which these statements are based and to examine their deficiencies.

To date, only two studies have examined changes in the mean species numbers of plants throughout the Phanerozoic (Niklas et al., 1980; Knoll, 1986). In both cases, fossil assemblages (= "floras") were selected from similar depositional environments so as to minimize the differential effects of sedimentological factors on preservation. The floras were selected from what were inferred to be warm climates. Comparison between the mean species numbers per flora for representative time periods is given in Table 1. Despite differences in the sources of data, both studies reported remarkably similar trends. Mean species numbers within floras have increased significantly at least twice during the last 420 million years—doubling between Late Devonian and Late Mississippian floras, and once again between Early and Late Cretaceous floras. (The lack of an objective baseline comparison for the Late Devonian floras precludes evaluation of the data from Early and Late Devonian floras.)

Each of the two increases in mean species number coincides with an increase in overall species diversity (Niklas et al., 1980, 1985). This is to be expected, since the latter incorporates data used to compile within-floras species numbers. However, each of the two increases in mean species numbers correlates with major transitions in the taxonomic composition of floras. This is shown elegantly in a study by Knoll (1986), who presented a unique analysis of the taxonomic composition of floras throughout the Phanerozoic. Figure 10 (redrawn from Knoll's study) shows two significant resortings of suprageneric groups within floras. One occurs with the advent of seed plants in the Late Devonian and Mississippian; another reflects the radiation of flowering plants in the Cretaceous. If the various plant lineages within Knoll's data set are grouped according to their principal modes of reproduction, then the changes in taxonomic composition are seen more clearly (Fig. 11). As in the plots of large-scale species numbers (Fig. 1), the early Paleozoic floras dominated by pteridophytes are replaced by gymnosperm-dominated Mesozoic floras, which in turn are replaced by floras dominated by angiosperms.

However, Figure 11 masks the taxonomic restructuring in floras that occurs within each category of reproductive mode. The expansion of gymnosperm species in Mesozoic floras occurs at the expense of pteridophytes made up of lineages that did not fall off at equal rates. In general, the numbers of fern species are much less affected than those of lycopods and sphenopsids. Similarly, gymnosperm lineages undergo a more or less continuous intrataxonomic restructuring.

The evolutionary appearance of novel modes of reproduction, for example, seeds and flowers, is often associated with alterations in growth habit (Tiffney, 1981; Tiffney & Niklas, 1985). The number of plant families characterized by cryptogamic (pteridophytes) and phanerogamic reproduction (gymnosperms and angiosperms), as well as the number of families with principally nonarborescent and arborescent growth forms, are plotted through time in Figure 12. In this figure a number of "cross-overs" are seen which can be related to changes in taxonomic composition. For example, during the Carboniferous and Permian, arborescence rises even though cryptogamic reproduction remains more common. Although seed plant species dominate Mesozoic floras, nonarborescence is more common than arborescence during the Jurassic. During the Cretaceous, the number of phanerogamic plant families gradually increases, until by the Late Cretaceous, arborescent/phanerogamic-dominated floras which persist through the Tertiary are established. The Permo-Triassic is a period of considerable restructuring in both the principal modes of reproduction and growth habits. Before the Triassic, arborescent cryptogamic families are dominant, while during the Triassic nonarborescent phanerogamic families are common.

From a much more comprehensive analysis, Tiffney & Niklas (1985) concluded that the history of clonality in land plants can be segregated into three stages: (1) *Silurian to lower Carboniferous* during which clonal lineages dominated, but in which arborescence appeared as a vegetative correlate with heterospory or the seed habit; (2) *Permo-Triassic to Cretaceous*, in which families of arborescent gymnosperms gradually increased and gained numerical dominance over families of arborescent and nonarborescent pteridophytes; and (3) *Cretaceous to present*, which marks the combination of rhizomatous growth and the seed habit (herbaceous angiosperms) which became increasingly more important in the later Tertiary and Quaternary.

Unfortunately these analyses are based on familial data (whole-plant reconstructions are too few to determine large-scale patterns in the evolution of tracheophyte growth habits). Accordingly they provide few insights into species patterns of growth habit or values of relative abundance. Although nonarborescent families dominate much of the early and middle Mesozoic, the abundance of arborescent gymnosperm species in these floras is much higher than that of pteridophytes (Fig. 10). Clearly the family-diversity plots shown in Figure 12 are not reflective of community structure.

As Schopf et al. (1975) pointed out, it is possible that paleontologists fail to recognize the true diversity of morphologically simple organisms and overestimate the diversity of morphologically complex organisms. Thus, periods of rapid taxonomic diversification may be inherently related to (and possibly the product of) episodes of rapid morphological diversification. New vegetative and reproductive features provide the potential to discriminate new phenetic taxa (= paleospecies). As the number of potential taxonomic characters increases, the number of possible permutations of characters increases exponentially. There is little agreement among specialists as to which feature(s) (anatomy, morphology, reproduction, or even geologic age) contribute(s) to identification of a new species. Certainly among disparate taxonomic groups of plants, species are recognized on often very divergent categories of features: more derived taxa, such as the angiosperms, have more numerous and potentially more complex fea-

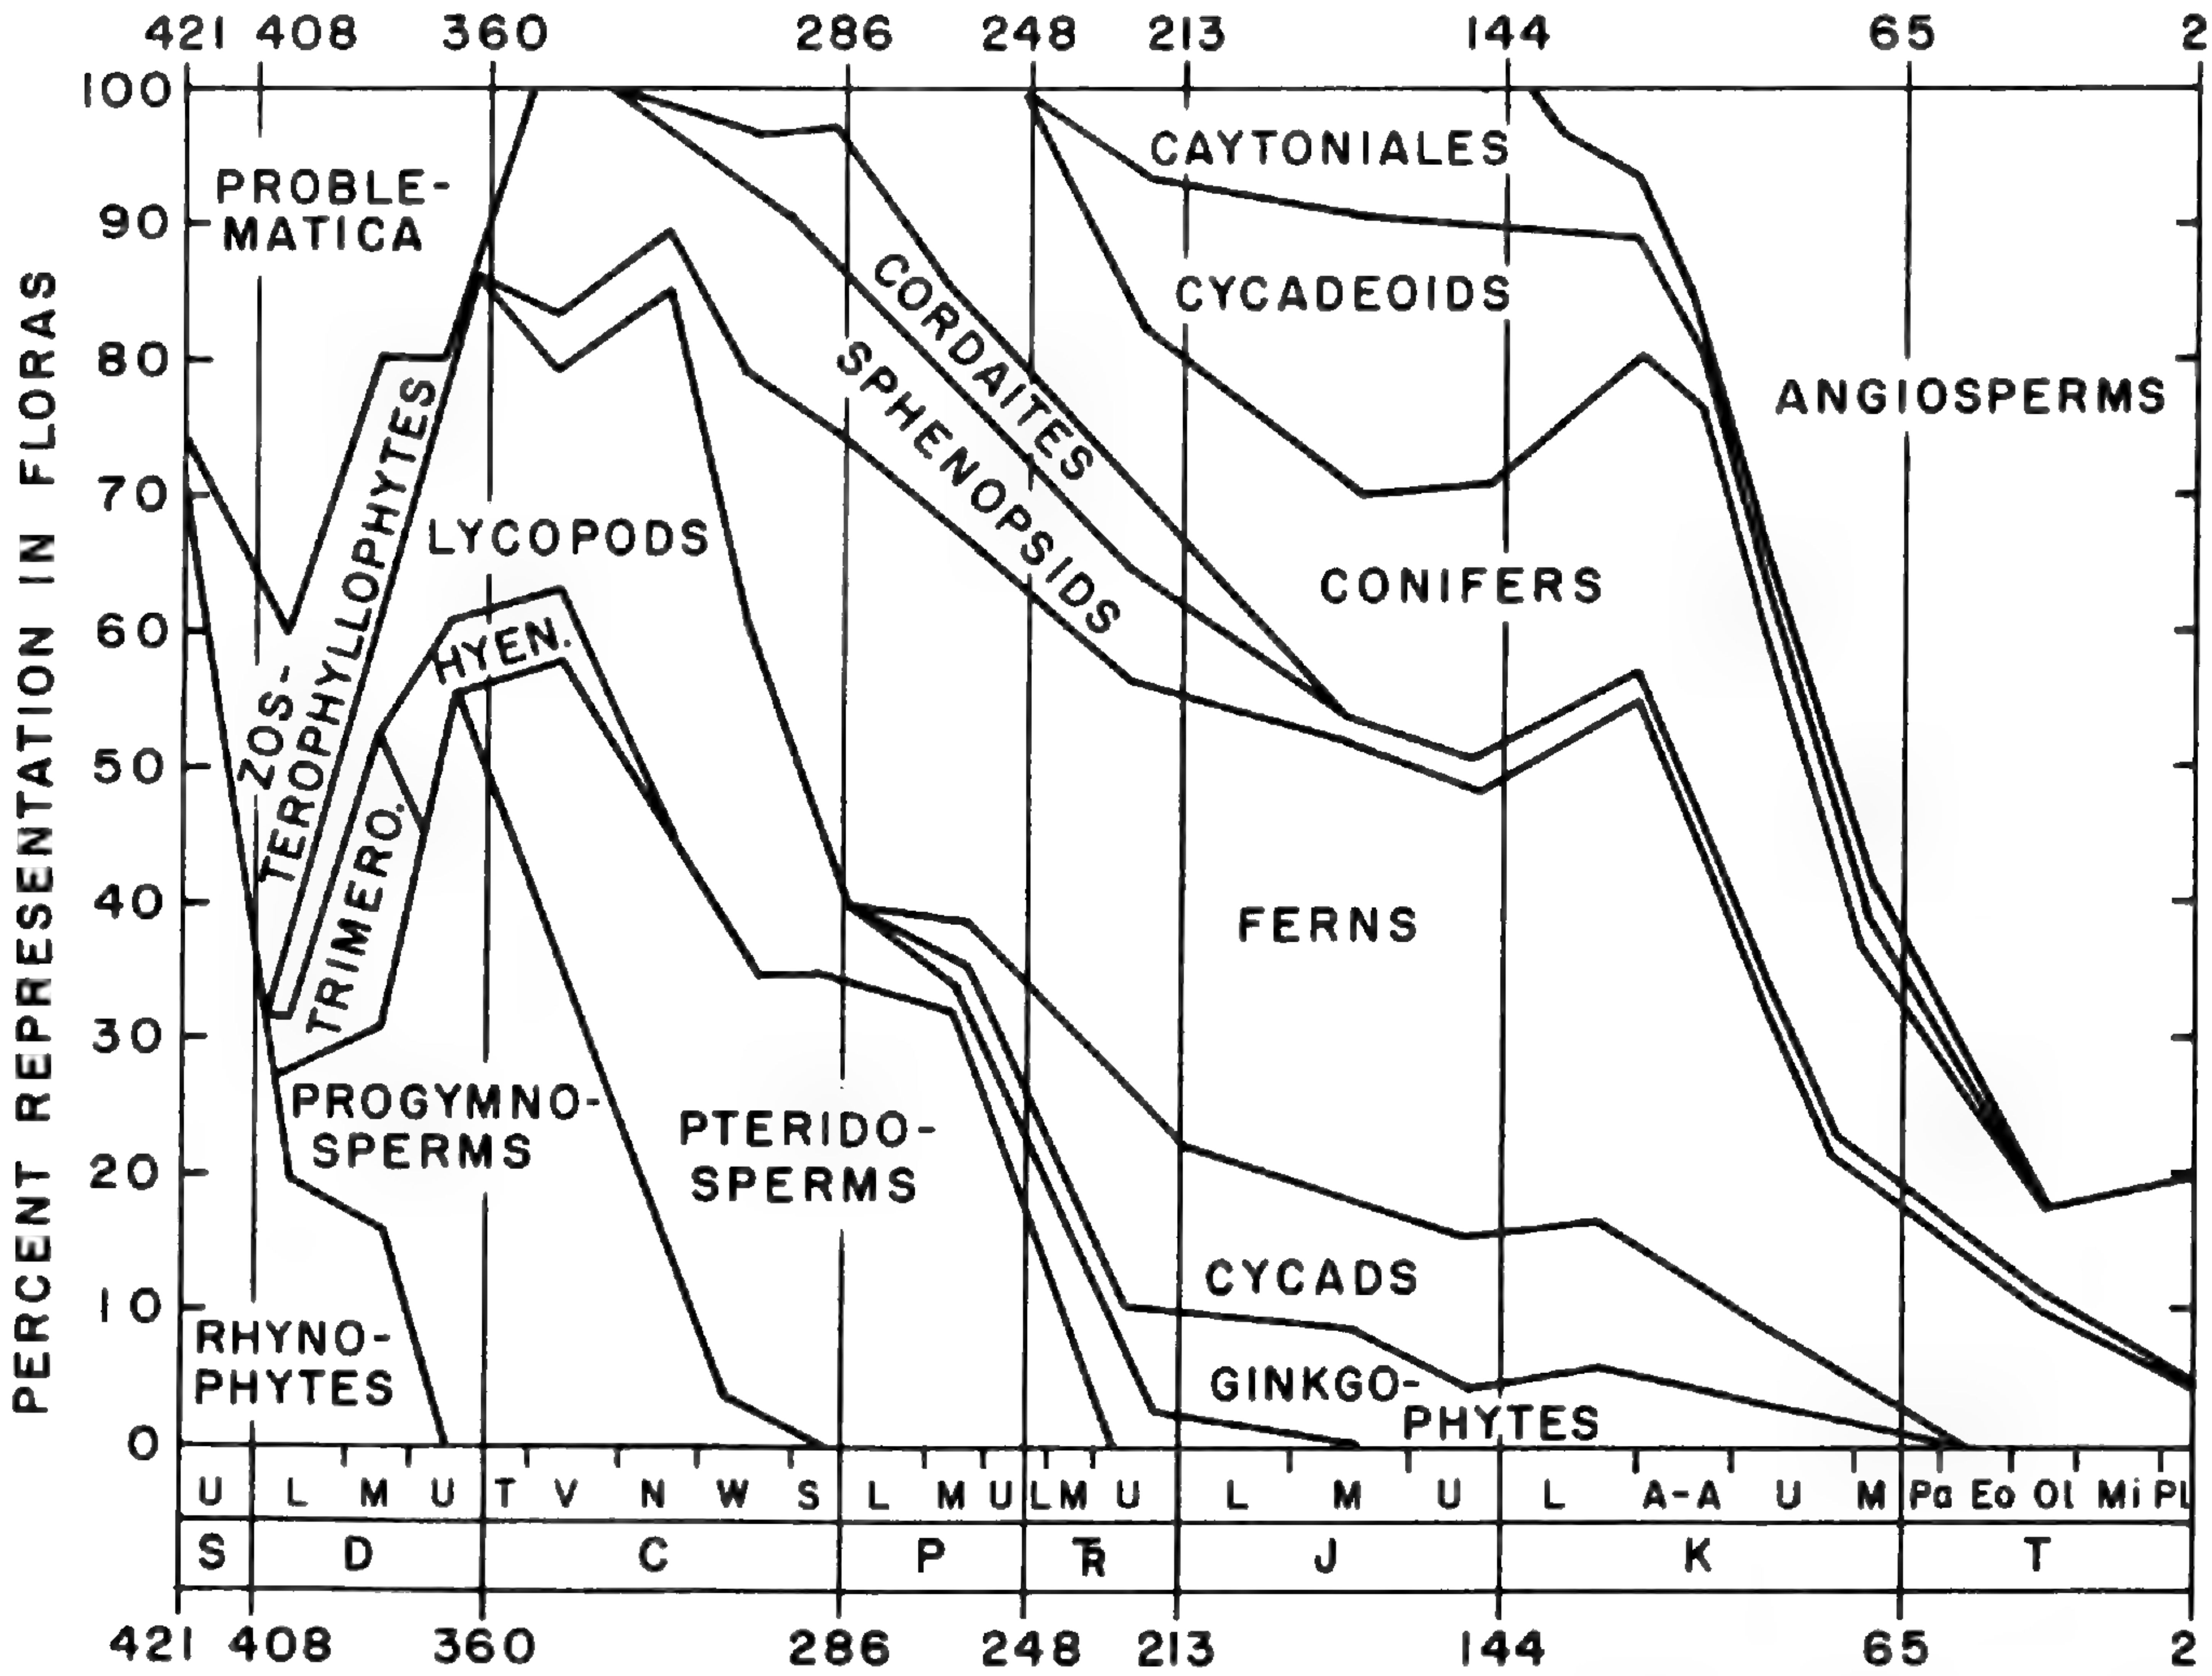

FIGURE 10. *Percent taxonomic composition of tracheophytes in fossil assemblages through the Phanerozoic (data redrawn from Knoll, 1986; courtesy of A. H. Knoll). These data show similarities with those presented by Niklas et al. (1985) for overall patterns in diversification within separate lineages of vascular land plants. Early Paleozoic floras were dominated by archaic pteridophytic groups (rhyniophytes, zosterophyllophytes, trimerophytes) which radiated into variously more derived groups during the Carboniferous. Mesozoic floras consist of diverse gymnosperm lineages supplemented by numerous ferns. With the radiation of angiosperms, the percent taxonomic representation of nonflowering groups declines abruptly during the Late Cretaceous and Tertiary.*

tures with which to identify species (e.g., floral structure) than more archaic taxa, such as pteridophytes (e.g., stelar anatomy, spore-wall characters).

The Devonian flora provides a convenient illustration of the potential relationship between taxonomic and morphological rates of evolution. There is considerable agreement among specialists as to the features that distinguish Devonian genera and higher taxa. Additionally, there are authoritative treatments of the stratigraphic occurrences of taxa and the first and last occurrences of various vegetative and reproductive features upon which they are based. For example, Chaloner & Sheerin (1979) provided a comprehensive stratigraphic treatment of Devonian genera as well as the first and last occurrences of various reproductive and vegetative features. Their data are plotted in Figures 13 and 14. (Nonvascular genera, such as *Sporogonites*, *Parka*, *Pachytheca*, or those having dubious status as tracheophytes, such as *Taeniocrada*, are excluded from these plots.) Anatomical (tracheid, stelar, and stomatal type; Chaloner & Sheerin, 1979, figs. 2, 3) features are plotted separately from reproductive features, such as the position, shape, and type of dehiscence of sporangia (Chaloner & Sheerin, 1979, fig. 4). The data indicate that the number of Devonian genera increases from the Pridolian to the Givetian and then undergoes a modest decline in the Frasnian and Famennian (Fig. 13). By contrast, the number of vegetative and reproductive features upon which Devonian taxa are based increases

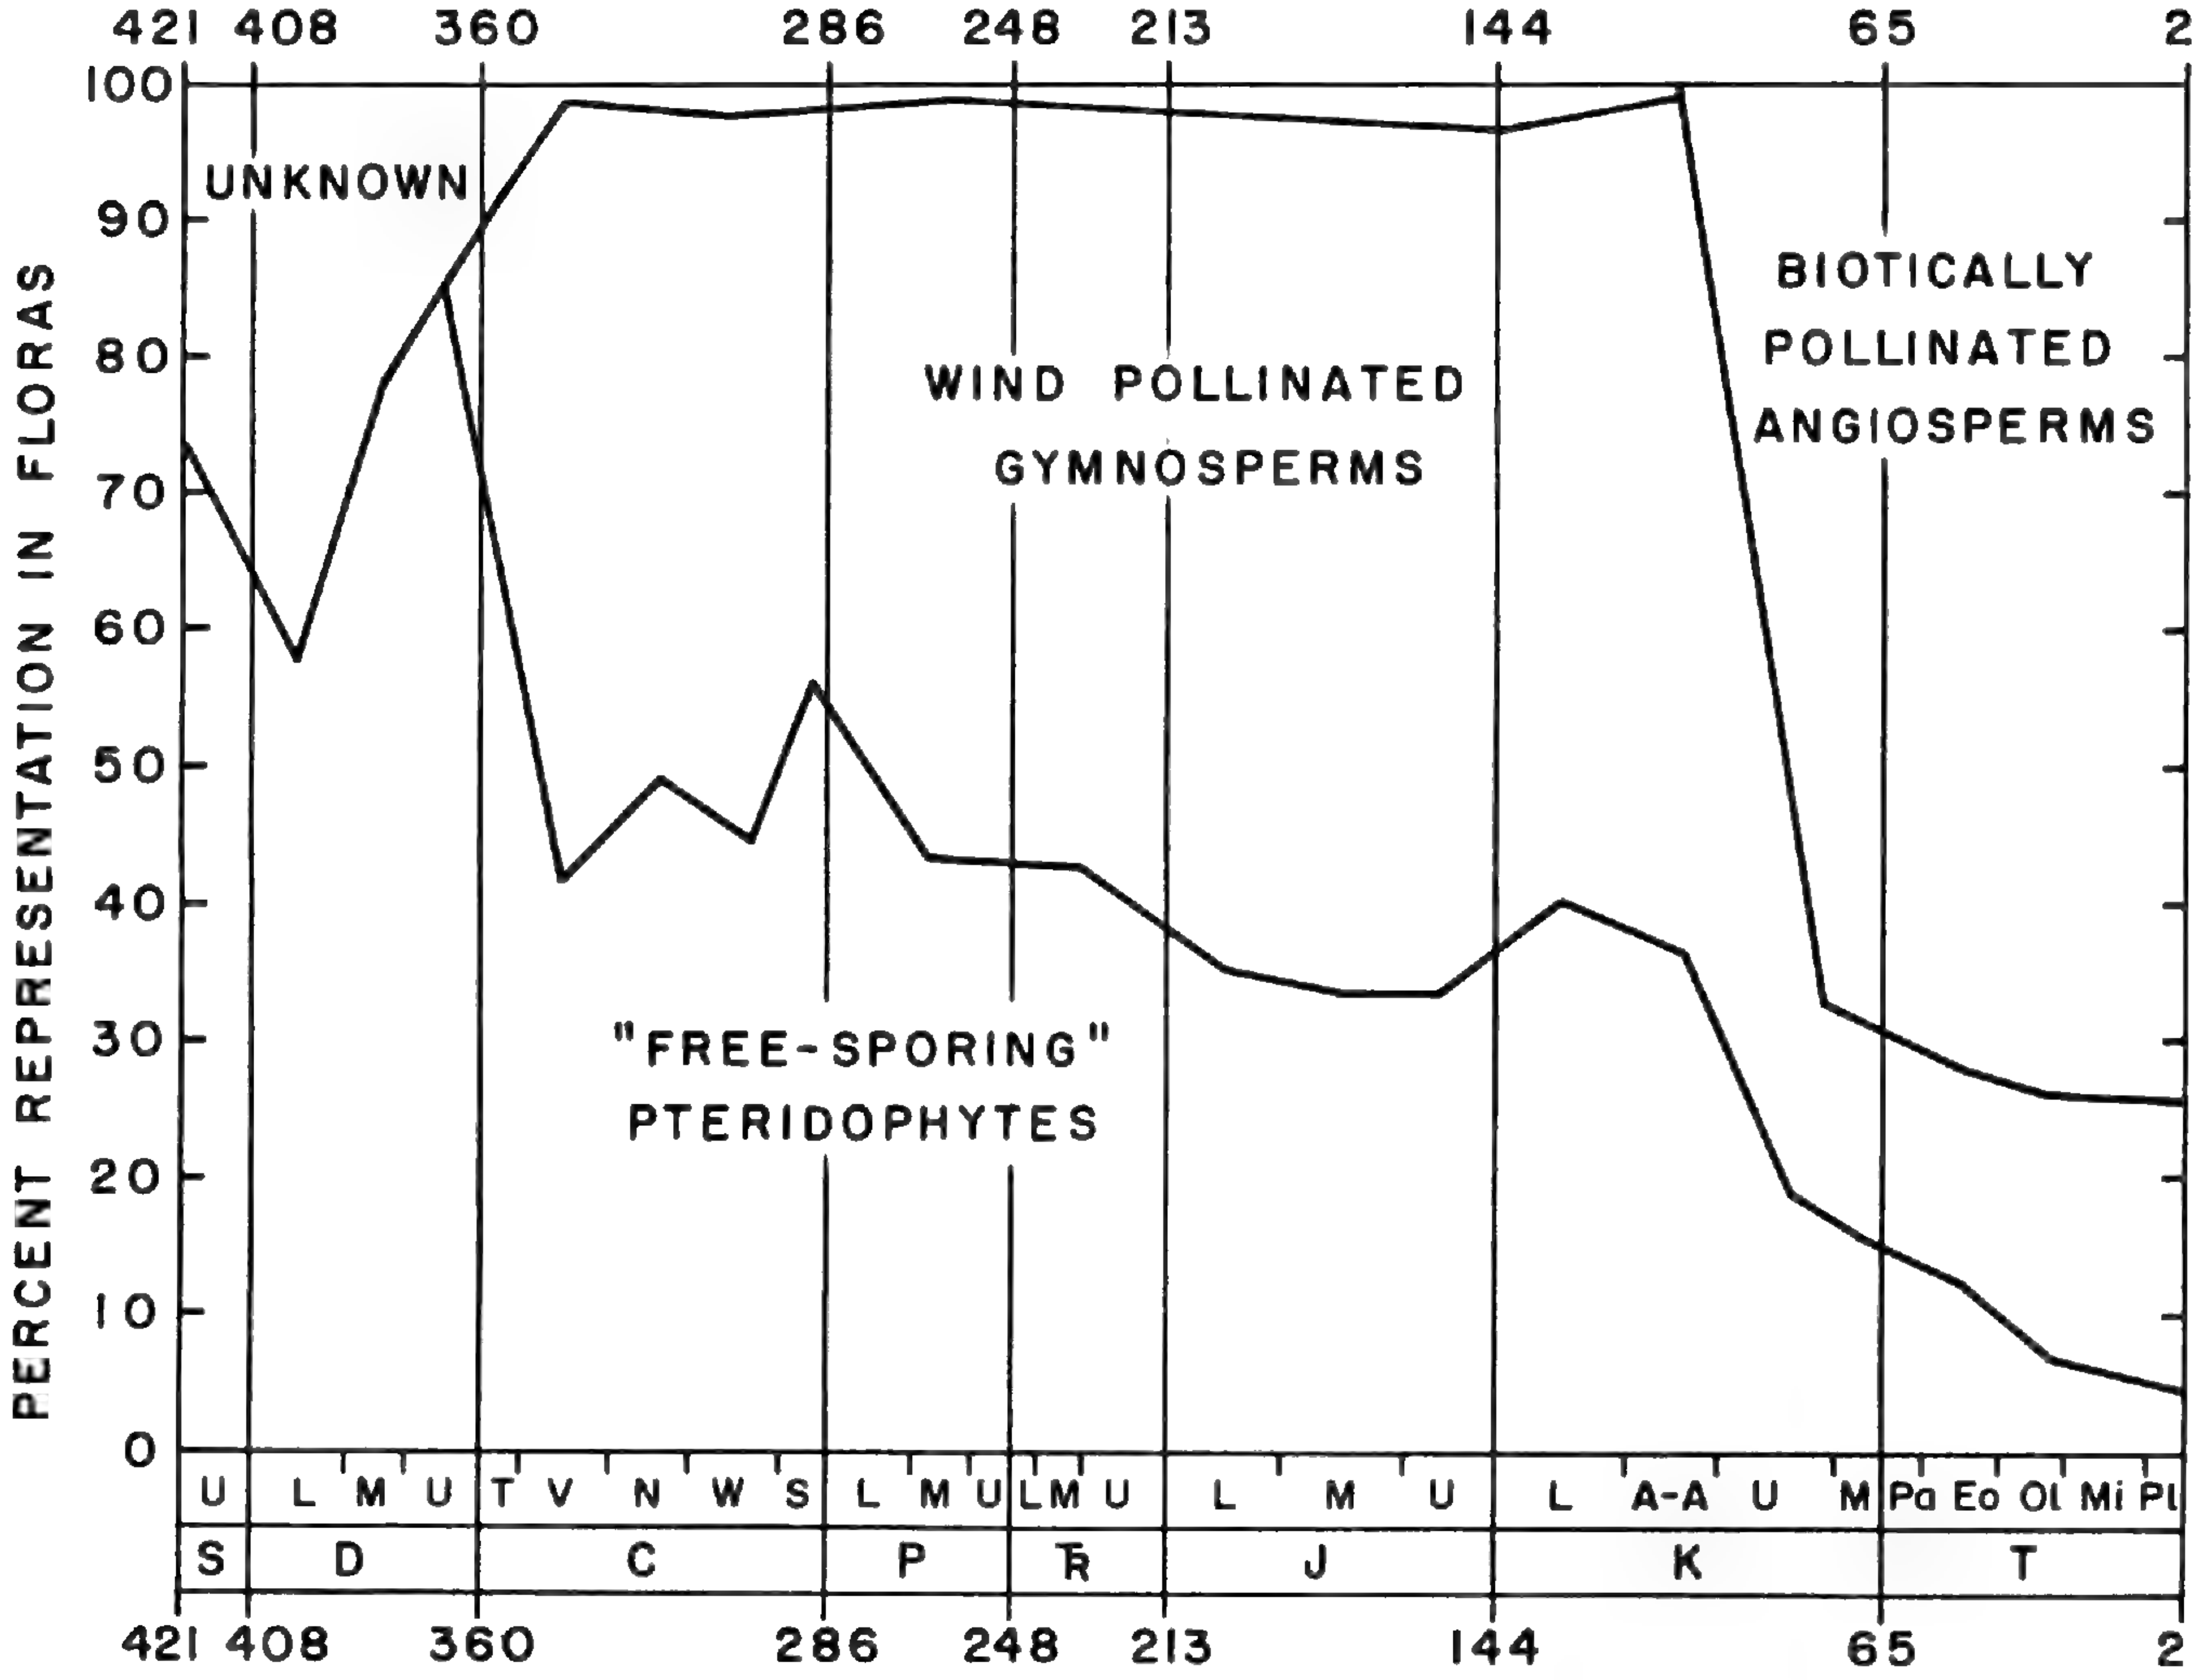

FIGURE 11. *Percent taxonomic composition of tracheophytes (shown in Fig. 10) converted to represent major categories of sexual reproduction. Free-sporing pteridophytes dominate most of the early Paleozoic floras; gymnosperms predominate through most of the Mesozoic; and angiosperms dominate the Late Cretaceous and Tertiary.*

throughout this interval. Linear regression analysis of the total number of taxonomic characters versus the number of genera yields $r = 0.96$ (N = 8), which is significant at the 1% level. This correlation, however, reveals very little with regard to the quantitative decrease in Late Devonian genera despite an increase in the potential number of taxonomic characters in the Frasnian-Famennian. Clearly, as the number of genera increases it is reasonable to expect an increase in the number of taxonomically distinguishable features. Analyses of the appearance of new genera and of new vegetative/reproductive features yield poor correlations (Fig. 14). For example, a regression of the number of new genera against that of the number of reproductive features yields $r = 0.283$. Regressions of either the number of vegetative or the total number of features against the number of Devonian genera yield lower coefficients of correlation. Consequently, the taxonomic recognition of new Devonian genera does not appear to be correlated necessarily with the evolutionary appearance of novel reproductive or vegetative features. In addition, a review of the generic descriptions for Devonian vascular plants compiled by Gensel & Andrews (1984) suggests that paleobotanical treatments of early Paleozoic floras are taxonomically conservative. Therefore, at least at the generic level, it does not appear that estimates of taxonomic diversification in the Devonian are artifacts of rapid morphological evolution. Since most Devonian genera have few species, this conclusion appears warranted at the species level as well (cf. Knoll et al., 1984).

Although the perceived taxonomic diversification of early vascular land plants appears not to be biased by rapid morphological evolution, other episodes of large-scale increases

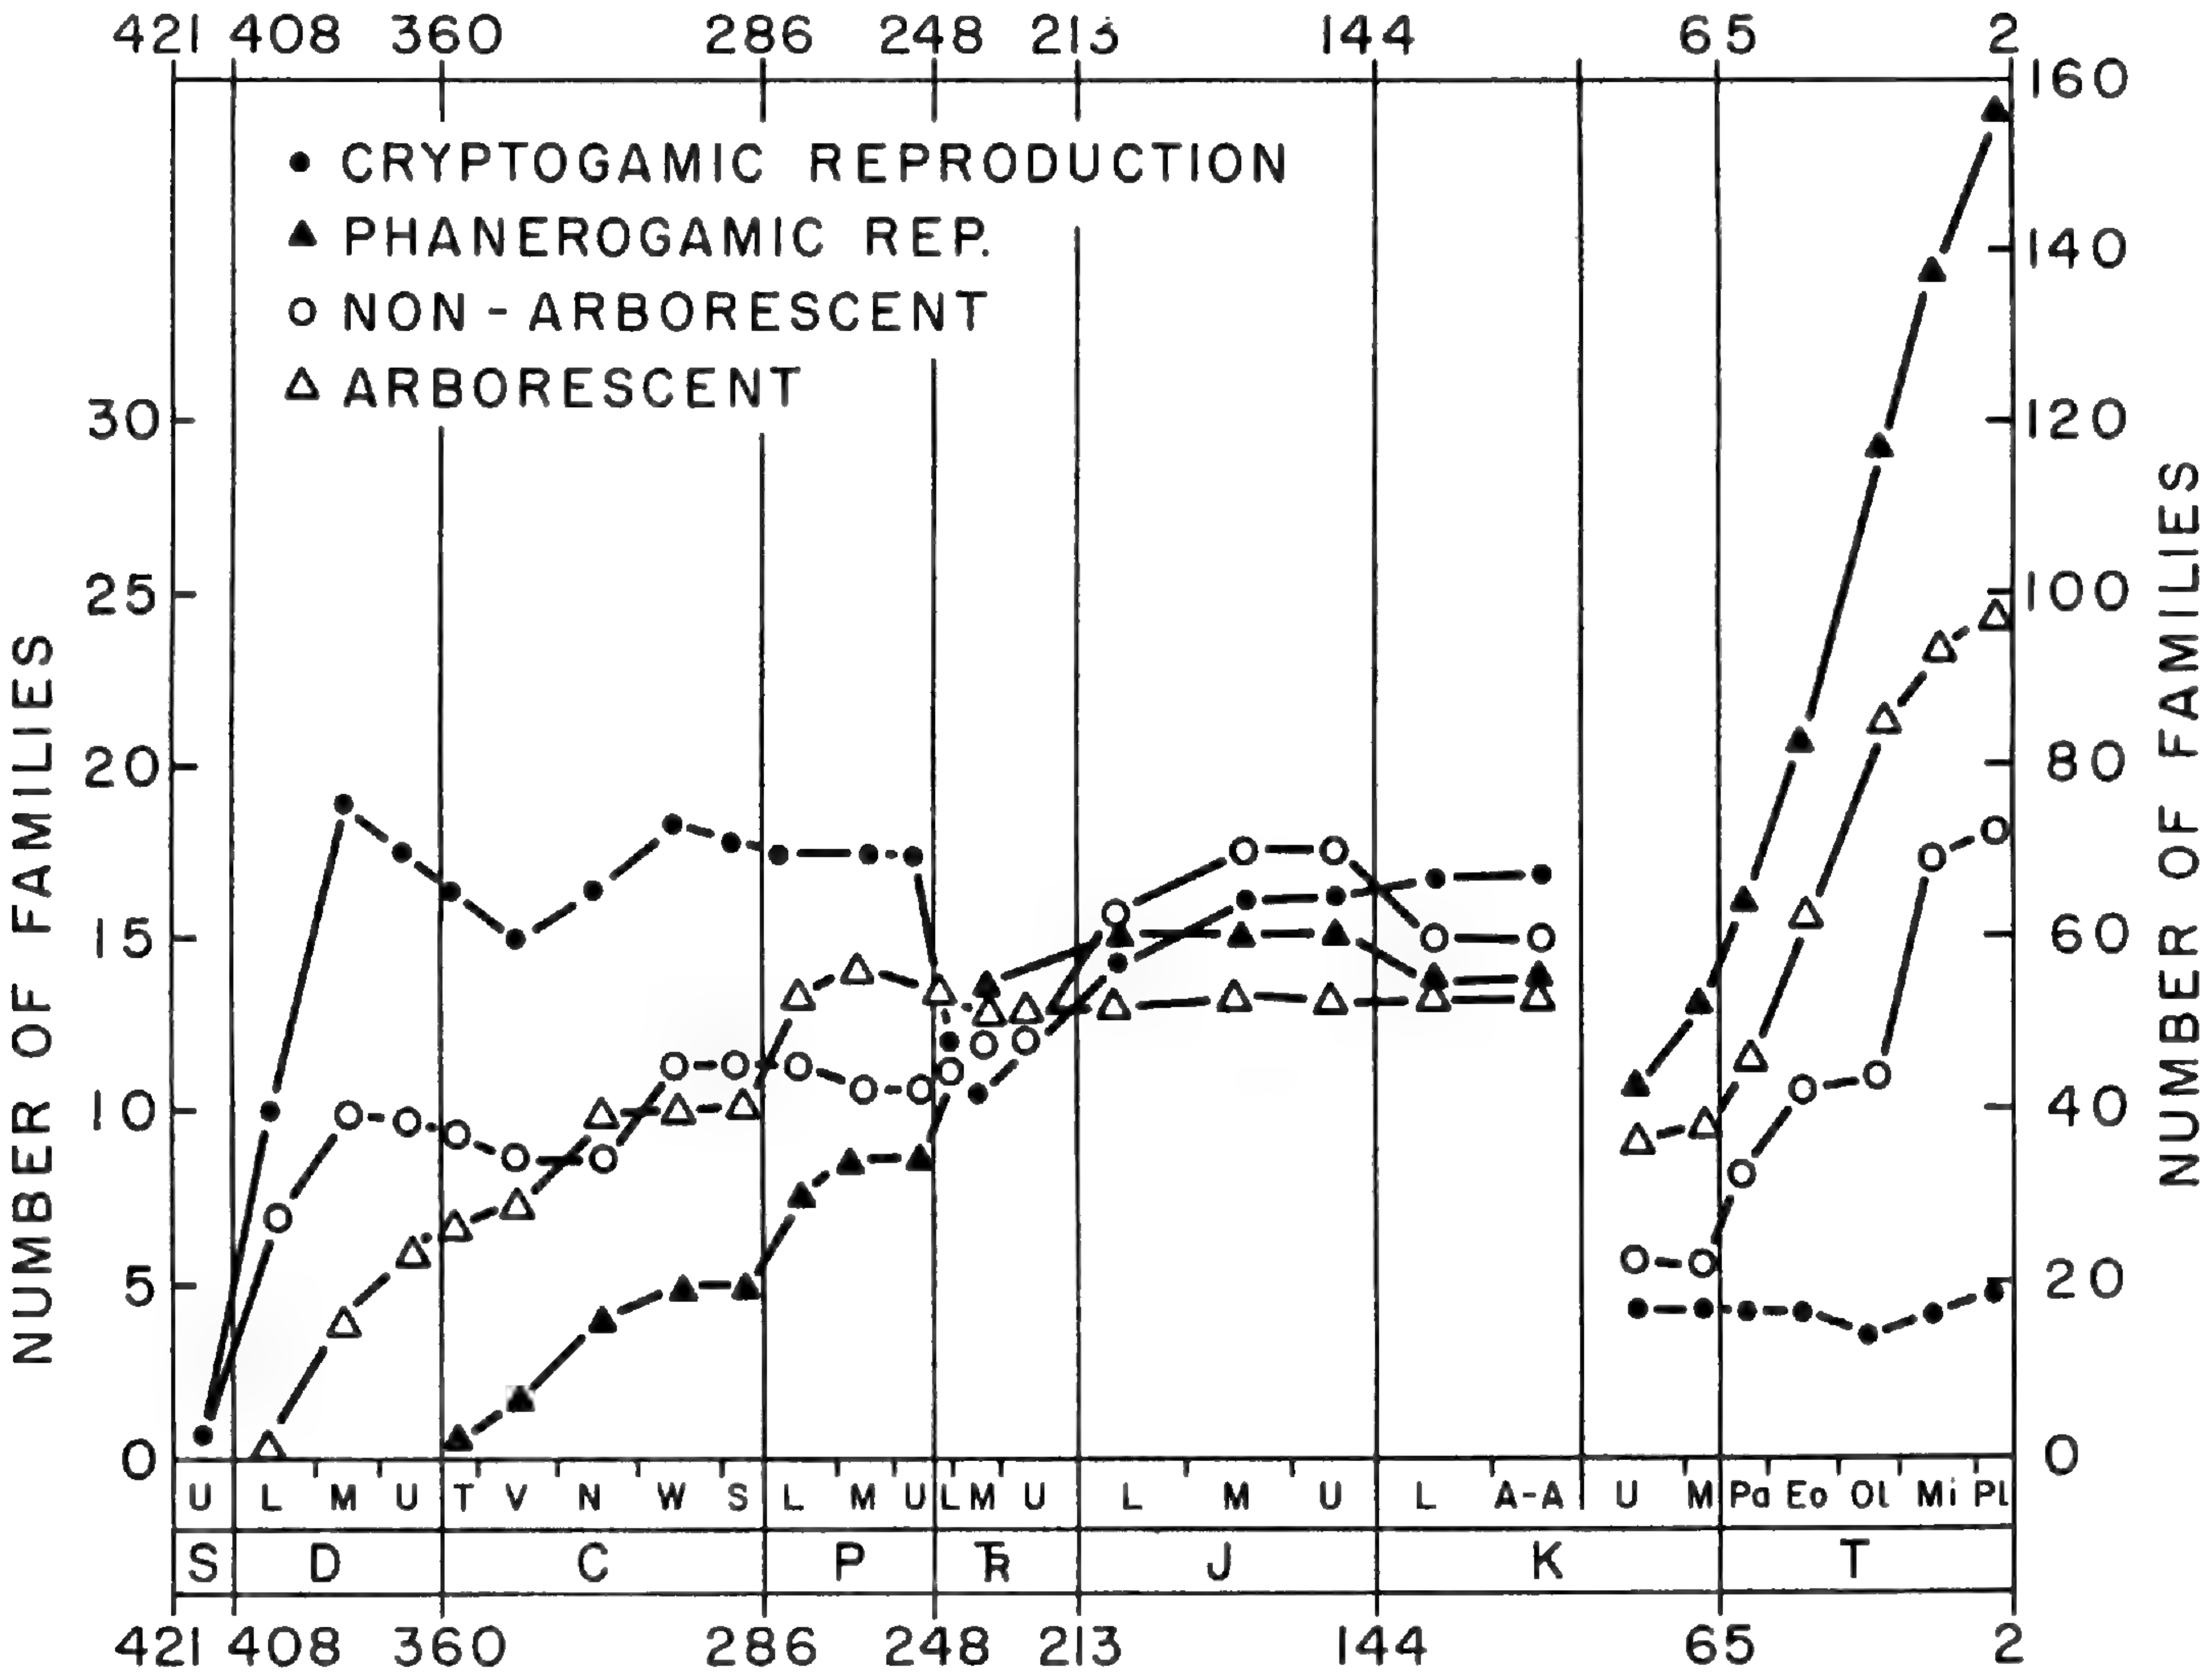

FIGURE 12. *Absolute numbers of spore- and seed-bearing, nonarborescent and arborescent tracheophyte families through the Phanerozoic (redrawn from Tiffney & Niklas, 1985). The scale of the vertical axis changes from increments of five families to increments of 20 between the Lower and Upper Cretaceous.*

in numbers of species have not been rigorously examined. For philosophical and practical reasons, therefore, it is reasonable to view conservatively the overall patterns of tracheophyte species diversification in terms of anatomical, morphological, and reproductive evolutionary trends, rather than strictly in the context of patterns of species origination.

NULL OR BIOLOGICAL HYPOTHESES?

Historically, evolutionary theory has come almost exclusively from observations made on living organisms. Charles Darwin was able to use the fossil record as evidence for evolution but derived his notion of natural selection from insights gained from animal and plant breeding, biogeography, and natural history. Indeed, he found the fossil record singularly intractable in supporting many features of his theory (Rudwick, 1976). The Modern Synthesis incorporated paleontology, but even the work of George Gaylord Simpson may be viewed as an ad hoc rationalization of patterns seen in the fossil record based on neontologically derived theory (cf. Gould, 1980). Recently, however, paleontology has generated evolutionary hypotheses based on patterns seen in the fossil record. This significant shift in the source of evolutionary speculation has had many effects, not the least of which is a re-evaluation of the biases, artifacts, and limitations that are inherent to paleontological data. Clearly, the fossil record can be used to generate evolutionary hypotheses, but only provided it reasonably reflects biological phenomena. For a long time paleontologists have recognized the numerous geological factors that contrive to filter and distort biological processes preserved in the record. Much of the recent literature focuses on attempts to

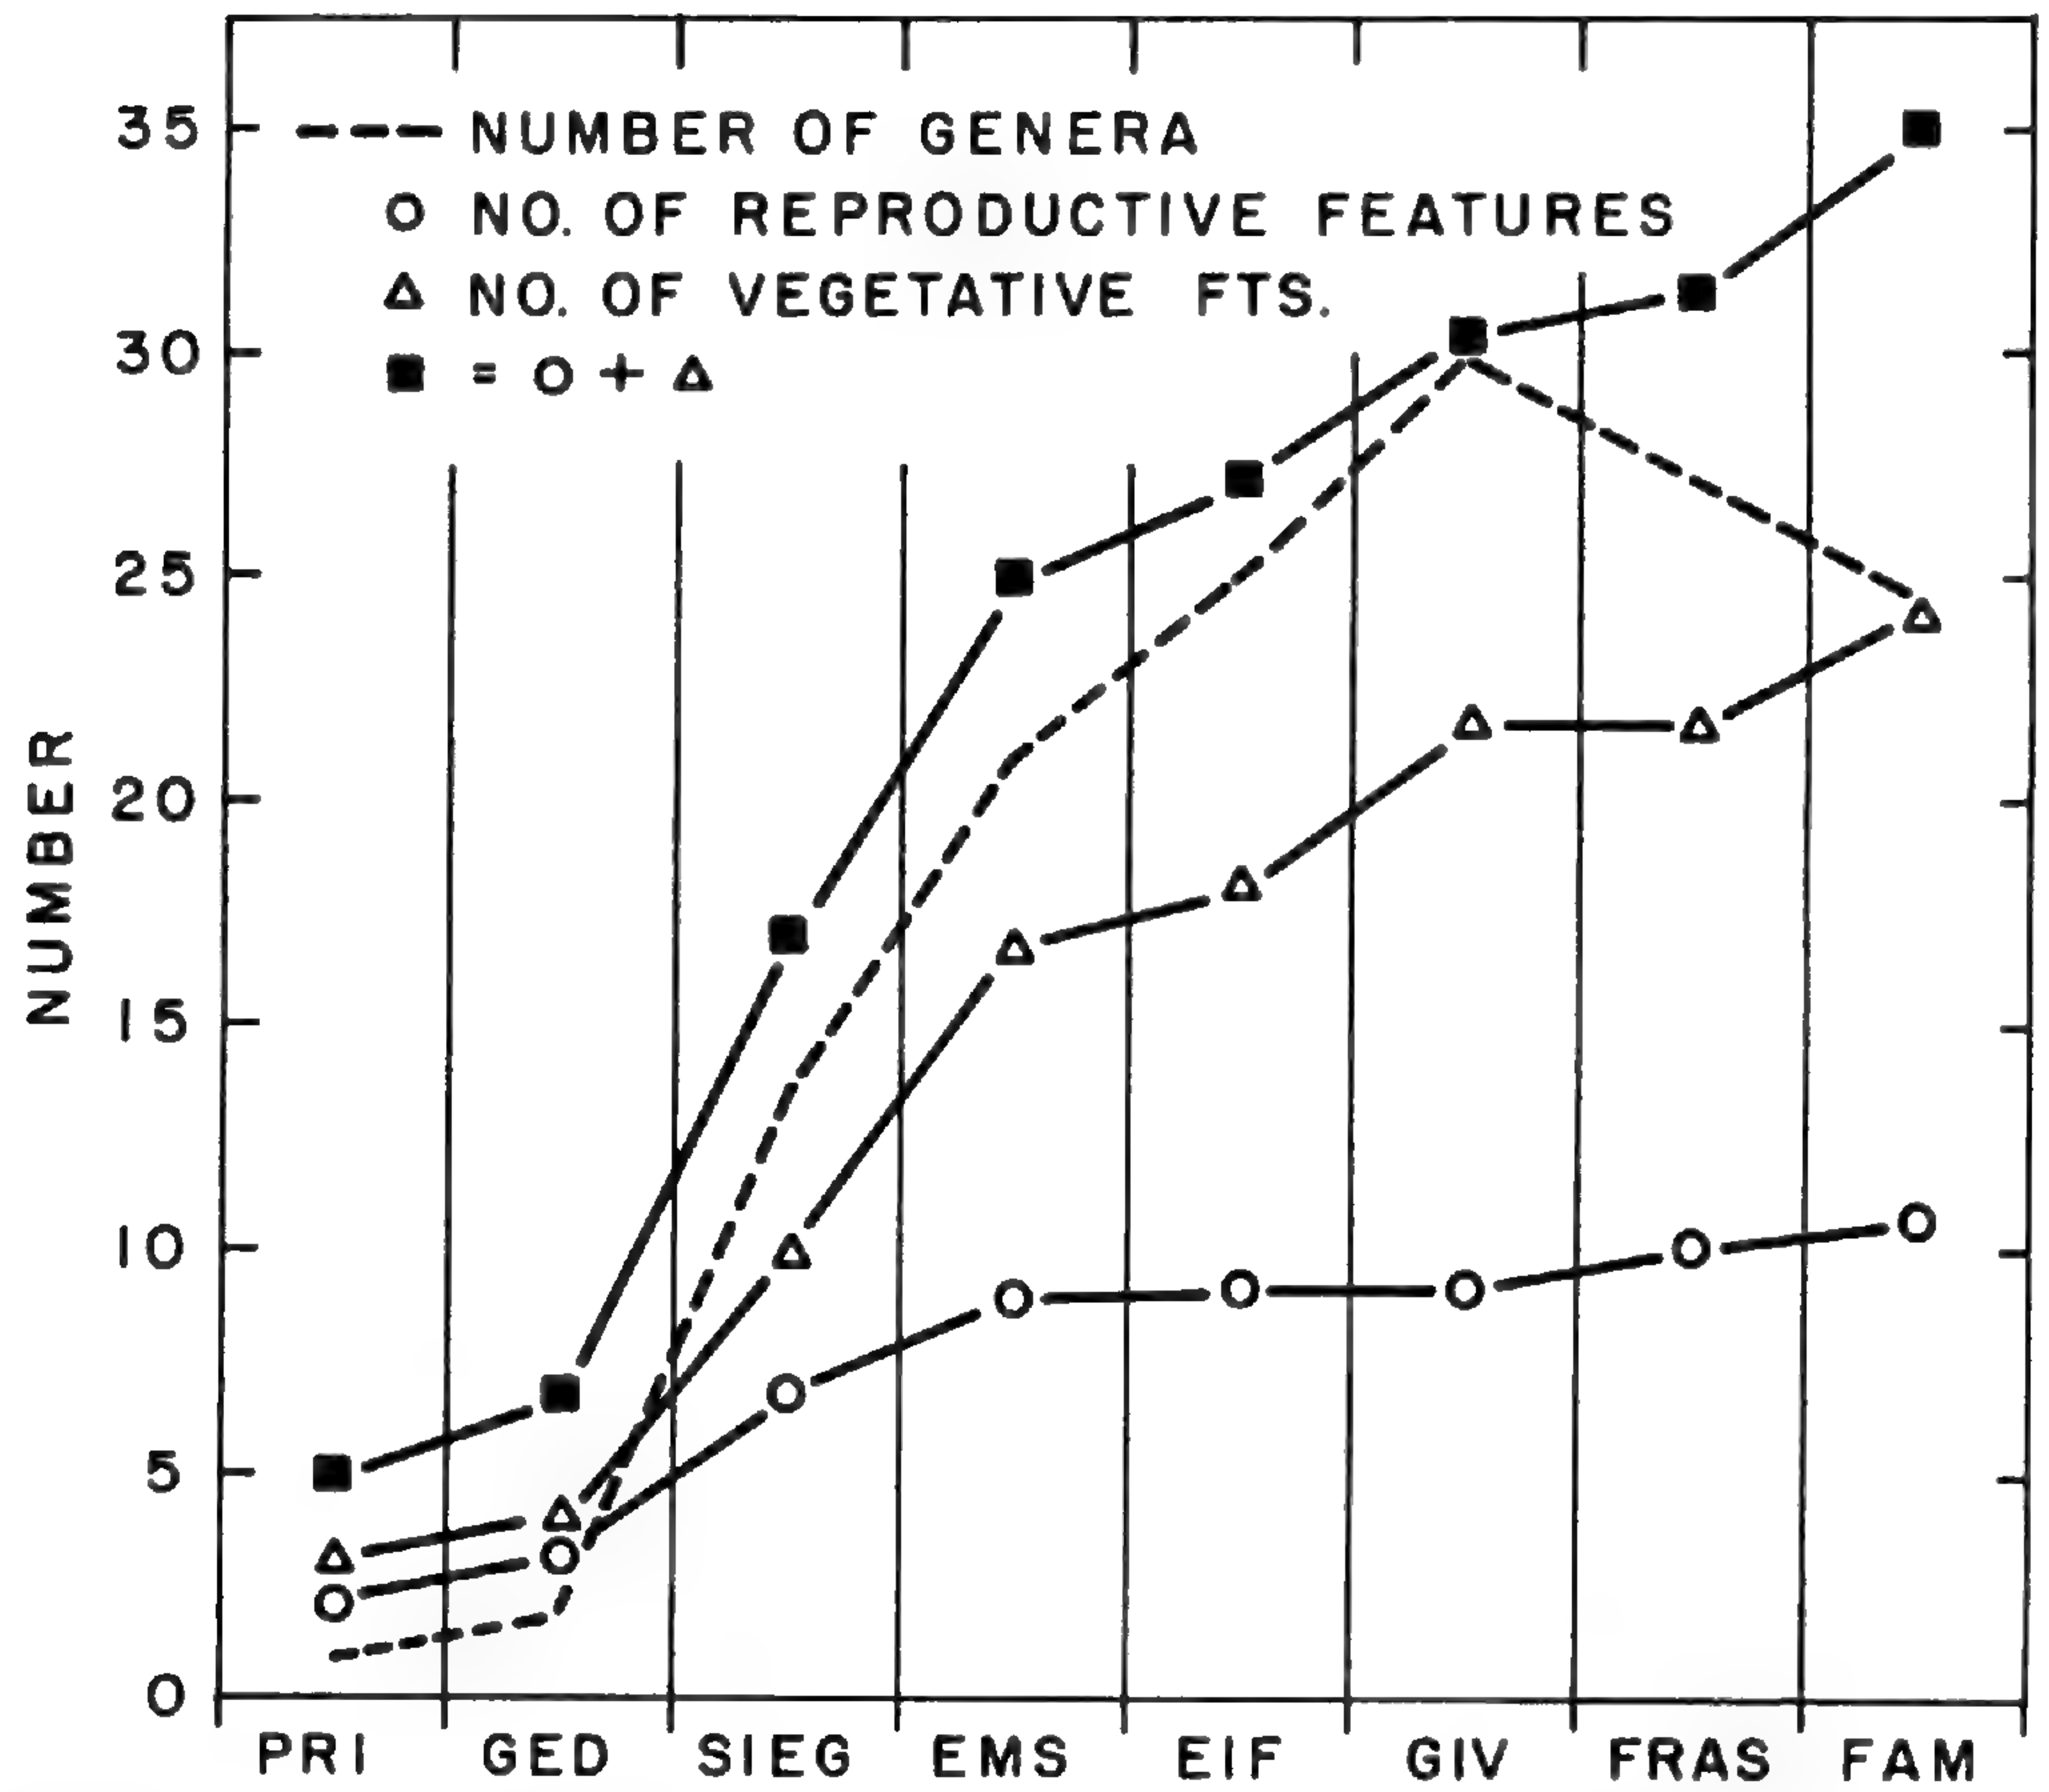

FIGURE 13. *Changes in the total number of Devonian vascular plant genera and the number of reproductive and vegetative characters used to identify taxa. Data taken from Chaloner & Sheerin (1979, figs. 1–4). Devonian genera are exclusive of nonvascular and dubiously vascular plants (e.g.,* Parka, Pachytheca, Taeniocrada, Prototaxites, Sporogonites, Spongiophyton, Protosalvinia*): Pri = Pridolian, Ged = Gedinnian, Sieg = Siegenian, Ems = Emsian, Eif = Eifelian, Giv = Givetian, Fras = Frasnian, Fam = Famennian.*

deal with these factors and to reconstruct information lost from the fossil record (Nichols & Pollock, 1983).

The fossil record is the principal source of information on long-term patterns of evolution. Retained within it are imperfect records of taxonomic diversification, major episodes of adaptive radiations, and major extinctions. This paper has focused on the quality of these patterns for vascular land plants. Quantitative analyses of the paleobotanical literature provide a basis for reconstructing the broad patterns of floristic and vegetational change occurring over the last 400 million years. In particular, large-scale patterns in numbers of species have been used to reconstruct and identify two major floristic changes, one at the end of the Paleozoic and another toward the end of the Mesozoic; within-assemblage taxonomic compositions have been used to treat broad patterns in vascular plant ecology; and morphological/anatomical data have been used to reconstruct trends in organography and adaptation. As has been seen, however, potentially serious limitations and distortions exist in the data. In almost all cases, quantitative analyses can be used comfortably only to draw qualitative conclusions.

The most serious difficulty with the fossil record comes from attempts to infer mechanisms from patterns. Ecologists are currently debating the use of patterns as data, as the recent furor over the use of null models attests (Harvey et al., 1983). Is there a null hypothesis for the pattern of species diversification seen in the fossil record? The answer is an equivocal yes. The fossil record of land plants exists because of processes of nonmarine clastic and pyroclastic deposition. The vast majority of fossil plants are preserved in lowland flood plain or lakeside environments or are entombed in volcanic ashfalls and mudflows. Consequently, it is conceivable and even probable that much of the patterns seen in tracheophyte species diversification can be explained in terms of factors that influence patterns of nonmarine sedimentation. Principal among these is tectonics, which controls

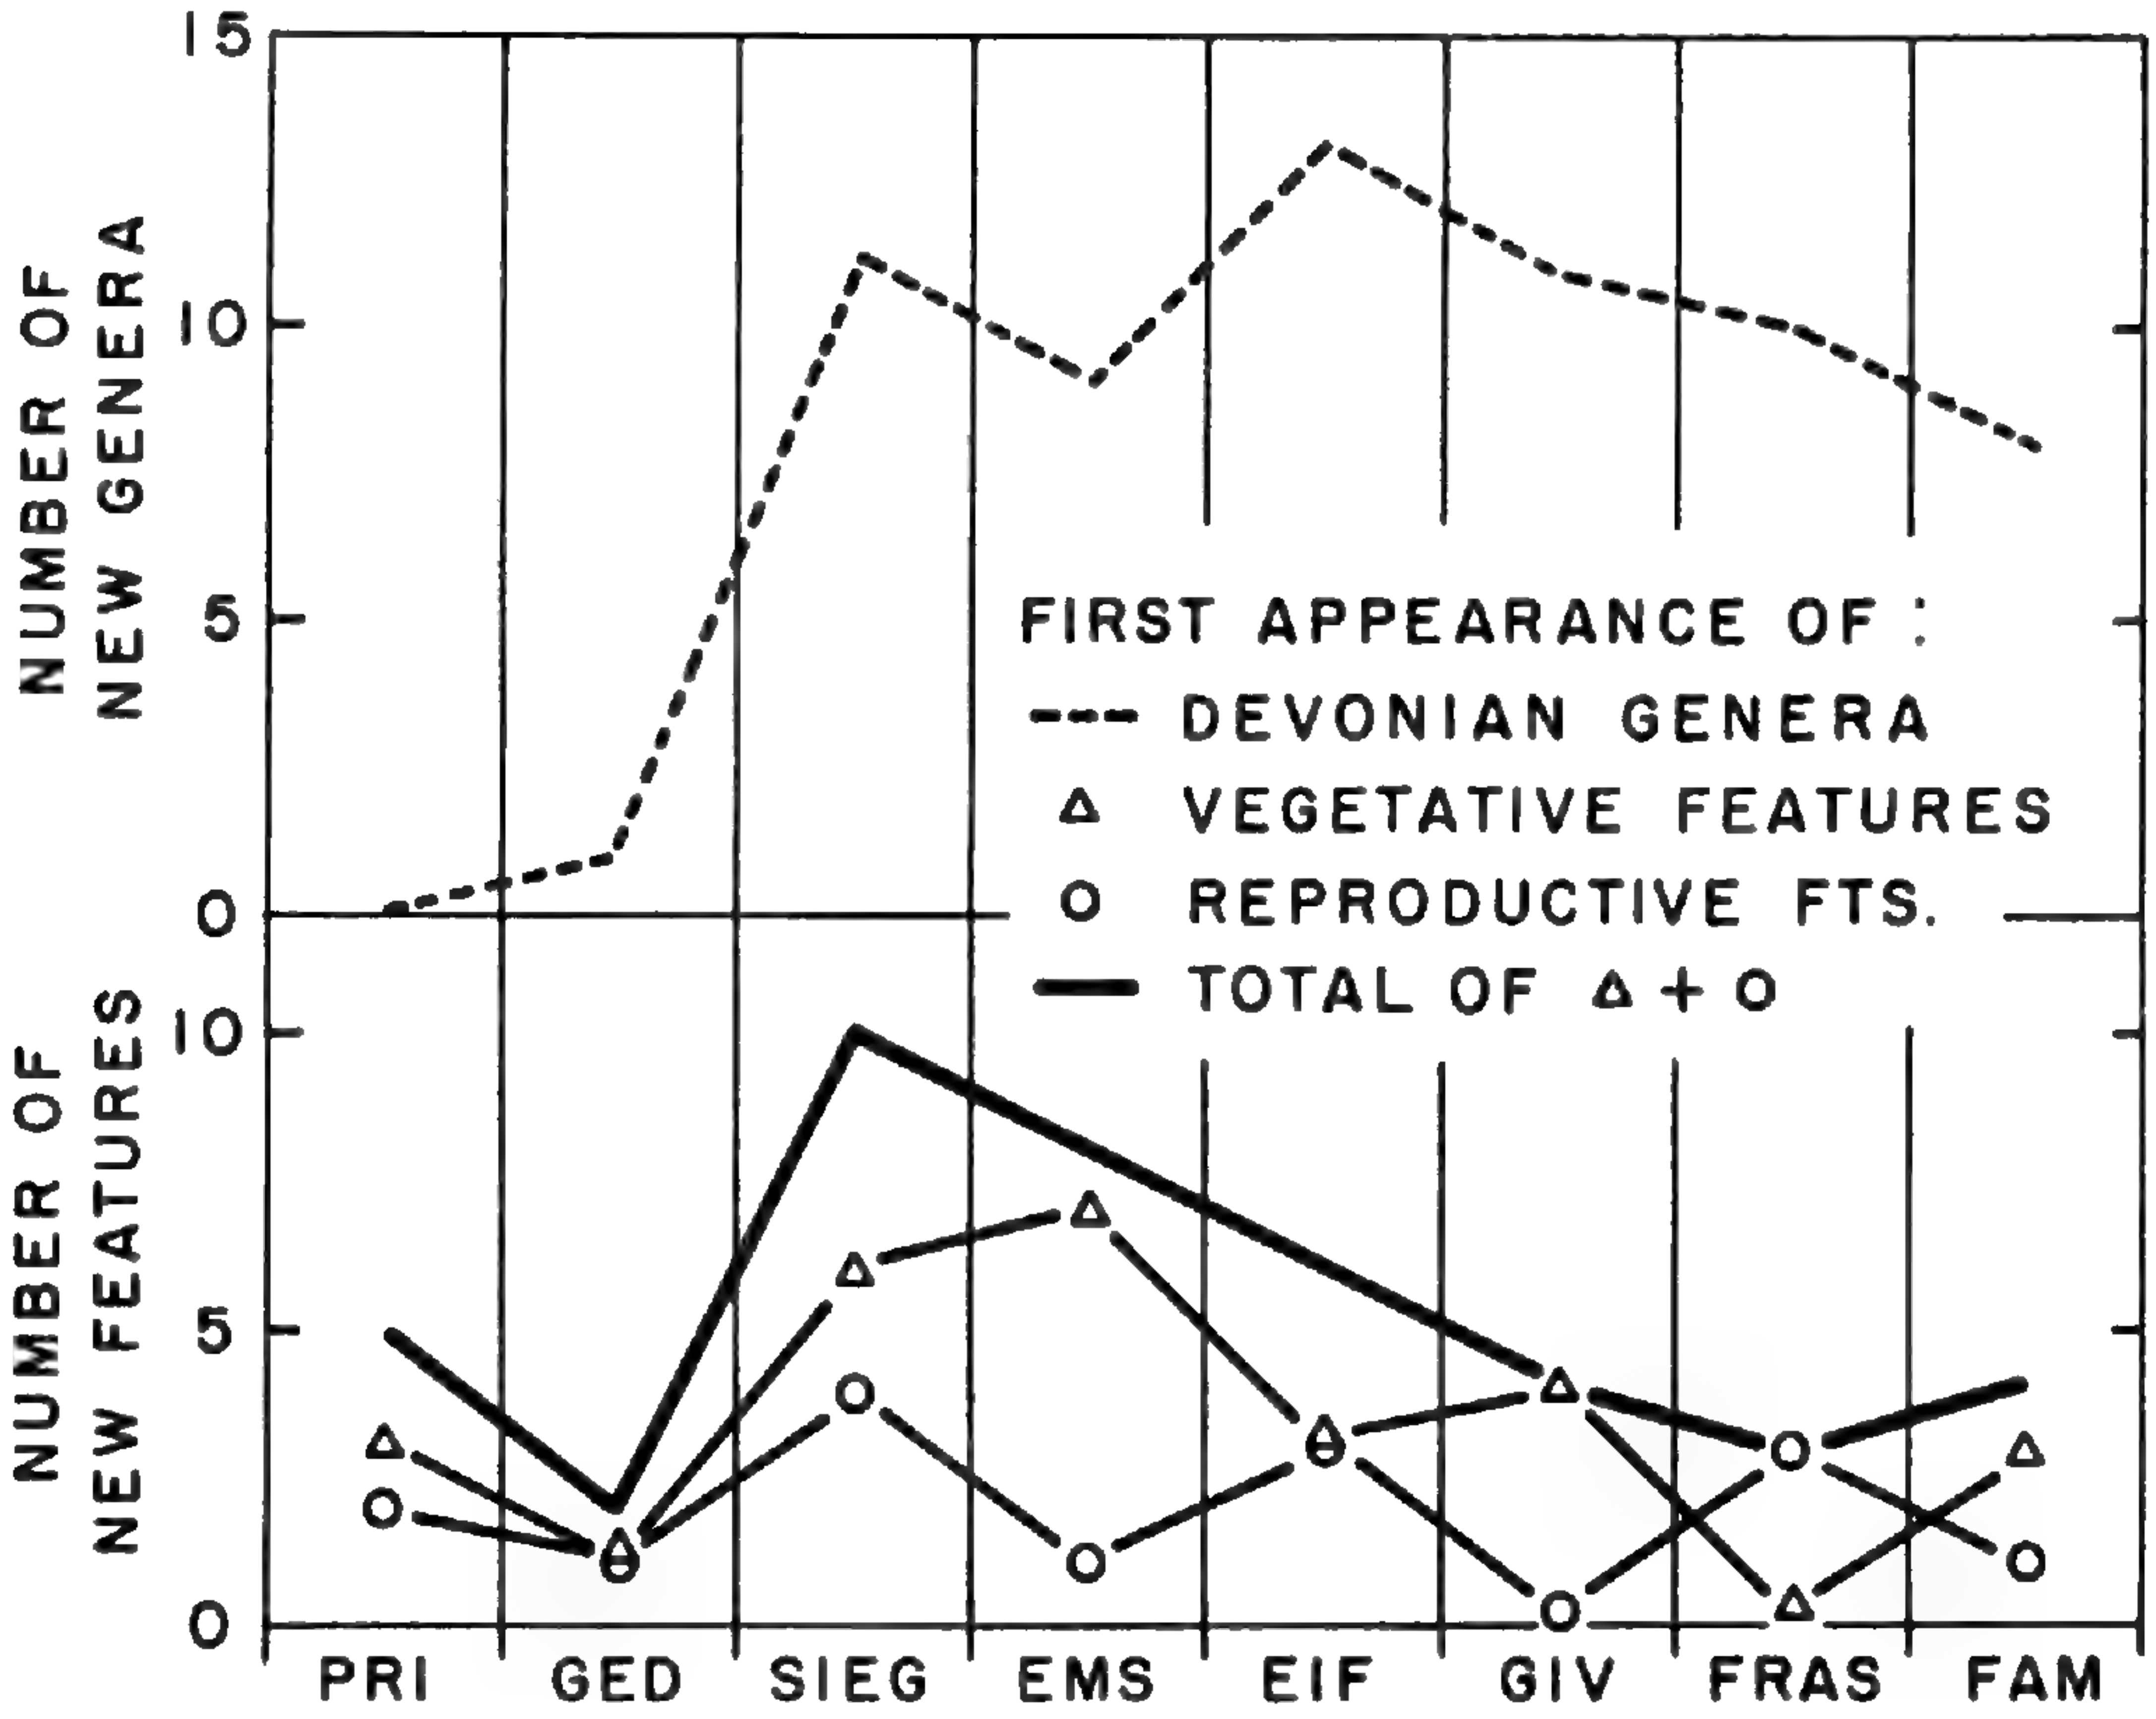

FIGURE 14. *Numbers of first appearances of Devonian genera, and vegetative and reproductive features. Data from Chaloner & Sheerin (1979, figs. 2–4).*

rates of uplift, erosion, subsidence of sediment-accumulating basins, and volcanism (Blatt et al., 1972).

For example, variation in the type of nonmarine sediments deposited during a geologic period could contribute to the apparent pattern of species diversification. Are periods of high numbers of species also those in which geological factors favored the deposition of sediments in which fossils are easily recovered? Fossil plants are preserved most often and with high morphological fidelity in fine-grained carbonaceous detrital sediments and volcanic ash deposits. Niklas et al. (1980) attempted a limited analysis of data on coal resources to estimate coarsely the variation in nonmarine carbonaceous sediments through the Phanerozoic. We concluded that the Carboniferous, Cretaceous, and Tertiary were qualitatively different from other geologic periods. These three "coal eras" have large coal tonnages *per unit of outcrop area.* High numbers of species for these three coal-rich eras could reflect a combination of extensive sedimentological "sampling" of terrestrial floras, excellent preservation (e.g., coal ball petrifactions), and the consequence of intensive economic exploration of coal resources. These factors probably account for the unusually high numbers of species reported for the Carboniferous and Cretaceous-Tertiary.

Therefore, it is safe to assume that tectonics and erosional patterns of deposition have contributed to the fluctuation in numbers of species in substantial ways. Nonetheless, these nonbiological or null hypotheses are inadequate to explain the patterns of taxonomic turnover within fossil assemblages or broad patterns in plant organographic/reproductive evolution. Regardless of the quantity of sediment deposited or the preservational status of plant parts recorded for a geologic period, there exists no necessary and sufficient correlation between the magnitude and direction of physical factors operating in the fossil record and patterns in taxonomic turnover and morphological evolution. Patterns in plant fossil record can be viewed either from the perspective of "objects" (taxa and their origination, persistence, and extinction) or "properties" (morphological and reproductive innovations and elaborations). A strictly exclusive treatment of either perspective is unlikely to lead to any insights into the relationship between evolutionary patterns and mechanisms (Sober, 1985). Null hypotheses are an essential component to this type of inquiry, but the assessment of alternative hypotheses and multiple-causation in paleontology requires both geological and biological insights.

The salient conclusions that emerge from a review of the plant fossil record can be briefly summarized under five points. (1) The concepts of a paleospecies and an extant species are significantly different (see Gingerich, 1985). (2) Consequently, the fossil record of species diversification is best viewed as a document of trends in morphological/reproductive diversification. Quantitative estimates of "diversity" can be used to draw primarily qualitative conclusions. (3) The taxonomic richness recorded for any geologic period does not provide information on species equitability, which is an essential component to considerations of paleoecology and the ramifications of phenomena such as extinction. (4) Although the properties of taxa above the level of species are potentially interesting, they do not necessarily reflect those of species, which are the primary focus of evolutionary mechanisms. Finally, (5) much of the pattern of taxonomic diversification could be explained by factors operating in a strictly geological context; however, identification of long-term patterns in biological phenomena requires the examination of trends in morphology, anatomy, and reproductive systems, in conjunction with patterns of species diversification (Raup, 1983).

EFFECTS OF ARIDITY ON PLANT DIVERSITY IN THE NORTHERN CHILEAN ANDES: RESULTS OF A NATURAL EXPERIMENT[1]

Mary T. Kalin Arroyo,[2,3]
Francisco A. Squeo,[4] *Juan J. Armesto*[2]
and Carolina Villagrán[2]

ABSTRACT

Hyperarid climates in western South America from 15°S to 29°S, extending up to 3,000 m in the northern Chilean Andes, result primarily from the Andes intercepting precipitation from the Intertropical Convergence and the drying effect of the equatorward-running Humboldt Current bathing much of the Pacific coast of South America. Paleobotanical, paleontological, and geological evidence suggests that such harsh climatic conditions developed very recently in Holocene times, following a turbulent Pleistocene history of alternating wet/cold and warm/dry periods. Seasonal climates probably first emerged in the Pliocene after a long, warm/wet Miocene during which precipitation is thought to have increased from east to west, as opposed to west to east, as occurs north of 25°S today. For the three remaining intact vegetation belts (desert scrub, Andean, and high Andean) in the northern Chilean Andes above the Atacama Desert, surveys on six transects, each approximately one-fourth of a degree latitude wide, located at 18°S, 19°S, 21°S, 24°S, 26°S, 28°S, revealed only 769 species of vascular plants in 290 genera. Altitudinally, species richness decreases with elevation in the winter rainfall zone, where precipitation is received from the southwest ("invierno chileno"; transects 26°S, 28°S), to peak at mid elevations in the summer rainfall zone where precipitation is received from the east ("invierno boliviano"; transects 18°S, 19°S, 21°S, 24°S). Species richness decreases by 80% and cover by 50% over the very severe rainfall gradient from 18–24°S. In spite of its greater reliance on water, the azonal bog flora has been less affected than the zonal flora by aridity, probably because of greater chances of reintroduction of species following their loss through long-distance dispersal. Species richness, when considered on a broad biogeographical scale, was significantly positively correlated with mean annual rainfall, as it was for most 500-m elevational levels when considered separately. The effect of cold temperatures at the higher elevations was completely obliterated by aridity on a biogeographical scale. Although diversity (measured as a synthetic characteristic combining richness and abundance) and species richness showed similar trends as aridity increases, loss of diversity tended to be more gradual in comparison with reductions in species richness. Aridity leads to community features analogous to those seen in the early stages of primary succession, maintained on a permanent basis. Losses in species richness with aridity along the western side of the Andes and from east to west across the Andes were overlain by highly characteristic life form tendencies. Perennial herbs are proportionately most abundant in areas of highest rainfall, annual herbs gain greatest prominence in areas of intermediate aridity, while woody species were proportionately most strongly represented under extreme dry/warm and extreme dry/cold conditions. The woody habit is generally more common in the northern Andes than in some similar North American plant communities. The maintenance of considerable diversity (in spite of severe loss in species richness) coupled with emphasis on long-lived woody species in the harshest environments in the northern Chilean Andes are tendencies also seen in many species-rich, climatically benign tropical plant communities. The hypothesis is developed that convergence in these features results from the similar selective effects of certain abiotic and biotic factors in the harsh arid environments of the northern Chilean Andes and in species-rich tropical communities, respectively. We predict that additional life-history trait similarities (e.g., in breeding systems) will emerge for the plant species of abiotically and biotically "harsh" environments, respectively.

ANN. MISSOURI BOT. GARD. 75: 55–78. 1988.

Areas of the earth's surface where local mountain ranges exert strong influence over precipitation and temperature patterns experience especially radical environmental alterations during major global climatic changes. How floras adjust to rapidly emerging harsh environmental conditions, and the patterns of species richness and community diversity resulting from such restructuring should be just as relevant for the development of comprehensive diversity theory as phenomena seen in highly productive, abiotically benign environments. Diversity trends in harsh habitats should also have direct bearing for conservation in that changes induced in ecosystems by human activities are frequently similar in nature and magnitude to those engendered by natural climatic change. Yet, as perusal of the literature on species diversity and community structure (e.g., Tilman, 1986) will show, harsh habitats have received relatively little attention.

Apriorily, reductions in species richness are expected in harsh habitats because productivity is limited by abiotic factors. Such losses, moreover, might be exponential due to the compound direct (physiological) and indirect (historical and, on other organisms such as pollinators, seed dispersal agents) effects of habitat harshness. Patterns of species loss in harsh habitats, nevertheless, are likely to be far more complex than this. Expected losses could be mitigated by a number of factors related to community dynamics. During their evolutionary histories, floras accumulate many life forms varying in ecophysiological and demographic properties. At the onset of harsh conditions, loss of richness could be suppressed by life-form shuffling. In many warm deserts, for example, the annual habit is selectively favored (Raven & Axelrod, 1978; Pavlik, 1985), and species richness levels may be relatively high. Much present knowledge of life form shifts derives from comparative studies of distinct plant communities with floras of heterogeneous phytogeographic origin. Because such comparisons could be confounded by phylogenetic constraints in certain taxa, a critical assessment as to whether life form shifts stall losses in diversity will be best obtained by comparing life forms in floristically homogeneous communities subject *internally* to different degrees of habitat harshness. To facilitate the interpretation of results, moreover, such gradients in habitat harshness must be well documented as to their abiotic characteristics.

Maintenance of diversity in harsh environments should also be affected by changes in the relative balance of biotic and abiotic selective factors. In early successional communities, because of low dominance levels, local diversity may be high despite total low numbers of species present (Houssard et al., 1980). In that resources are severely limited, and competition for light is reduced due to abiotically induced low productivity, harsh habitats may be likened to the early stages of primary succession maintained on a long-term basis. For harsh habitats with low species richness, then, diversity as reflected in the relative abundance of species might be relatively high. Another way of viewing this postulated analogy is that loss of diversity with greater harshness should be partially, and increasingly, counteracted as harshness increases. This hypothesis may be tested by comparing species numbers (species richness) with measurements of diversity as a synthetic characteristic combining richness and abundance, following Whittaker (1972).

The objectives of this paper are, first, to assess how plant species richness, life forms, and community diversity patterns are affected by severe aridity, and, second, to discuss some implications of diversity patterns in harsh habitats for community structure in general. The northern Chilean Andes located at 18°–28°S in western South America provide a unique setting for this. Close to 10 degrees latitude of absolute desert at low elevations gives way to a sequence of three high-elevation vegetation belts (desert scrub, Andean, and high Andean), these exhibiting varying degrees of aridity latitudinally and altitudinally. Because aridity gradients are overlain by temperature variation, the Andean system is also ideal for assessing the relative effects of temperature versus aridity on plant diversity.

As Diamond (1986) pointed out, to interpret the results of any "natural experiment," as the above would be classed, clear understanding of the timing of historical events that led to the "observed results" is essential. As we mentioned above, the identification of salient present-day abiotic parameters responsible for maintaining the "particular species mix in the test tube" is equally important if unequivocal answers to the kinds of theoretical questions outlined earlier are sought. Consequently, before examining plant diversity patterns in the northern Andes (Section III), we will devote considerable space to outlining the present climatic characteristics of the northern Andes (Section I), and the historical development of arid climates at subtropical latitudes in western South America in general will be reviewed in detail (Section II).

DATA BASE AND METHODS

For species richness patterns and estimates of diversity we compiled data over a number of years in six altitudinal transects (18°S, 19°S, 21°S, 24°S, 26°S, 28°S) running from the upper margin of the Atacama Desert (1,500–3,000 m elevation) to the upper limit for vascular plants (4,500–5,000 m, depending on latitude) (Fig. 1). Records of species present every 50 or 100 m of elevation were obtained by walking the transects and by climbing a number of high summits in each area. The transects followed the main Andean penetration routes and for this reason had no fixed courses. In each case routes taken traversed approximately one-fourth of a degree of latitude. For these transects plant cover was measured in altogether 1,620 minimum area quadrats. Replicate quadrats were sampled at 50–100 m elevational intervals along each transect. Cover of shrub and perennial herb species was estimated from the surface area projected by each individual of a species within a quadrat. The largest and smallest diameter of the individual's crown was measured for calculation of an elliptic to circular area. Annual herb cover was initially measured on a phytosociological scale (transects 18°S and 19°S). In later work annual herb cover was estimated from the percentage of points 10 cm apart on line transects intercepted. The data for all 50–100 m elevational sampling intervals was subsequently pooled for 500–1,000 m elevational intervals.

Species richness for equivalent 500 m elevational intervals at different latitudes was compared with mean annual precipitation using regression analysis, employing linear, semilogarithmic and log–log models, and with mean annual precipitation and mean annual temperature using multiple regression analysis. Precipitation and temperature for the series of 500 m elevational levels on each transect were estimated from curves constructed from weather station data available for the particular area under consideration. Weather data were obtained from di Castri & Hajek (1976) and from records supplied by the Ministerio de Obras Publicas (MOP) in Santiago.

For life form analyses, species were classed as annual herbs, perennial herbs, and woody plants (primarily shrubs). For the small number of Cactaceae present, columnar species and large cushion species were included in the woody category. The smaller cacti species were categorized as perennial herbs. To facilitate statistical analysis (*G*-tests) the life form data for pairs of adjacent transects were combined.

The indices exp H' where

$$H' = -\sum_i p_i \ln p_i,$$

and $1/\lambda$ where $\lambda = p_i^2$ (Peet, 1974), were employed to measure community diversity. In these indices p_i = the proportional abundance of the *i*th species. Relative cover was used as the proportional abundance of a species. Details on some of these transects appear in Arroyo et al. (1982, 1984) and in Villagrán et al. (1982, 1983).

TERRITORIO CHILENO ANTARTICO

Loa, or in coastal fog pockets such as Paposo and Taltal) occurs south of 17°S to 25°S (Fig. 1). The desert rises abruptly from a narrow coastal strip to 1,500 m at the Arica deflection (18°S) in northern Chile and reaches a maximum elevation of 3,000 m at 24°–25°S, in from the coastal cities of Antofagasta and Taltal. South of 25°S aridity decreases again.

The Chilean–Peruvian arid diagonal is a "rain shadow" and a "cold air" desert (Rauh, 1983). The present climate (Figs. 2, 3) is determined primarily by the annual behavior of the Intertropical Convergence situated over equatorial latitudes (Gomez & Little, 1981) which brings moisture from the northeast, and by a Polar front bringing precipitation from the southwest, together with the interplay of these precipitation sources and the major ocean currents. South of 24°–25°S, most precipitation is received during the winter months (May–August; "invierno chileno") from a northward extension of the Polar front. Consequently, the climate is essentially an arid version of the true Mediterranean climate further south at 30°–38°S. Here there is no east–west reduction in rainfall (Fig. 2). Most precipitation above 3,000 m in the Chilean Andes for these latitudes is in the form of snow.

North of 24°S, where a southward extension of the Intertropical Convergence during the summer months comes into play and the Polar front is negligible, precipitation is received during the summer months (November–March; "invierno boliviano") as rainfall below 4,000 m or as transient snow and hail above 4,000 m. The winters are cold and dry. At these latitudes the Andes generate a rain shadow by forcing moisture-laden air from the northeast to rise and cool on their eastern slopes. The greatly diminished saturated air masses ascending onto the western side of the Andes undergo adiabatic heating, further reducing potential precipitation. As the air masses reach lower elevations towards the Pacific, they are further dried by cold surface waters from the Circumantarctic Current carried northward by the equatorward-running Humboldt Current (Peru Current) (Zinsmeister, 1978) and by cold bottom water upwelled from the Pacific by the Humboldt Current as it is deflected away from the coast by the Coriolis effect in subequatorial latitudes. As a result of these features and southward weakening of the Intertropical Convergence, the Chilean Andes north of 24°–25°S are characterized by steep east–west and north–south reductions in precipitation (Fig. 2). Typical of the east–west gradient, recorded annual precipitation for Parinacota (18°S), situated at 4,395 m, is 372 mm. Murmuntane, situated at 3,280 m and less than 100 km to the west, receives only an average of 156 mm of rainfall annually, while mean annual rainfall for Arica on the coast (29 m) is less than 1 mm. Southwards at 21°S, recorded annual precipitation for Cebollar at 3,730 m is 53 mm, while at 24°S (at Imilac, 3,232 m) recorded annual rainfall is 2.4 mm.

In the northern Chilean Andes, as a result of reduced cloudiness due to higher than average adiabatic heating, the normal latitudinal decrease in temperature is essentially absent to at least around 24°S (Fig. 3) (from 25° to 28°S there are too few temperature records for the Andean highlands). This fortuitous situation avails easy temperature control of comparisons of diversity with increasing aridity. The average lapse rate above 1,000 m is about 6.5°C per 1,000 m increase in elevation. Below 1,000 m, where coastal fog results in abnormal cooling, the lapse rate is lower. Mean annual temperature at Murmuntane (3,280 m) is 9.7°C. Mean annual temperature at Parinacota (4,395 m) is 2.5°C.

II: HISTORICAL DEVELOPMENT OF ARIDITY IN THE NORTHERN CHILEAN ANDES

Proposed timetables for development of arid climate in western South America span Miocene (e.g., Muizon & DeVries, 1985) to Quaternary initiation dates (e.g., Ochsenius, 1983a). Ochsenius & Santana (1974), Ochsenius (1983b), and Axelrod (1979b) agree that maximum aridity was reached very recently.

EMERGENCE OF THE ANDES

That many of the high Andean summits rose rapidly and only very recently is critical to understanding the development of harsh arid climates at subtropical latitudes in western South America.

From the late Cretaceous into early Paleocene times, volcanic rocks and associated sediments, deposited close to the present continental margin in Mesozoic times as a result of the closure of the Nazca and American plates (Rutland, 1971; Mortimer et al., 1974), were uplifted to form a proto-Andean divide west of the present Cordillera Occidental (Mortimer, 1980). This primitive axis, however, was almost entirely eroded away, leaving the Altos de Camilica Formation in southern Peru (Tosdal et al., 1984) and the Putani Formation east of Arica (Mortimer & Saric, 1972). The modern landscape differentiated

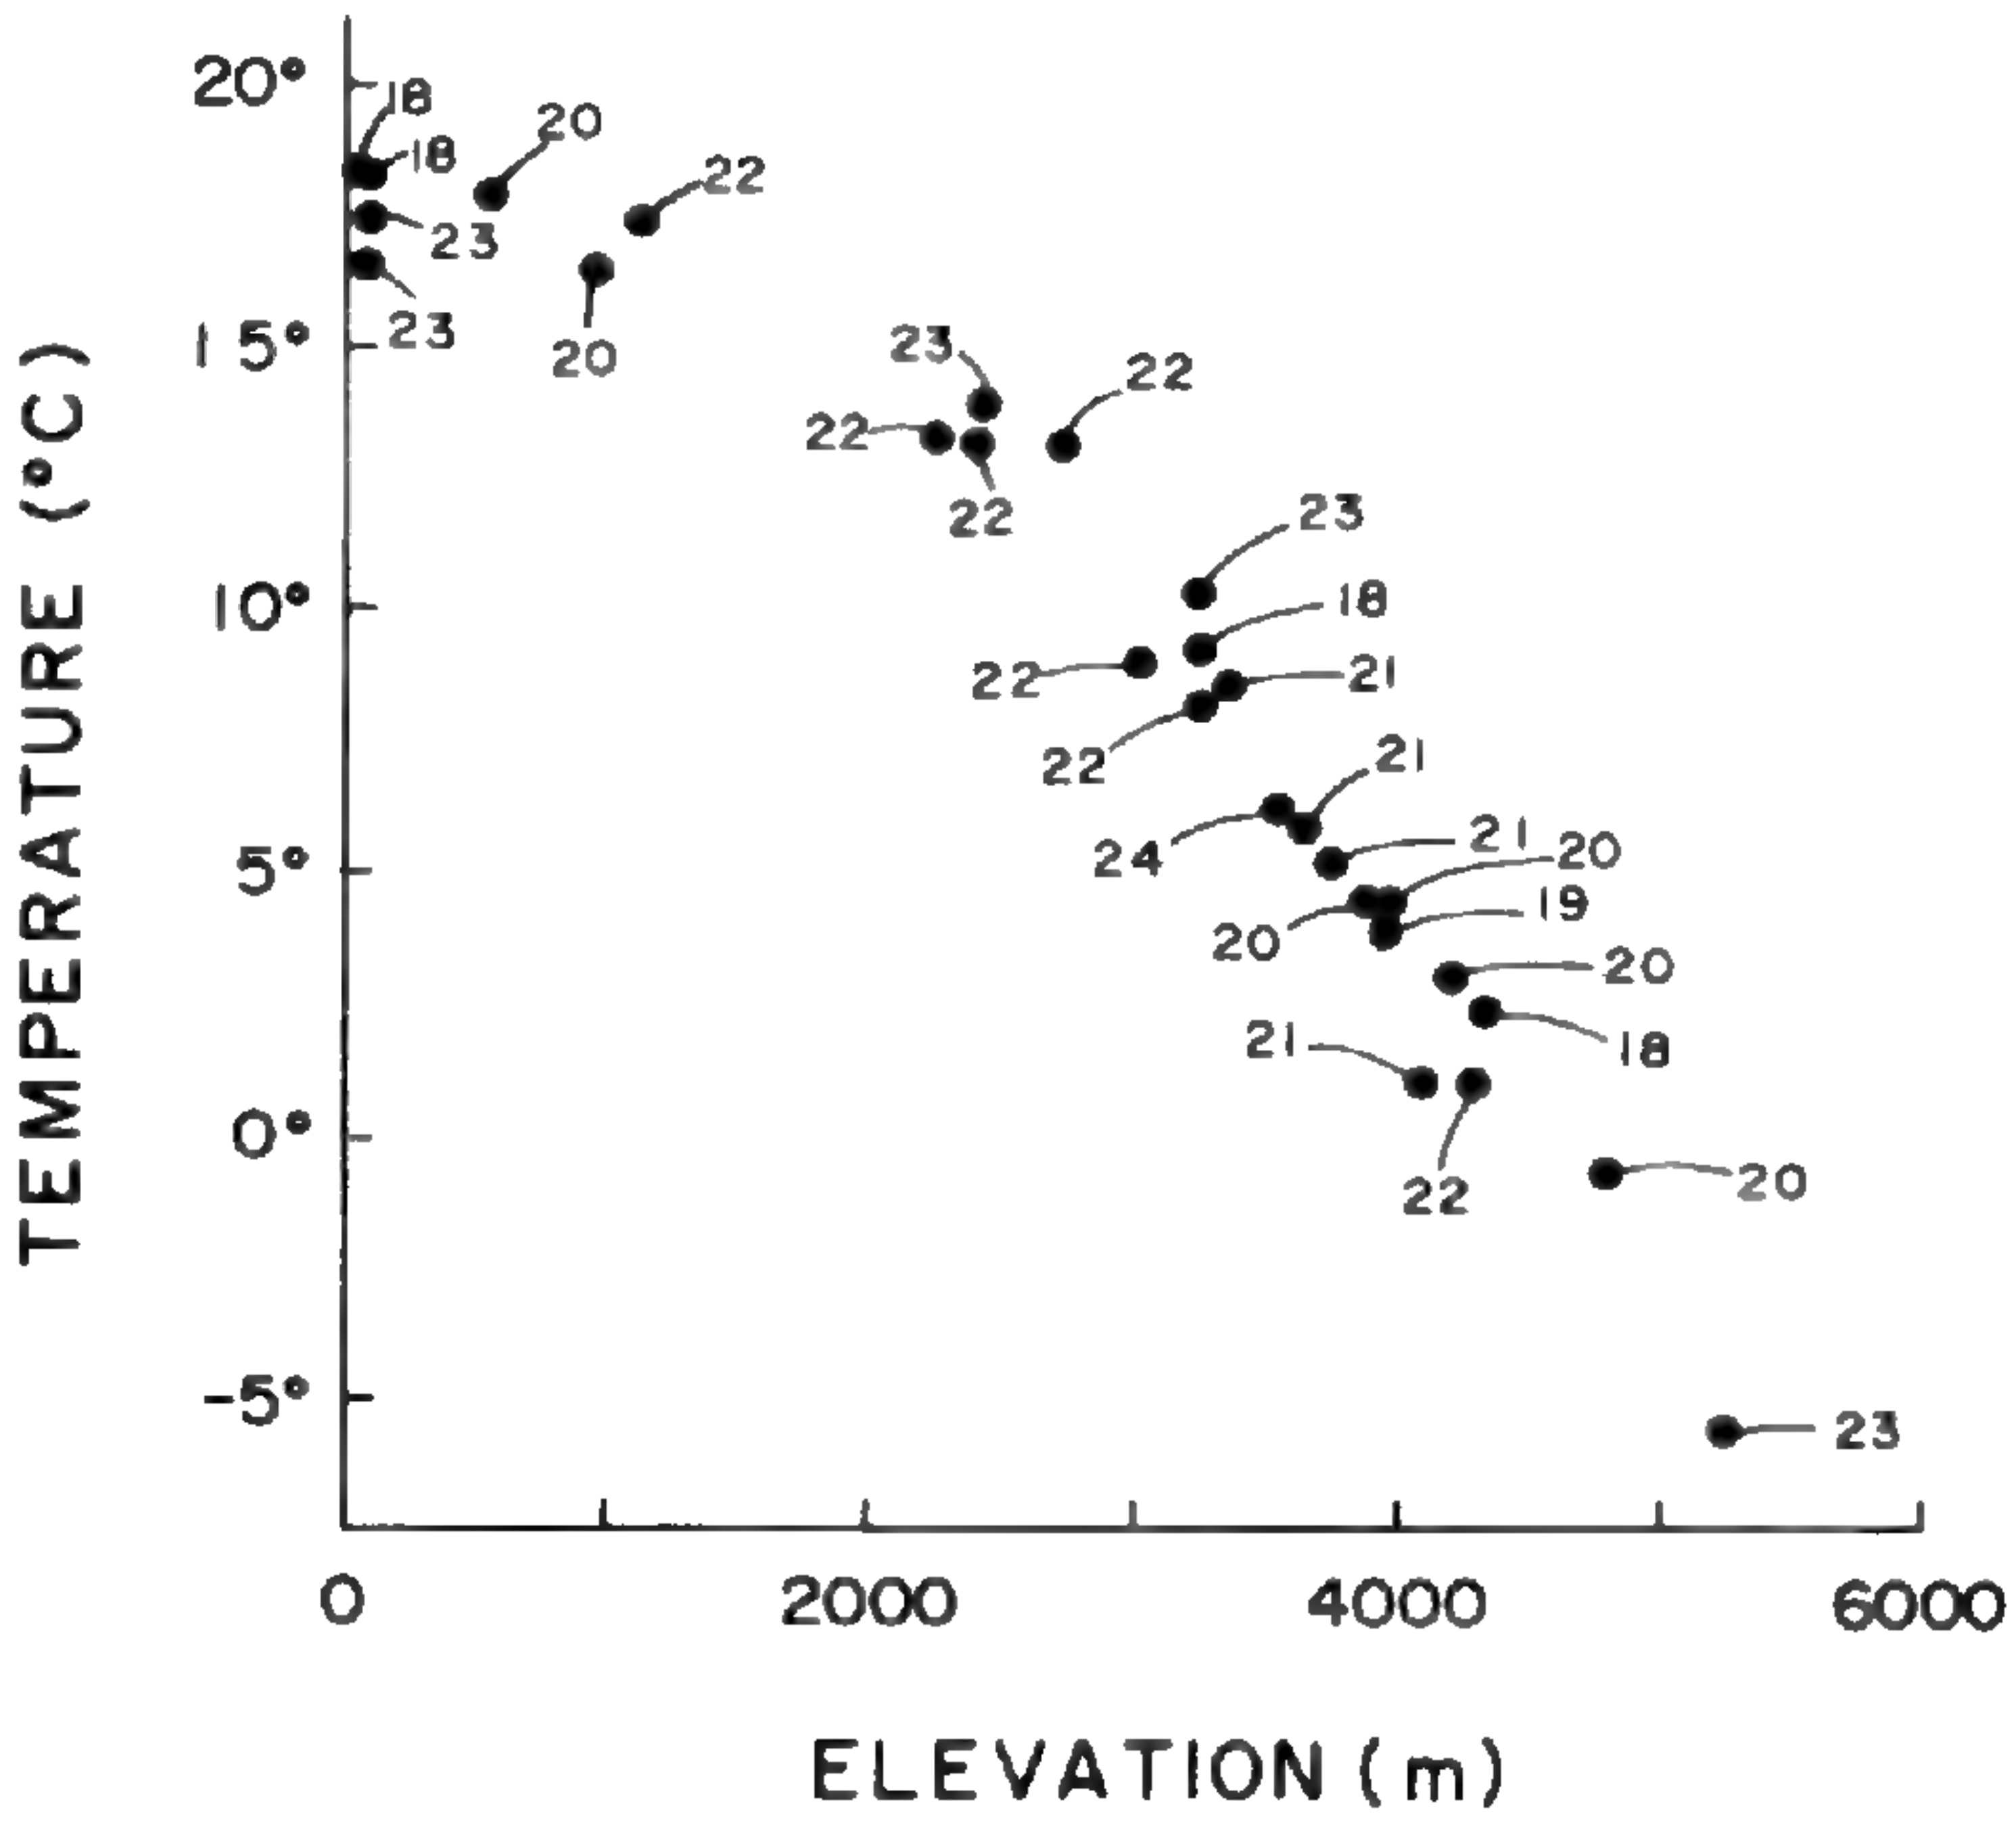

FIGURE 3. *Mean temperature plotted against elevation for areas between latitude 18° and 24°S in the northern Chilean Andes. Data sources as for Figure 2. Data point for 5,300 m at 23°S is from Corrida de Cori (Ruthsatz, 1977), Argentina, close to the Chilean border. The numbers associated with each datum point indicate the corresponding latitude.*

initially in the late Paleocene–early Miocene interval. It comprises (a) the nonvolcanic Cordillera de la Costa, (b) a low-lying depositional basin referred to as the Pampa de Tamarugal in northern Chile or Llanuras Costaneras in southern Peru, (c) the precordillera, a loosely defined transition zone at 2,000–4,000 m, and (d) the parallel cordilleras Occidental and Oriental with summits close to 7,000 m. These cordilleras are separated by (e) a broad intervening high-altitude plain, the Altiplano, of some 500,000 km^2 (Allmendinger, 1986) at 3,700–4,000 m (Fig. 4).

The Cordillera Occidental and the Cordillera Oriental emerged relatively late after two major focal points of rhyolitic volcanic activity developed in the late Oligocene and into the early Miocene (Tosdal et al., 1984; Naranjo & Paskoff, 1985) following extensive north–south block faulting and differential uplifting (Mortimer & Saric, 1972). Such activity persisted well into the late Miocene and early Pliocene (Megard et al., 1985), by which time deposition of sediments derived from the surrounding eroding volcanic axes produced the Altiplano (Fig. 4). During the same epoch, lava flows moving westward and sediments from the Cordillera Occidental backed up against the Cordillera de la Costa (Naranjo & Paskoff, 1985), elevating the northern part of the Pampa de Tamarugal in Chile and the Llanuras Costaneras in southern Peru.

The major increase in height in the Andes, nevertheless, occurred only as of the middle Miocene and onward (Mortimer et al., 1974) in north Chile and the Pliocene in southern Peru (Tosdal et al., 1984) as the result of andesitic volcanism (Fig. 4). Andesitic activity continued across the Cordillera Occidental and Cordillera Oriental throughout the Pliocene and Pleistocene into the Holocene, giving rise to the some 800 volcanoes present in northern Chile. Over 30 of these exceed 6,000 m elevation. Tosdal et al. (1984) estimated that the southern Peruvian Andes were uplifted 0.06–0.19 mm per year throughout the Neogene. The Cordillera Occidental at its southern edge is thought to have increased in height by 0.5 mm per year as of Holocene times (Rutland et al., 1965).

MIOCENE CLIMATES

Although significant uplifting had occurred by the Miocene, there is no evidence at this stage of the strong east Andean rain shadow seen in the Andes today. Axelrod (1979b) reviewed the limited paleobotanical evidence for the Miocene. Berry (1919) described leaf remains from the Tumbez area in northern Peru. Included is material identified as *Annona*, *Banisteriopsis*, *Ficus*, *Persea*, and *Styrax*. Although Berry's identifications require verification, the leaf types present are indicative of a fairly closed tropical viney forest and of productive environments.

A second flora studied by Berry (1917, 1939) from Potosí, Bolivia, now above 4,000 m and immediately to the east of the Cordillera Occidental, was considered by Ahlfeld (1956) to be of Miocene age and would have thus been deposited during the early phases of the uplifting of the Altiplano. It reportedly contains *Calliandra*, *Cassia*, *Copaifera*, *Dalbergia*, *Escallonia*, *Passiflora*, *Terminalia*, *Inga*, and *Weinmannia*. Today similar floras strongly dominated by woody leguminous taxa typically occur in neotropical formations under high rainfall regimes but usually with a distinct dry season in the Venezuelan llanos and adjacent Orinocan forests and areas transitional between Amazonia and the Brazilian Planalto. Elements reminiscent of *Weinmannia*, *Escallonia*, and *Inga* suggest that a semiseasonal forest gave way to a middle-altitude montane forest similar to that seen today further north in the Andes in Colombia where rainfall is very high.

A third flora, from Psillypampa, Bolivia, still further to the east of the main Andean axis, today at 2,600 m, was regarded as Pliocene age by Berry (1922) but suspected by Axelrod (1979a) as possibly of Miocene age. It contains material identified as *Heliconia*, *Myrica*, *Pisonia*, and *Pithecellobium* and many other genera with fairly small leaves. For the Miocene then, there appears to have been a transition from viney forest on the extreme Pacific border, into semiseasonal vegetation types at mid elevations on the Altiplano, and finally into more xeric, small-

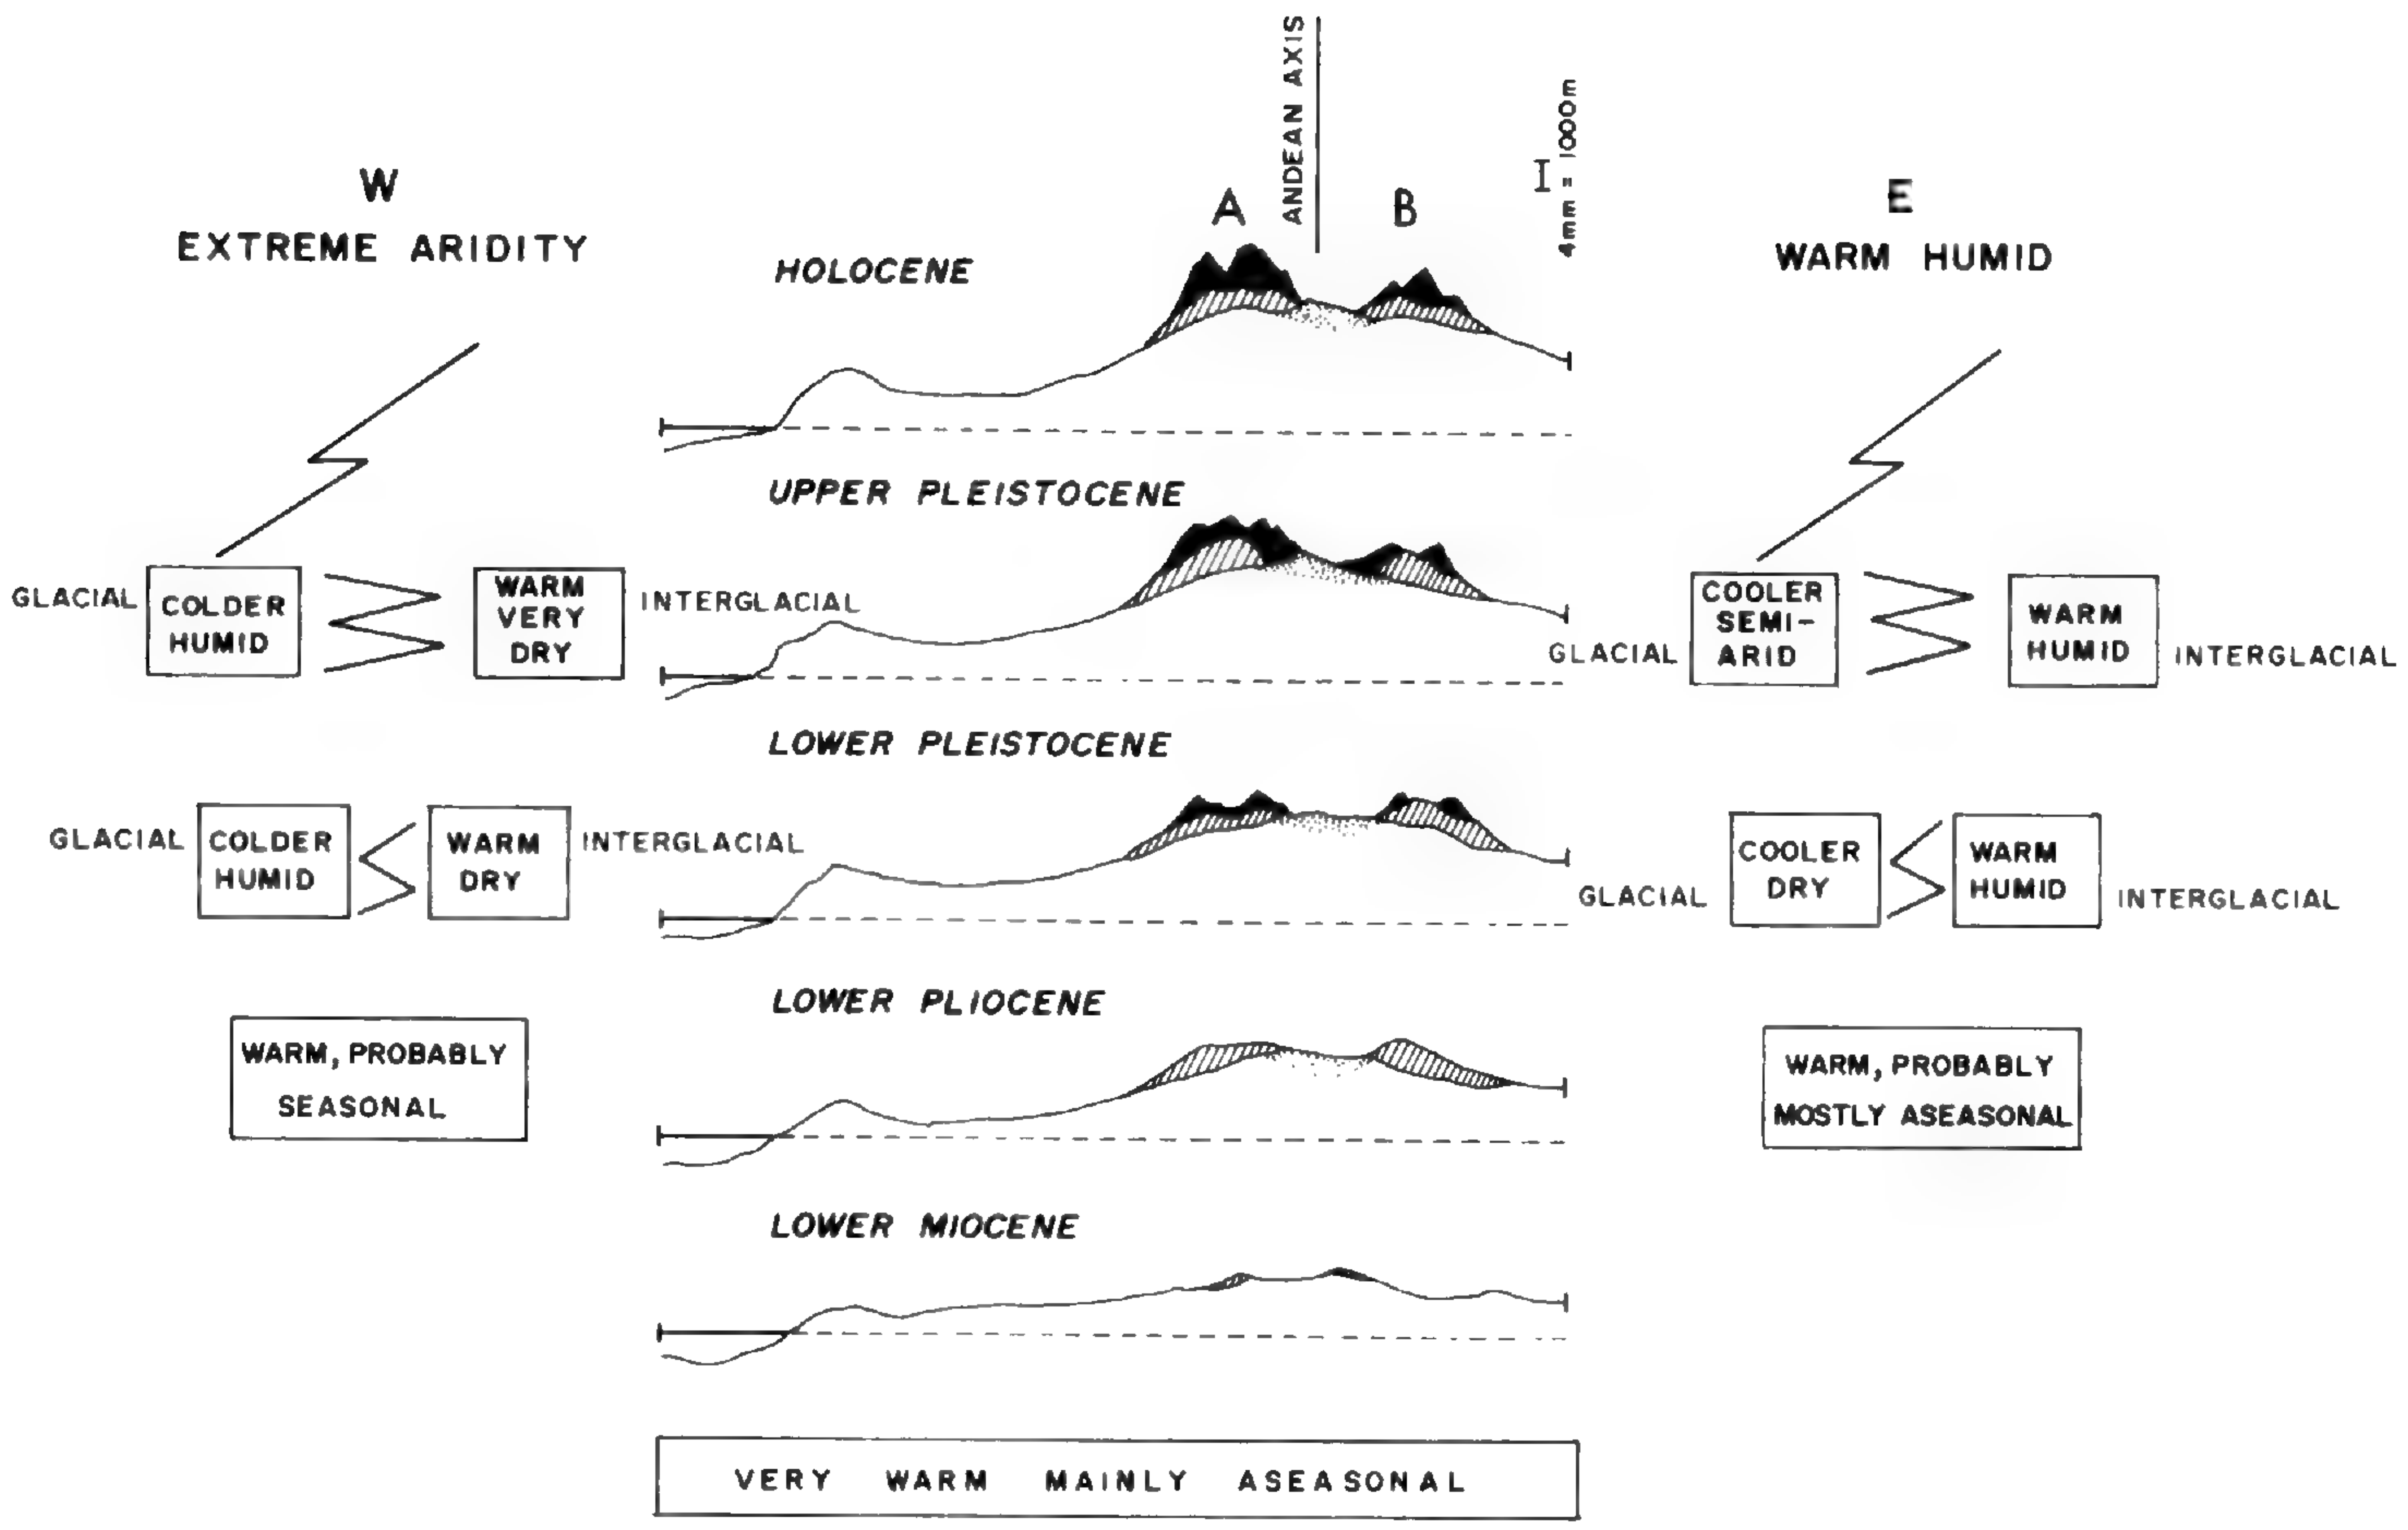

FIGURE 4. *Stages in the evolution of the Cordillera Occidental (A) and Cordillera Oriental (B) as of the Miocene and climatic tendencies west and east of the northern Andes during the Quaternary. leaved forms at lower elevations on the eastern side of the Altiplano. This suggests that, in contrast to today, the western side of the Miocene Andes may have been wetter than the eastern side.

The expected positions and water temperatures of currents in the Pacific Ocean support the above interpretation. Prior to the consolidation of the Antarctic Icesheet, the west wind drift is believed to have lain further south than today; moreover, as Zinsmeister (1978) suggested, cold surface waters would have been directed between East and West Antarctica rather than up the South American coast. With a less active and considerably warmer Humboldt Current in the Miocene, the counter-running warm current bathing the coasts of Ecuador and Peru today most likely extended south of its present position, very possibly engendering precipitation patterns similar to that in recent El Niño events (Cane, 1983), which brought torrential rains to coastal and lowland areas of southern Ecuador and northern Peru (Rasmusson & Wallace, 1983).

A warm, wet Miocene for the western flanks of the subtropical Andes finds good support from marine fossils deposited in high coastal cliffs in northern and central Chile during marine transgressions (Mortimer, 1972) and in the related Pisco Formation in the Llanuras Costaneras of southern Peru (Muizon & DeVries, 1985). At 30°S on the coast of Chile, dendrophyllid corals accompanied a warm-water ostracod fauna, of which some subtropical elements extended as far south as 47°S (Herm & Paskoff, 1967; Herm, 1969). The Pisco Formation contains turtles, sloths, terrestrial carnivores, and other large-bodied animals that could only have existed under fairly productive environments. Vertical incisions up to 1,000 m deep traverse the central depression in northern Chile (e.g., quebradas Vitor, Azapa, Lluta, Camarones). These, which geologists agree are indicative of high pluviosity, were initially cut down in the Miocene (see Mortimer, 1973; Paskoff & Naranjo, 1979; Naranjo & Paskoff, 1980a). Finally, the Miocene was the time of maximum copper enrichment in the Chilean Andes

(Clark et al., 1967). The high water table that this process requires and an active period of erosion seen in canyon development seem to be indisputable evidence against dry climates in the western deserts at this stage.

PLIOCENE CLIMATES

The Pliocene is poorly known for arid subtropical latitudes in western South America. Marine faunas on the Chilean coast at 30°S (Herm, 1969) and in the Pisco Formation in southern Peru (Muizon & DeVries, 1985) show declines in species richness and an influx of elements from cooler waters at the Miocene–Pliocene boundary. Zinsmeister (1978) related such changes to increased incorporation of cold water into the Humboldt Current due to northward displacement of the west wind drift and reduced flow through Drake Passage. Certain periods in the Pliocene in the Colombian Andes, situated away from the influence of the Humboldt Current, saw lower tree lines than at present and the first appearance of a high-elevation flora (Hooghiemstra, 1984). Thus changes in marine faunas along the Pacific coast must have been due at least partially to a general global trend toward climatic cooling. Climates were evidently drier than in the Miocene—canyon cutting in the Atacama ceased abruptly at this stage (Mortimer, 1973). *Vallea, Borreria, Niphogeton,* and *Eryngium,* genera considered indicative of open conditions, became abundant occasionally in high-elevation Colombian forests (Hooghiemstra, 1984). During this period large mammals (*Equus, Megatherium*) appeared in the present area of the Atacama desert. This scant information for the Pliocene suggests a gradual transition from the closed Miocene forests into more open, savannalike vegetation at low elevations, with small, evergreen treelets developing at mid elevations. The presently disjunct montane genus *Kageneckia* (Rosaceae), which occurs in central Chile and again in eastern Bolivia and southern Peru, could have been present in these Pliocene montane forests. *Prosopis,* the only surviving tree genus at low elevations in the Atacama today, probably dates to lowland Pliocene vegetation.

PLEISTOCENE–HOLOCENE CLIMATES

The fairly uneventful, drier and cooler, but far from hyperarid Pliocene of the western margin of subtropical South America gave way to a Pleistocene characterized by marked alternating wet and dry periods.

For tropical and subtropical lowland areas east of the Andes in South America the glacials were *cold-dry* times of forest contraction, while the interglacials were *wet-warm* times of forest expansion (Damuth & Fairbridge, 1970; Colinvaux, 1979; Ab'Saber, 1982; Prance, 1982). It has not been sufficiently appreciated that the wind systems proposed by Damuth & Fairbridge (1970) to account for dry glacial periods in the Amazon Basin predict precisely the opposite climatic trends for corresponding periods on the western side of the Andes, i.e., *warm-dry* periods alternating with *wet-cold* periods (Fig. 5).

During the glacials, the Damuth & Fairbridge model sees a low-pressure focus over Antarctica moving northward, bringing increased moisture from a southwestern source to mid- and subtropical latitudes in South America (Fig. 5). Because the cordilleras were now strongly elevated, the destination of much of this precipitation would have been the western side of the central Andes. Geological evidence suggests that the Atacaman area indeed experienced very wet climates in the Pleistocene. Many of the salt lakes (salares) presently occupying 2,800 km^2 bear extensive deposits of Pleistocene lacustrine and diatomaceous earth (Stoertz & Ericksen, 1974; Naranjo & Paskoff, 1980b). Analyses of old shoreline lines (Tricart, 1969) indicate that approximately one-half of the present salares in northern Chile (e.g., salares de San Martín, Ollague, Uyuni, Coipasa) formerly constituted extensive, deep, perennial lake systems (Stoertz & Ericksen, 1974). Wet glacial periods on the western side of the central Andes are also suggested by the fact that the Pleistocene snow line was depressed to a greater

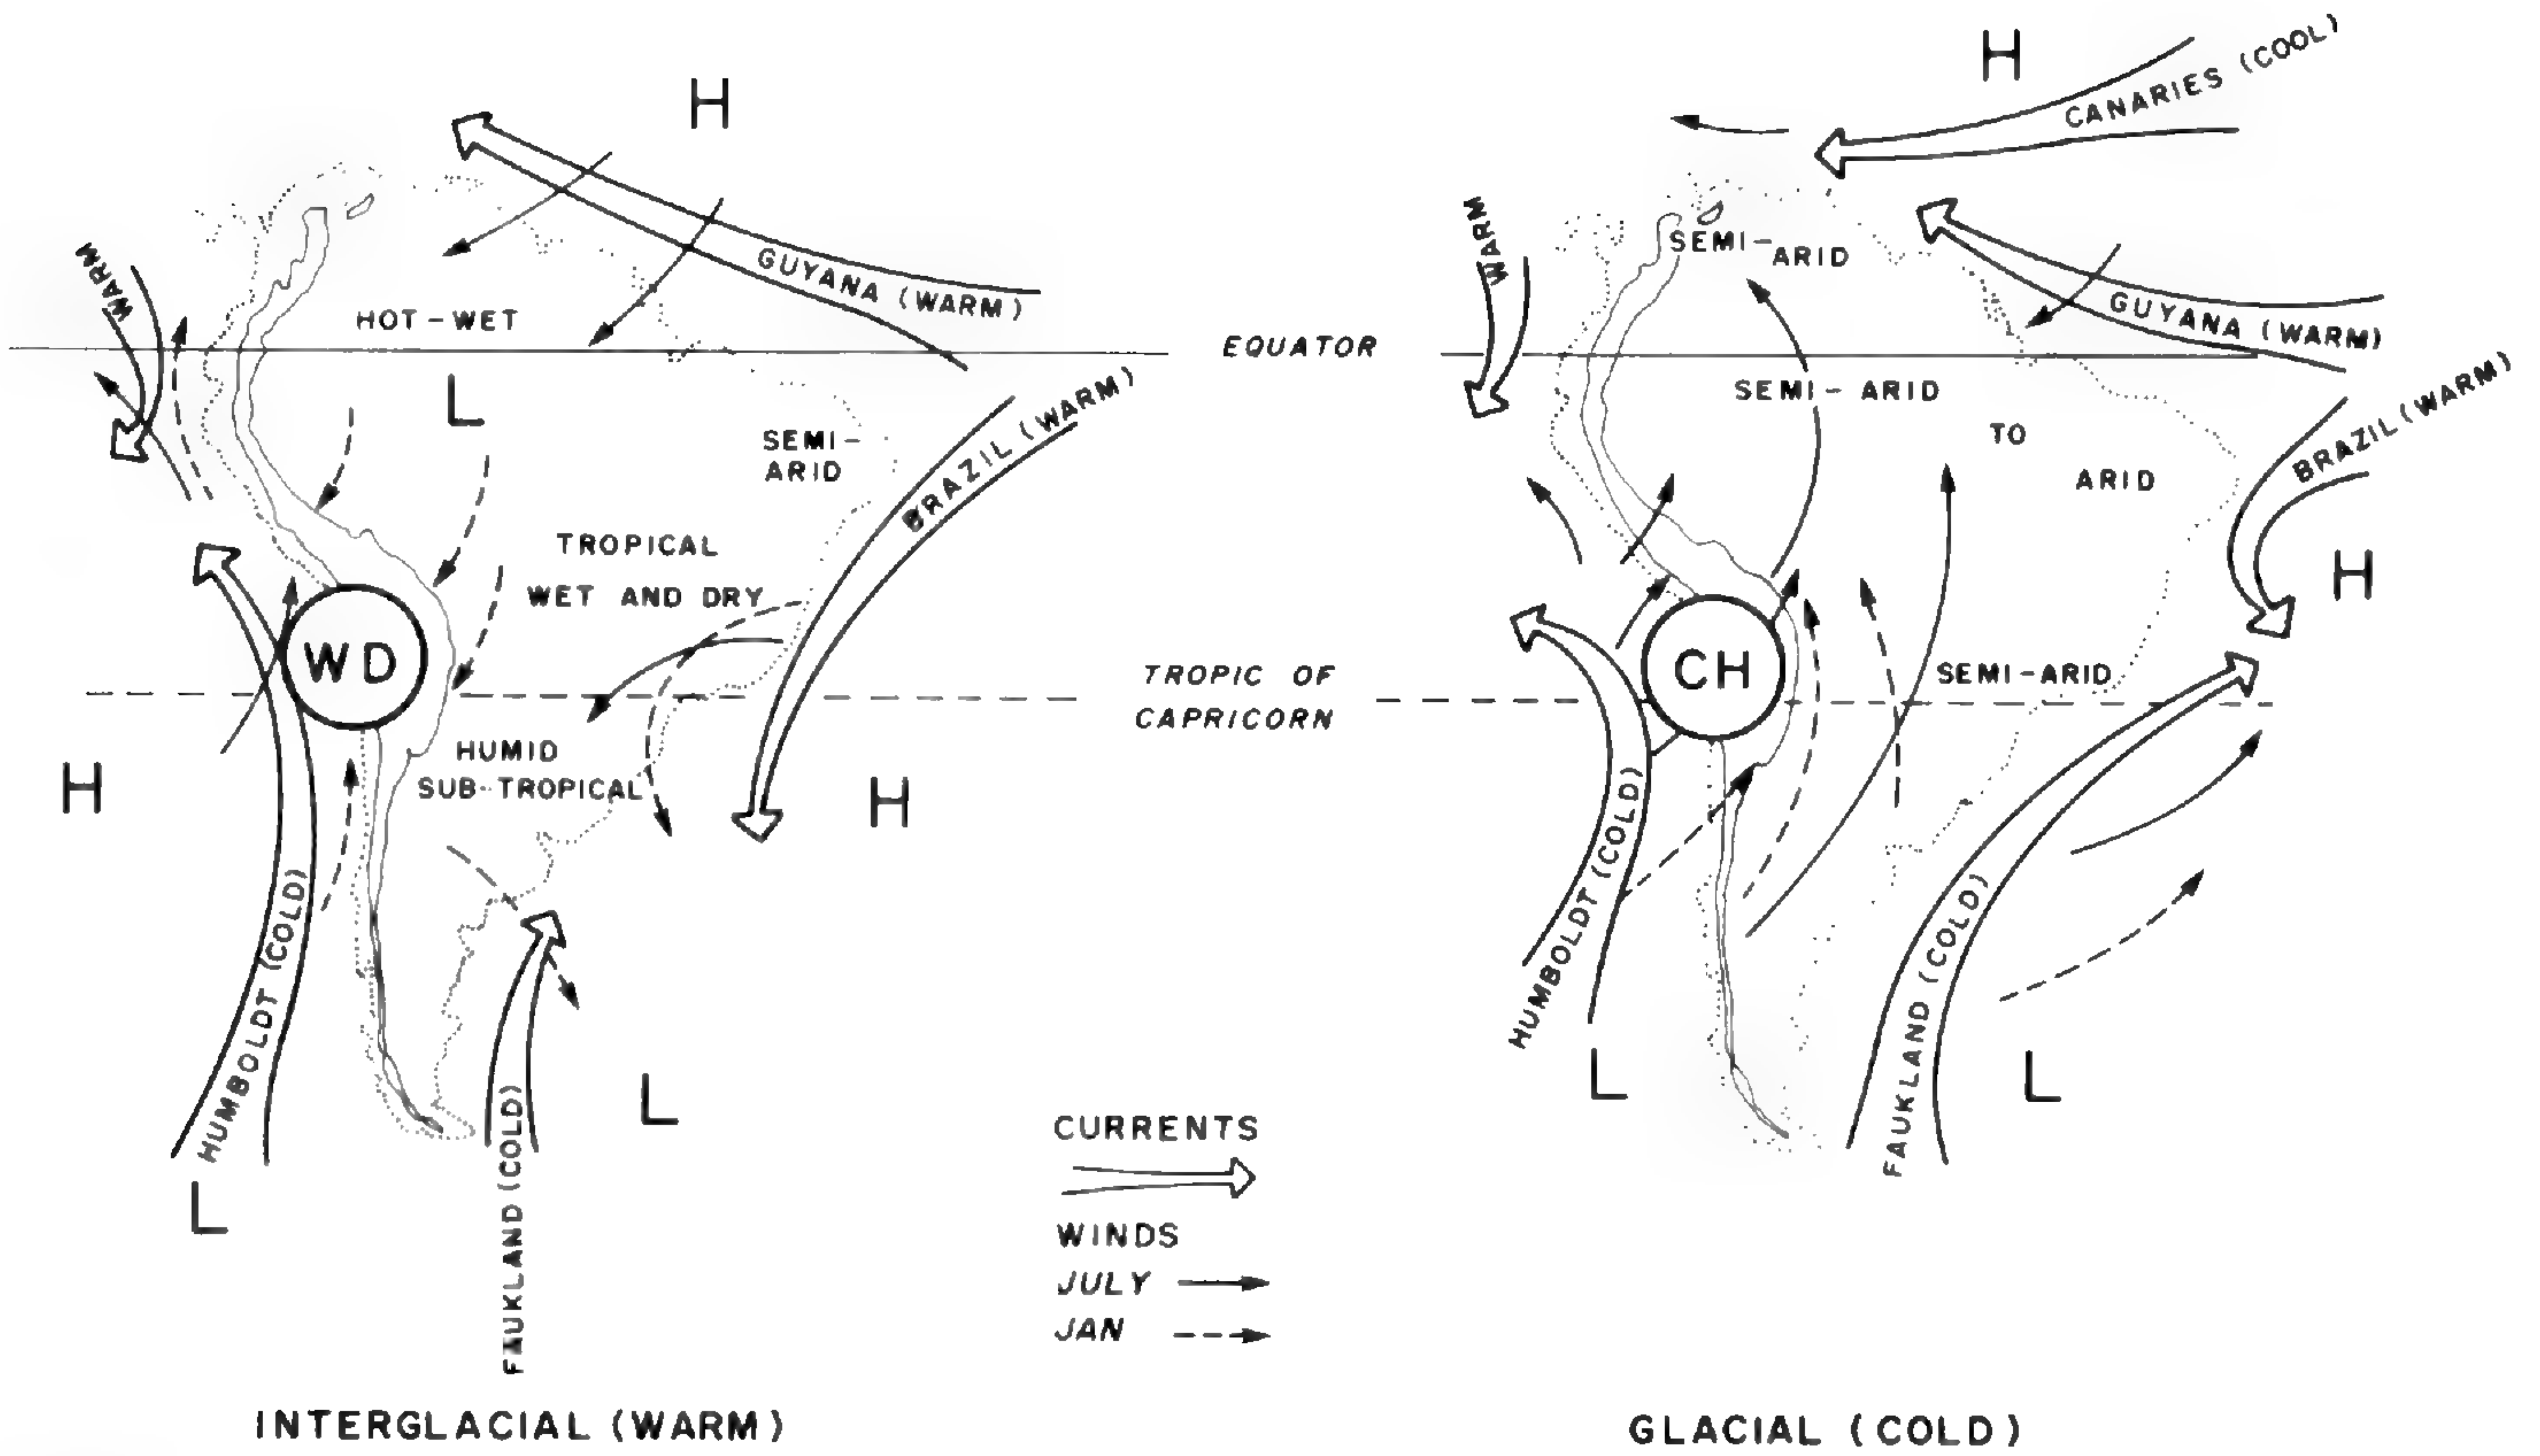

FIGURE 5. *Probable glacial and interglacial climates for the present Atacama desert region (area under large circles) in relation to the rest of South America. WD: warm-dry. CH: cold-humid. Modified from Damuth & Fairbridge (1970).*

extent on the western side of the Andes (Hastenrath, 1967).

The pollen record for the Andes, although still sparse, is also consistent with strong east–west climatic differentiation in the northern Andes during the Pleistocene. Heusser (1983) provided evidence of northward migrations of *Nothofagus* and *Podocarpus* in central Chile during glacial phases. This evidence indicates wet-cold climates for the western side of the Andes. On the eastern side of the subtropical Andes, in contrast, drought-tolerant taxa appeared on the border of the puna in the Junín area in Peru (Hansen et al., 1984) and close to the Bolivian–Peruvian border (Graf, 1981) during cold periods of the Pleistocene and of the Holocene, respectively. Late glacial assemblages from eastern Patagonia at 41°S are also consistent with colder and drier conditions than today (Markgraf, 1983). Eastern high elevations at Mediterranean latitudes, however, and the extreme edge of the puna in Jujuy (unlike the puna further north in Bolivia and Peru, and the Patagonia further south) were wetter than today during cold periods (Markgraf, in press). Such simultaneously wetter climates on the western (cf. Heusser, 1983) *and* eastern sides of the Andes at Mediterranean latitudes (out of the range of the Intertropical Convergence and hence very dry during the interglacials) are not unexpected; the greatly increased westerlies there relative to interglacial periods would have increased precipitation on the Pacific side of the Andes and augmented that making its way across the Andes.

As each interglacial ensued and climates warmed, the southwesterlies would have resumed their present position (Fig. 5) with the Intertropical Convergence coming back into play in the northern Andes as seen today. Because the Andes rose significantly during the several wet-cold and warm-dry cycles of the Pleistocene, east–west climatic differentiation must have increased as the Pleistocene progressed. As a result, aridity should have intensified at each new interglacial.

Throughout the climatically turbulent Pleistocene, nevertheless, the Atacaman region continued to support large mammals, including *Mastodon* and *Macrauchenia* (Mares, 1985). That such animals did not

become extinct until the end of the Pleistocene (Ochsenius, 1983a) agrees entirely with Axelrod's (1979b) suggestion that the climate on the western slopes of the northern Chilean Andes reached its present intensely arid state only very recently in Holocene times.

III: PATTERN OF DIVERSITY IN THE NORTHERN CHILEAN ANDES

SPECIES RICHNESS

Excluding a small number of systematic problems that still require attention, the succession of vegetation belts (desert scrub, Andean, high Andean) up from the desert edge to the upper vegetation limit on the six transects (Fig. 1) yielded 769 species in 290 genera of vascular plants. Five hundred twenty-one species have been collected on the four northernmost summer-rainfall gradients (Table 1). Here species richness peaks at mid elevation, where conditions are intermediately arid and cold (Fig. 6). The resultant curves tend to be steeper towards the north where the east–west precipitation gradient is most severe.

Three hundred twenty-seven species occur on the winter-rainfall transects at 26°S and 28°S; here maximum species richness, in contrast with the northern transects, occurs at lower elevations. These winter-rainfall transects nevertheless tend to show a mid-elevation bulge of their own which reflects the lowermost elevation of permanent winter snow in these areas.

Latitudinally, species richness drops off by 80% from 18°S (maximum rainfall from the

[3] Significance levels for G-test: * $P < 0.05$; ** $P < 0.01$; *** $P < 0.005$; NS = not significant.

Intertropical Convergence) to 24°S (minimum rainfall from the Intertropical Convergence) (Table 1); however, recuperation is rapid around 26°S and 28°S in the influence of the winter-rainfall pattern. Species/genus ratios are low in all cases (1.4–2; Table 1), although *Senecio* (18°S: 26 species), *Adesmia* (28°S: 13 species), *Nototriche* and *Werneria* (18°S: 12 species each), *Stipa* (18°S: 11 species), *Deyeuxia* and *Baccharis* (18°S: 7 species each), *Calandrinia*, *Festuca*, and *Solanum* (18°S; 7 species each), and *Chaetanthera* (28°S: 7 species) are speciose. Under both precipitation regimes, as aridity increases, trends for fewer species per genus and fewer genera per family are seen (Table 1). Thus fewer genera and fewer species have survived in the most arid regions, and/or these appear to have undergone less local speciation. Precise records of precipitation for the highlands at 28°S are unavailable. Hydrological estimates (Ministerio de Obras Publicas, Santiago) suggest levels roughly similar to those midway between 18° and 19°S. Species richness is lower at 28°S than midway between 18° and 19°S, indicating that the decline in species richness from 18° to 24°S is probably slightly inflated by a small latitudinal effect independent of precipitation.

By comparing floras on the east side and west side of the Andes for areas with equivalent precipitation, the degree to which historical and biogeographical factors contribute to present richness patterns may be assessed. Similar amounts of precipitation are received at 18°–19°S on the Chilean side of the Andes and at 21°–24°S on the Argentinian side at 4,000–5,000 m (Table 2). Nevertheless, around a third more species occur on the eastern side, which experienced less severe fluctuations during the Pleistocene. Such lower richness levels on the western side of the Andes undoubtedly also reflect reduced north–south migration possibilities there on account of the desert extending above 3,000 m at 24°S (Arroyo et al., 1982; Villagrán et al., 1983). Thus, in addition to the direct effect of lowered precipitation on species richness, there seems to be a substantial indirect effect of the evolution of aridity.

TABLE 3. *Best fit regressions of number of species (species richness) on mean annual precipitation in the northern Chilean Andes. Each regression is based on species numbers at 18°S, 19°S, 21°S, and 24°S. Mean annual temperature for these latitudes is relatively constant with elevation (see Fig. 3)*. y = *number of species;* x = *mm precipitation. Degrees of freedom for all regressions = 2.*

4,500–5,000 m	$y = 0.12x + 5.03$	6.03*

[1] Significance levels for regressions: * $P < 0.05$; ** $P < 0.01$; *** $P < 0.005$; NS = not significant.

A more precise appreciation of the combined indirect and direct effects of aridity on species richness in the northern Chilean Andes may be obtained by relating species richness to precipitation for areas with similar mean annual temperatures. Most regressions (best fits varied from a linear, through semilog to log–log model) (Table 3) were significant. The degree of curvature where fits were curvilinear, however, was always very shallow. The overall regression of species richness on precipitation, combining all elevations, was also highly significant ($F = 14.087$; d.f. = 22; $P = 0.002$), emphasizing very high penetrance of precipitation on species richness on a biogeographical scale. Aridity, moreover, completely obliterates the effects of temperature regionally. In the multiple regression of species richness on mean annual precipitation and mean annual temperature as independent variables ($y = 0.216x_1 + 0.017x_2$; d.f. = 21; $P = 0.005$, where x_1 is mean annual precipitation and x_2 is mean annual temperature), the partial regression coefficient for precipitation was highly significant ($P = 0.007$), whereas that for temperature (normally a strong determinant of species-richness patterns along elevational gradients) was nonsignificant ($P = 0.991$).

There are also clear reductions in total plant cover with aridity (Fig. 7). In the most benign of the wettest areas in the northern Andes, total cover does not exceed 50%.

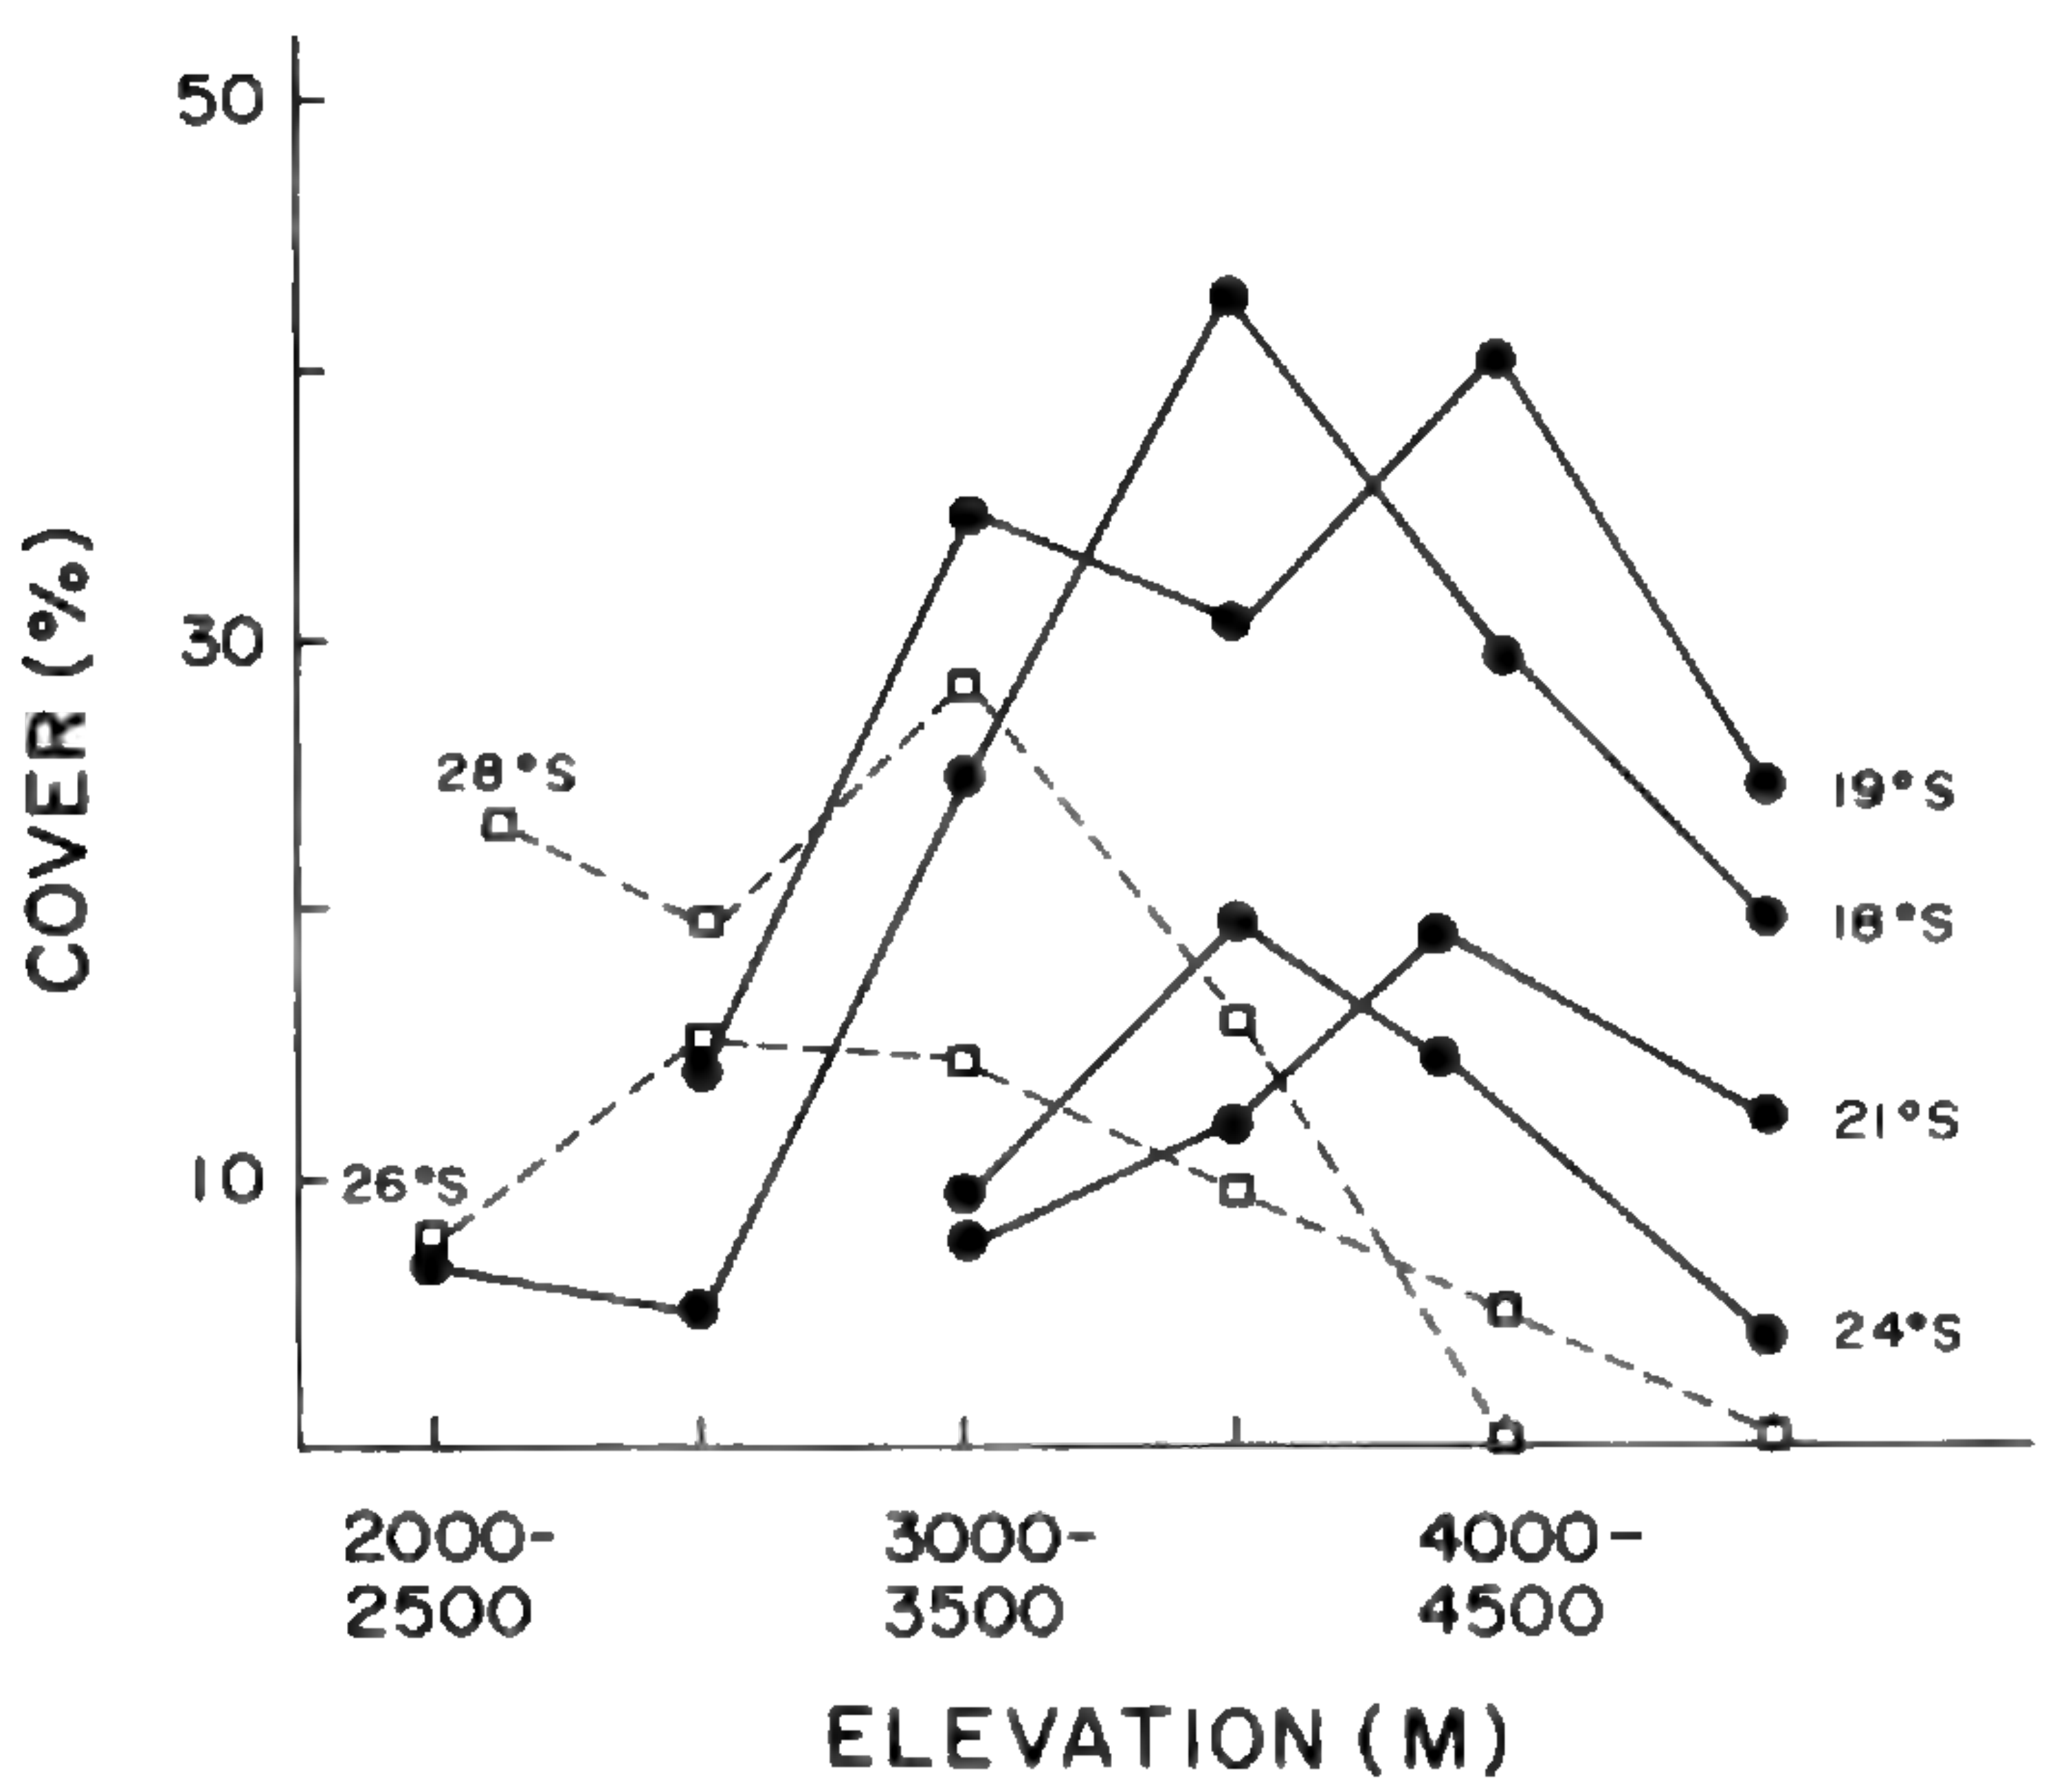

FIGURE 7. *Variation in plant cover (% of ground vegetated) with elevation at different latitudes in the northern Chilean Andes.* ● = *summer-rainfall zone (solid line);* □ = *winter-rainfall zone (broken line).*

However, at 24°S, less than 25% of total surface is covered. The regression of plant cover on plant species richness ($y = 0.22x + 8.21$; $F = 12.31$; d.f. = 17; $P = 0.003$) was highly significant. However, as indicated by the regression coefficient (also compare Figs. 6, 7), reduction in plant cover and species richness reduction are not strictly parallel. This suggests that although relatively few species survive on the most arid sectors of the northern Andes, some (e.g., *Adesmia polyphylla, Stipa frigida, Philippiamra fastigiata*) thrive. Species that are rare at latitudes 18°S and 19°S (e.g., *Portulaca philippii, Solanum phyllanthum, Dunalia spinosa,* many species of *Senecio*), on the other hand, are conspicuously absent on the drier 21°S and 24°S transects. Stochastic effects bearing on the smaller populations of such species perhaps have prevented survival in the most arid habitats. This last factor probably contributes to the lower species/genus ratios seen with severe aridity.

HIGH ANDEAN BOGS VERSUS ZONAL VEGETATION

In the wettest area of the northern Chilean Andes (18°S) above 4,000 m, previous freshwater lakes dating to the pluvial cycles of the Pleistocene support azonal cushion bogs (bofedales). In the driest areas (24°–26°S) such lakes have been reduced to salares with small marginal patches of bog vegetation. These important grazing resources for the Altiplano economy (Castro et al., 1982) contain such typical species as *Gentiana sedifolia, Azorella trifoliolata, Lachemilla* spp., *Werneria* spp., and *Colobanthus quitensis.* They are unique to the central and drier sectors of the southern Andes and are unknown in the far northern Andes, where azonal and zonal vegetation types tend to intergrade imperceptibly (Cleef, 1980).

Despite reduction in area suitable for development of bog vegetation towards 24°S in the northern Andes and the greater dependence of bog elements on fresh water, bog habitats have lost proportionately fewer species than zonal habitats (Table 1). For example, bog species constitute only 14.83% of the total flora at 18°S in comparison with 23.38% at 24°S.

Relatively lighter losses in species richness in the bog floras possibly result from new introductions repeatedly offsetting losses due to reduced habitat size. Figure 8 plots floristic divergence for zonal and azonal (bog) elements for all possible pairs of the six transects against the geographical distance separating each pair of transects. For both vegetation types, floristic divergence increases with distance; however, the bog floras are notably less disparate than the zonal floras for equivalent separation distances. Floristic affinity of the bog floras is higher because of lack of local endemic speciation and because the latitudinal ranges of bog species along the Andes are wider in comparison with zonal elements (Arroyo et al., 1982). The broader latitudinal ranges of bog species, in turn, may be related to aspects of reproductive biology. Many bog elements are strongly autogamous (e.g., *Colobanthus quitensis, Gentiana prostrata, Cardamine glacialis*), greater reliance on wind-pollination is also evident (Arroyo et al., 1983), and some dominant bog species (e.g., *Distichia muscoides, Oxychloe andina*) are clearly adapted for bird dispersal. These three features should facilitate long-distance dispersal between the islandlike high-Andean bogs, thereby maintaining their floras relatively homogeneous. They should also promote reintroductions of species lost due to reduced habitat size.

LIFE FORMS—INTERANDEAN TRENDS

Table 2 compares life-form spectra for the wettest (18°–19°S) and driest (21°–24°S) extremes of the summer-rainfall area (comparison A vs. B) and for the summer-rainfall areas vs. the winter-rainfall area (26°–28°S) (comparisons A vs. C & B vs. C) at three elevational levels. Comparing the wet and arid extremes of the summer-rainfall area, perennial herbs are statistically underrepresented at the arid extreme for 3,000–4,000 m and 4,000–5,000 m. Because of small numbers of species, the data for 2,000–3,000 m could not be tested statistically; however, a similar trend is evident with relatively fewer perennial herbs occurring at 21°–24°S. The difference is most pronounced in the upper Andean belt (4,000–5,000 m) and along the desert edge (2,000–3,000 m).

Woody species, in contrast, tend to be more strongly represented as aridity increases; the trend is clear in the driest (2,000–3,000 m) of the three vegetation belts and where aridity is overlain with cold stress (4,000–5,000 m). Contrary to expectations, annual herbs did not increase proportionately with greater aridity. For the mid-elevation belt (3,000–4,000 m) there is a weak, nonsignificant trend for more annual species at 21°–24°S; however, there were proportionately fewer annuals on the desert edge at 21°–24°S and no significant increase again in the upper Andean belt. The difference was exceedingly dramatic along the desert edge at 21°–24°S, where the flora is comprised of seven species of shrubs, two perennial herbs, and one annual (*Philippiamra fastigiata*). In the most stressful climate (aridity confounded by cold stress; 4,000–5,000 m; 21°–24°S) the relative loss of perennial herbs and annuals has been to the extent that the shrub life form becomes dominant for species number. Clearly therefore, in the summer-rainfall area in the northern Andes, the perennial herb life form has been most affected by aridity, followed by the annual herb life form; woody elements have been least affected.

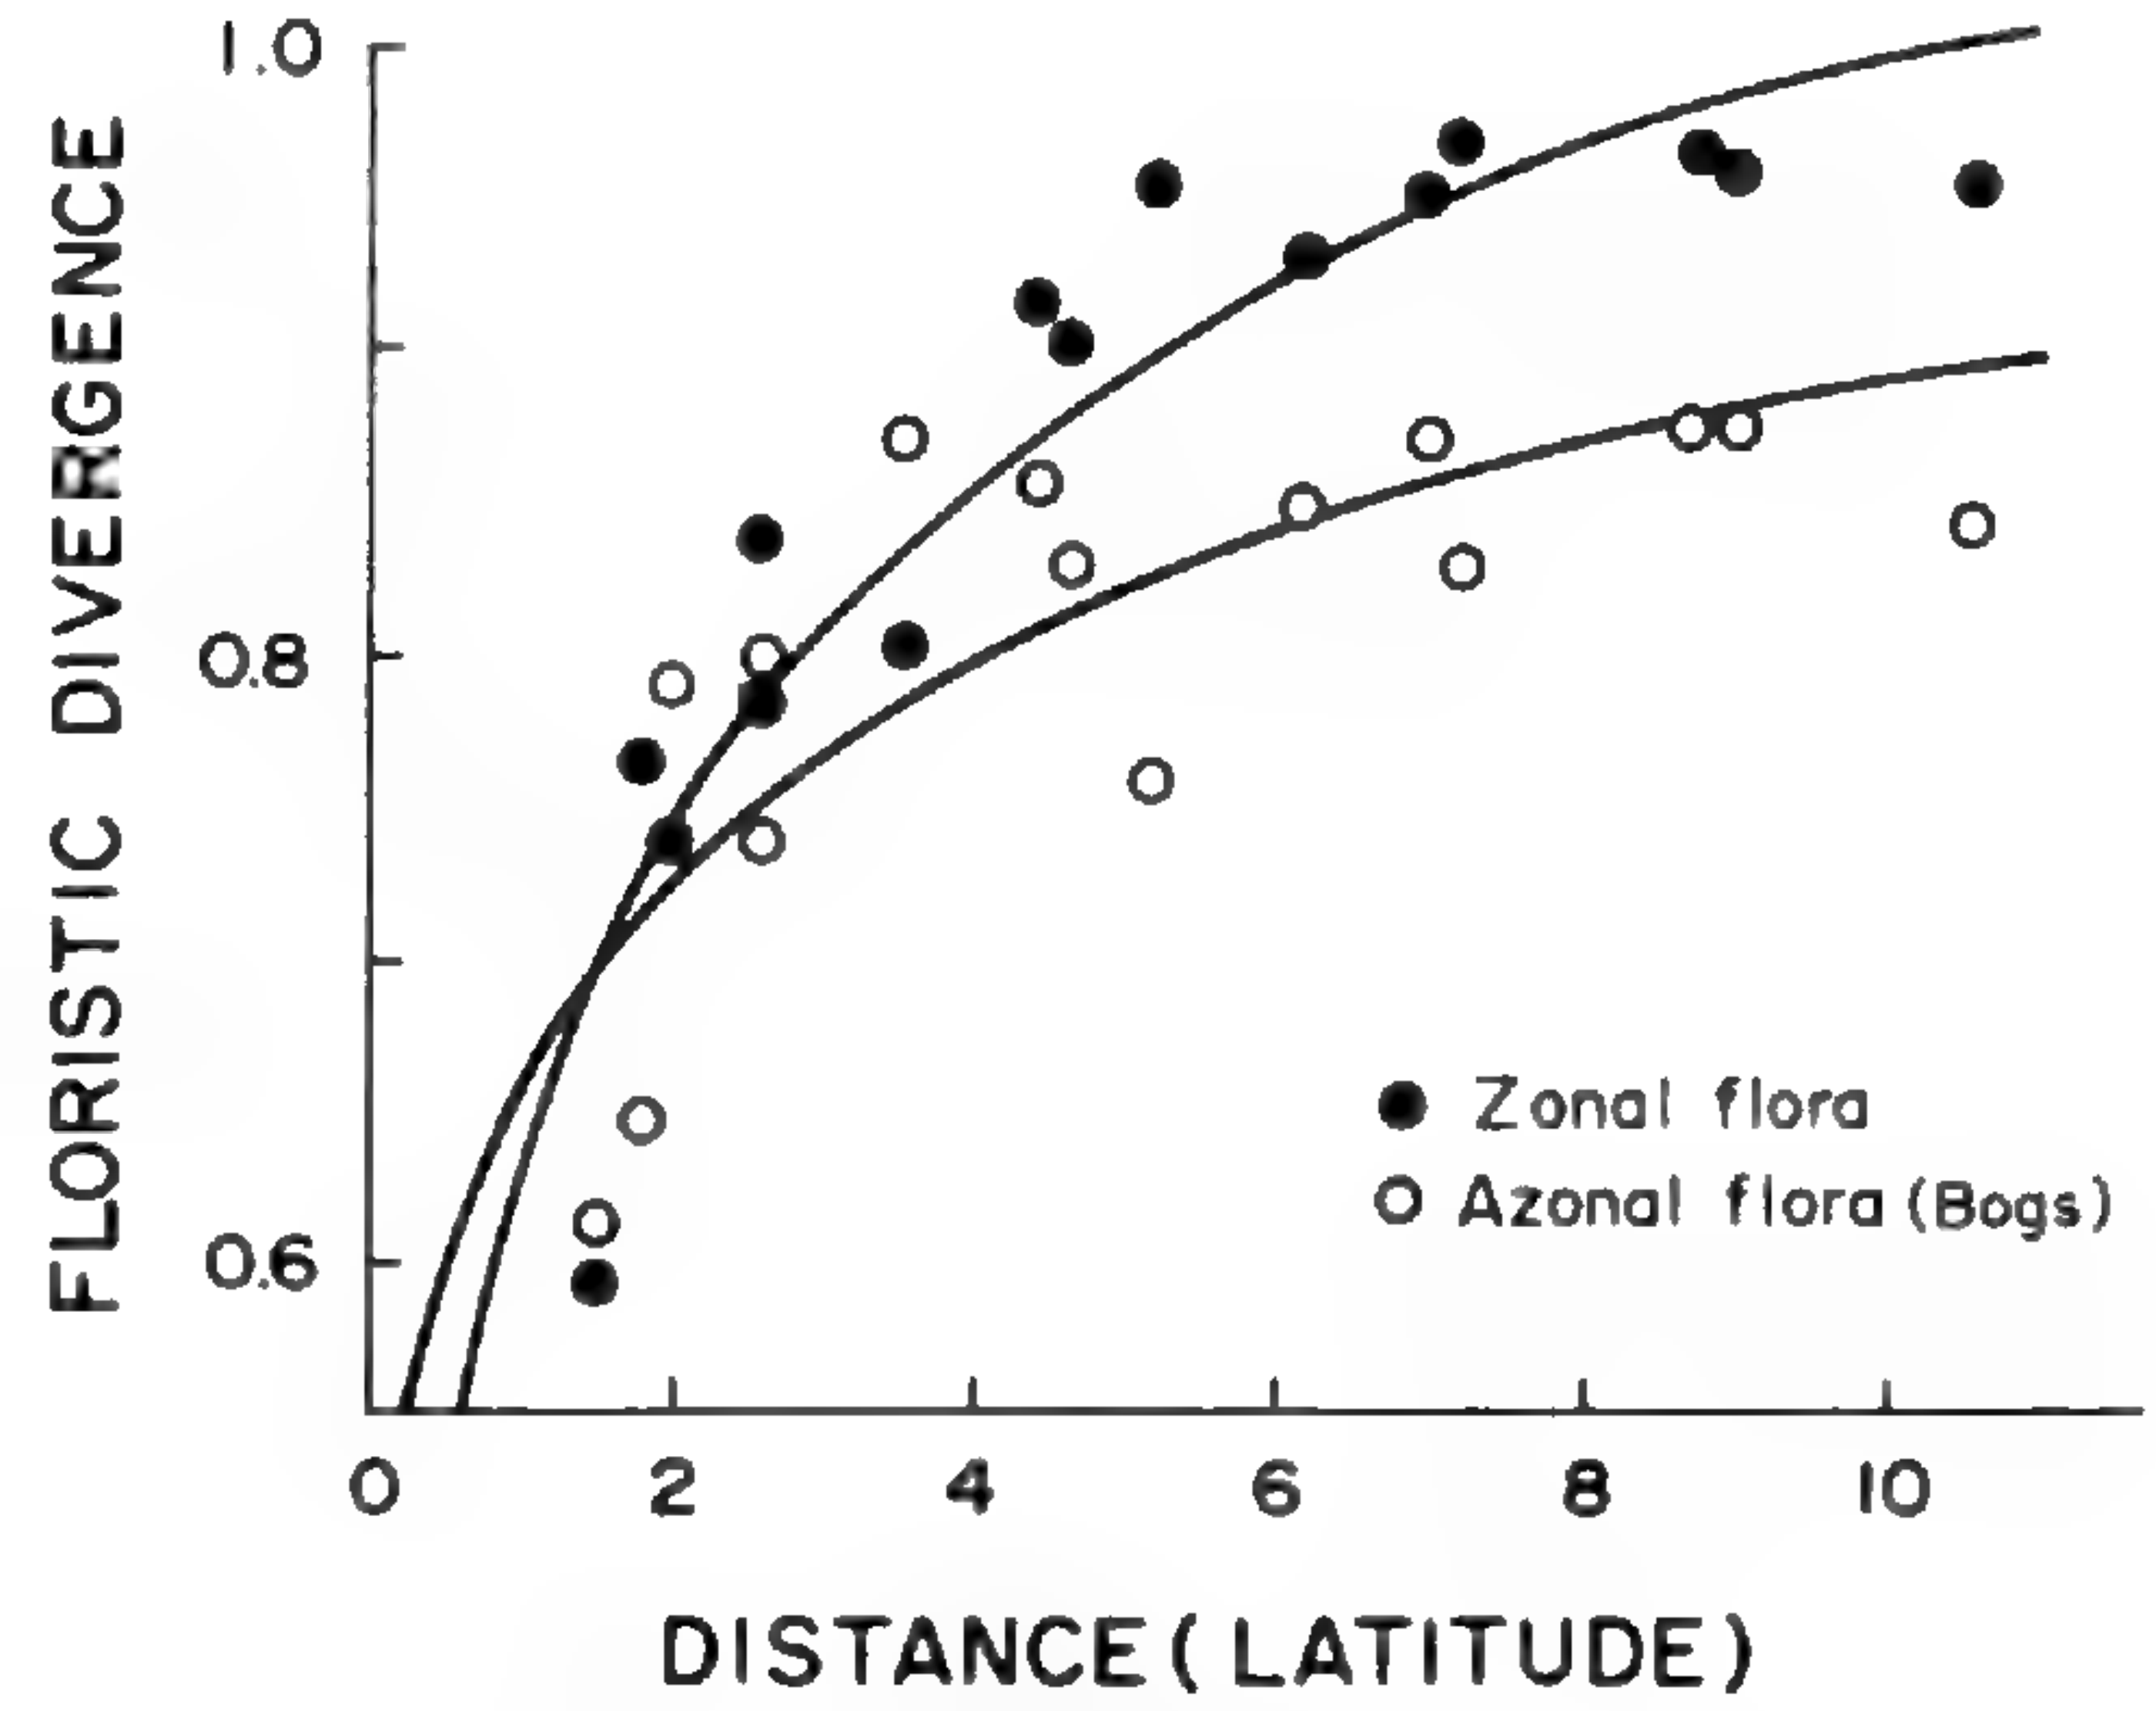

FIGURE 8. *Floristic divergence for all pairs of zonal and azonal (bog) floras between 18° and 28°S in the northern Chilean Andes plotted against the latitudinal distance in degrees separating the pairs of floras compared. Floristic divergence for pairs of floras* (A, B) = $(N_A + N_B) / (N_A + N_B + N_C)$, *where* N_A = *number of species confined to area* A; N_B = *number of species confined to area* B; N_C = *number of species common to areas* A *and* B.

For 26°–28°S (winter rainfall), intermediate proportions of annuals relative to 18°–19° and 21°–24°S were predicted. For the lowermost desert belt (2,000–3,000 m) and mid-elevation belt (3,000–4,000 m), there were no significant differences for any life form when 26°–28°S was compared with 18°–19°S (highest rainfall). For these latitudinal comparisons, however, annuals are more common and perennial herbs less common in the high-elevation (4,000–5,000 m) belt in the summer-rainfall area. When 26°–28°S is compared with 21°–24°S (lowest rainfall), contrary to expectation, annuals did not prove to be in excess in the 21°–24°S area. For the mid-elevation belt (3,000–4,000 m), as is indicated by the nonsignificant difference, the winter-rainfall area has proportionately just as many annual species as the much drier 21°–24°S summer-rainfall region. For the low- and high-elevation belts there are more annuals at 26°–28°S than in the very low rainfall area at 21°–24°S. The higher proportion of annuals at 26°–28°S, where there is winter snow (and hence much local moisture) in place of rainfall received gradually over the summer months, as at 21°–24°S, again suggests that the annual life form is only adaptive in arid climates up to a certain limit.

To test the robustness of these trends (decrease in perennial life form, increase in annual life form up to a certain level of aridity, dominance of shrub habit in areas of extreme aridity) over a wider sector of the Andes, we compared our data with higher rainfall Andean communities on the eastern side of the Andes (Ruthsatz, 1977) situated immediately opposite the most arid area of the Chilean Andes considered by us (Table 2). Ruthsatz (1977) gave the life forms of over 90% of the species she considered. For 22°–24°S (east) and 18°–19°S (west), most similar in precipitation amounts, there were no significant differences in life forms for any of the three altitudinal levels (comparison D vs. A; Table 2). From east (22°–24°S) to west (21°–24°S) over a very severe rainfall gradient (comparison D vs. B) the life form trends were in very good agreement with those seen previously in north–south comparisons along the western side of the Andes: i.e., perennial herbs are more strongly represented on the wetter eastern side of the Andes and shrubs more strongly represented on the drier western side in the most extreme environments, with annuals increasing only in the more benign mid-elevation belt on the western side. Thus the life-form tendencies revealed on the western side of the northern Andes are also valid on a regional scale.

LIFE FORMS—INTERCONTINENTAL COMPARISONS

Collins et al. (1983) provided life-form data for an altitudinal sequence of floras in the Great Basin in Utah, North America, sharing several floristic elements with the Andes (e.g., *Atriplex, Ephedra*) but where rainfall is generally higher. Comparisons for the Andes and Great Basin vegetation belts with similar mean annual temperature (Table 4) reveal the same life-form trends seen across aridity gradients within the Andes, now on an intercontinental scale. For the Andes, with lower precipitation, the woody life form is twice as common and the perennial herb life form only one-half to one-third as common as in the Great Basin. Annual herbs are in excess in the mid-elevation belt on the western side of the Andes compared with Mt. Nebo. However, despite the much lower rainfall along the desert margin and in the high-elevation belt compared with Arches and Bald Mountain, respectively, there is no proportional increase for annuals in these harshest climates in the Andes. This once again emphasizes that annuals increase with aridity but that there is a critical point at which the woody habit becomes relatively more appropriate for arid climates.

Most surprisingly, as the Arches vs. 2,000–3,000 m (22°–24°S, eastern Andes) shows, woody species continue to be in excess and perennials in deficit in the Andes when annual precipitation is relatively similar. This indicates that the northern Andes exhibit a generalized excess in woody species over the Great Basin beyond local trends in the latter for increased frequency of woody species with habitat harshness.

COMMUNITY DIVERSITY PATTERNS

In harsh arid habitats, as was argued earlier, relatively higher community diversity levels, as seen at the early stages of primary succession, are to be expected as a permanent community feature in spite of overall low species richness.

In the Andes, regressions of exp H' and $1/\lambda$ on species richness and cover show (Figs. 9, 10) that harsh environmental conditions, on a biogeographical scale, lead to an overall trend for loss of diversity. Thus the primary succession analogy proposed is not entirely supported. Over each gradient (Fig. 11) diversity peaks at mid elevations, where conditions are neither the coldest nor the most arid, as was seen for species richness and cover; however, decreases in diversity are not commensurate with reductions in species richness. This phenomenon is more easily appre-

TABLE 4. *Statistical comparisons (G-tests) for life forms in the flora of the northern Andes (west and east sides) and the Great Basin, Utah. Comparisons are made for elevational levels with the closest mean annual temperatures. Data for the Andean areas are those in Table 2. Data for the Great Basin taken from Collins et al. (1983).*

ciated in Figure 12, in which diversity and species richness are compared for equivalent elevations from the wetter 18°S to the drier 24°S. At 3,000–3,500 m and 3,500–4,000 m, where conditions are more favorable on each transect, there are significant reductions in diversity as aridity increases; however, they are shallower than for species richness. As higher elevations doubly stressed by aridity and cold temperature are reached, there is no significant difference in diversity from 18° to 24°S in spite of considerable reduction in species richness. Thus, in the sense that community diversity is maintained relatively high in the face of large losses in species richness, the diversity trends seen in the most arid areas of the northern Andes are indeed analogous to a primary succession situation.

The more gradual loss of diversity relative to species richness may be related to the relative contribution of each life form and the presence of far more rare species in the relatively benign areas. In the most productive environments (18°S), one life form typically stands out as strongly dominant. Moreover, within that life form a few fairly abundant species tend to be accompanied by large numbers of relatively rare species. At mid elevations at 18°S, for example, in spite of the fact that *perennial herbs* are well represented in numbers of species (see section on life forms), the woody life form is more abundant than the herbaceous life forms (which can persist in low densities because of the relatively benign conditions). Within the shrub guild, close coexistence, moreover, seems to have precipitated fairly strong dominance hierarchies as seen in great abundance of such

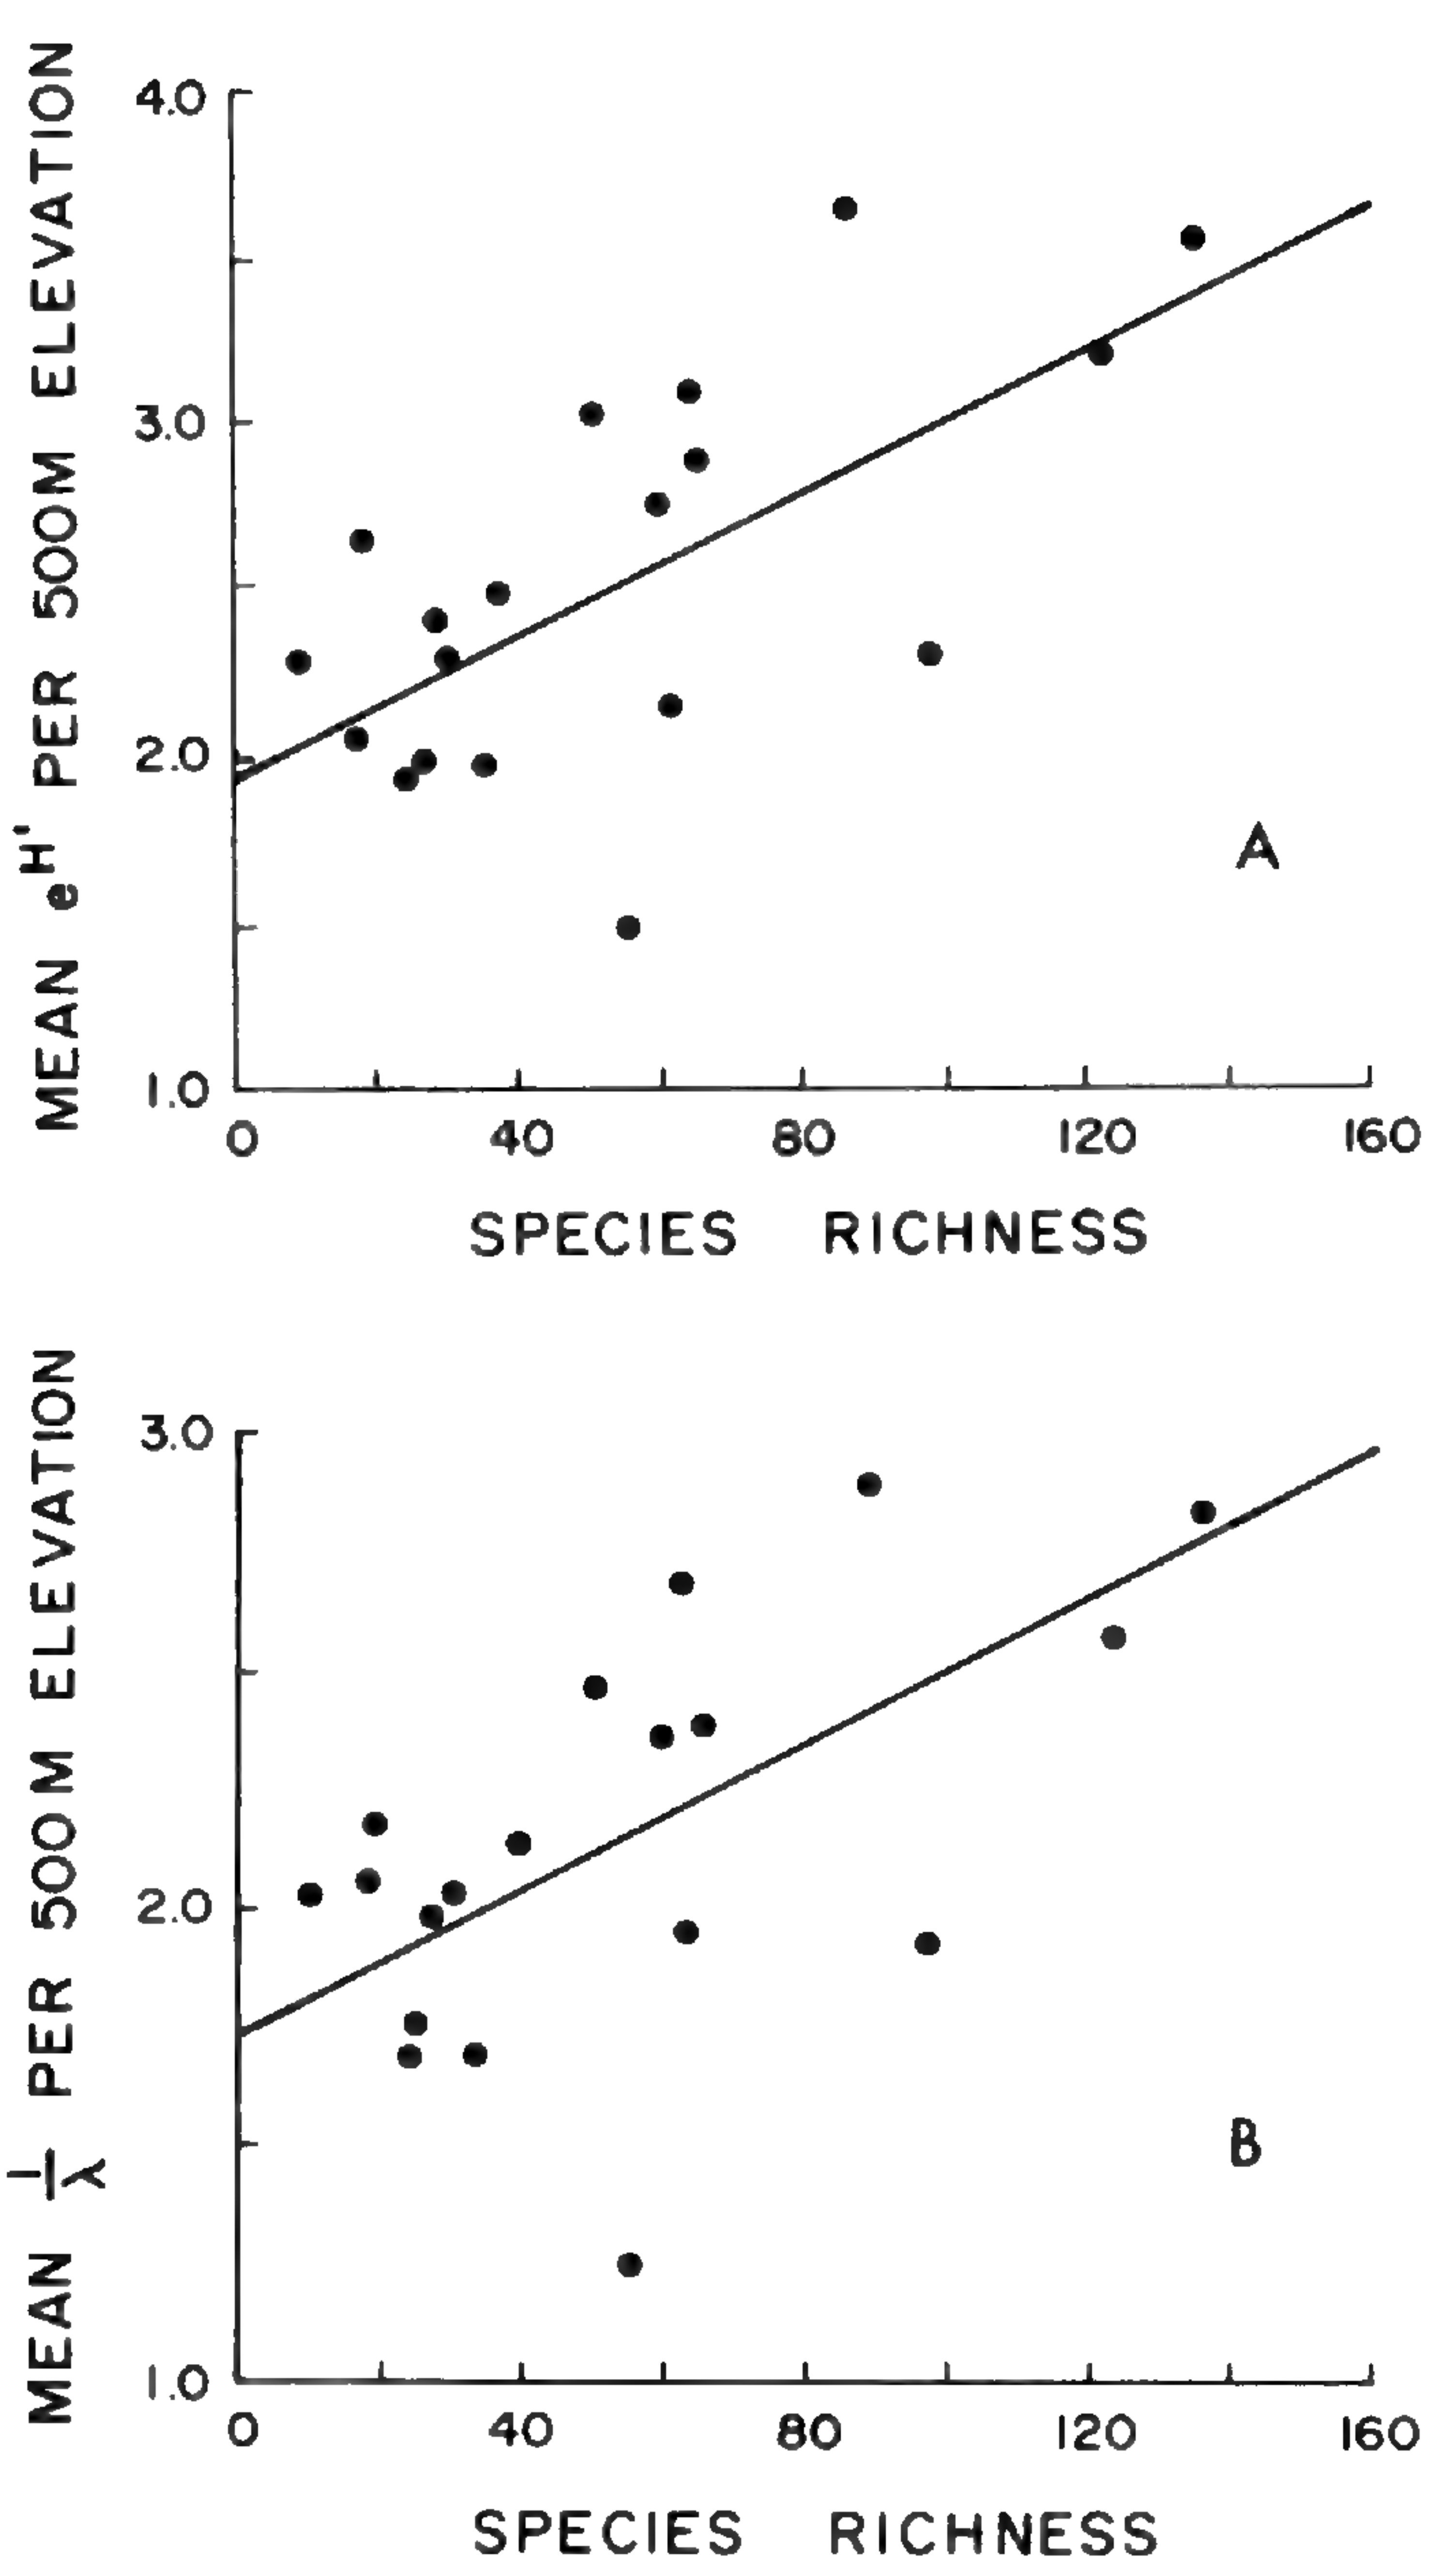

FIGURE 9. *Linear regressions of diversity on number of species (species richness).—A. exp H' vs. species richness* ($y = 0.010x + 1.96$; $F = 11.511$; *d.f.* $= 17$; $P = 0.003$, *where* $y = \exp H'$ *and* x = *species richness).—B.* $1/\lambda$ *vs. species richness* ($y = 0.019 + 0.007x + 1.78$; $F = 2.811$; *d.f.* $= 17$; $P = 0.01$, *where* $y = 1/\lambda$ *and* x = *species richness). species as *Fabiana densa, Baccharis boliviensis, Ephedra breana,* and *Diphlostephium meyenii.* From 4,500 to 5,000 m at 18°S, bunch grasses become strongly dominant over shrubs, and again there are few strongly dominant species (*Festuca orthophylla, Poa* sp.). In the less productive environments at 21°–24°S, in contrast, for the high elevations in particular, abundance levels for shrubs and herbaceous species are probably more equitable, in spite of the fact that there are relatively fewer species of perennial herbs. These last considerations are based on direct observation; much analytical work is still required to characterize dominance relations in the Andean flora.

DISCUSSION

Patterns of plant diversity have been described for an area that underwent dramatic environmental upheavals in the Pleistocene and which acquired its present extreme arid character over a relatively short period.

The effects of aridity on species richness in the northern Andes clearly have been severe. The 769 species for all transects are believed to include about 75% of all species

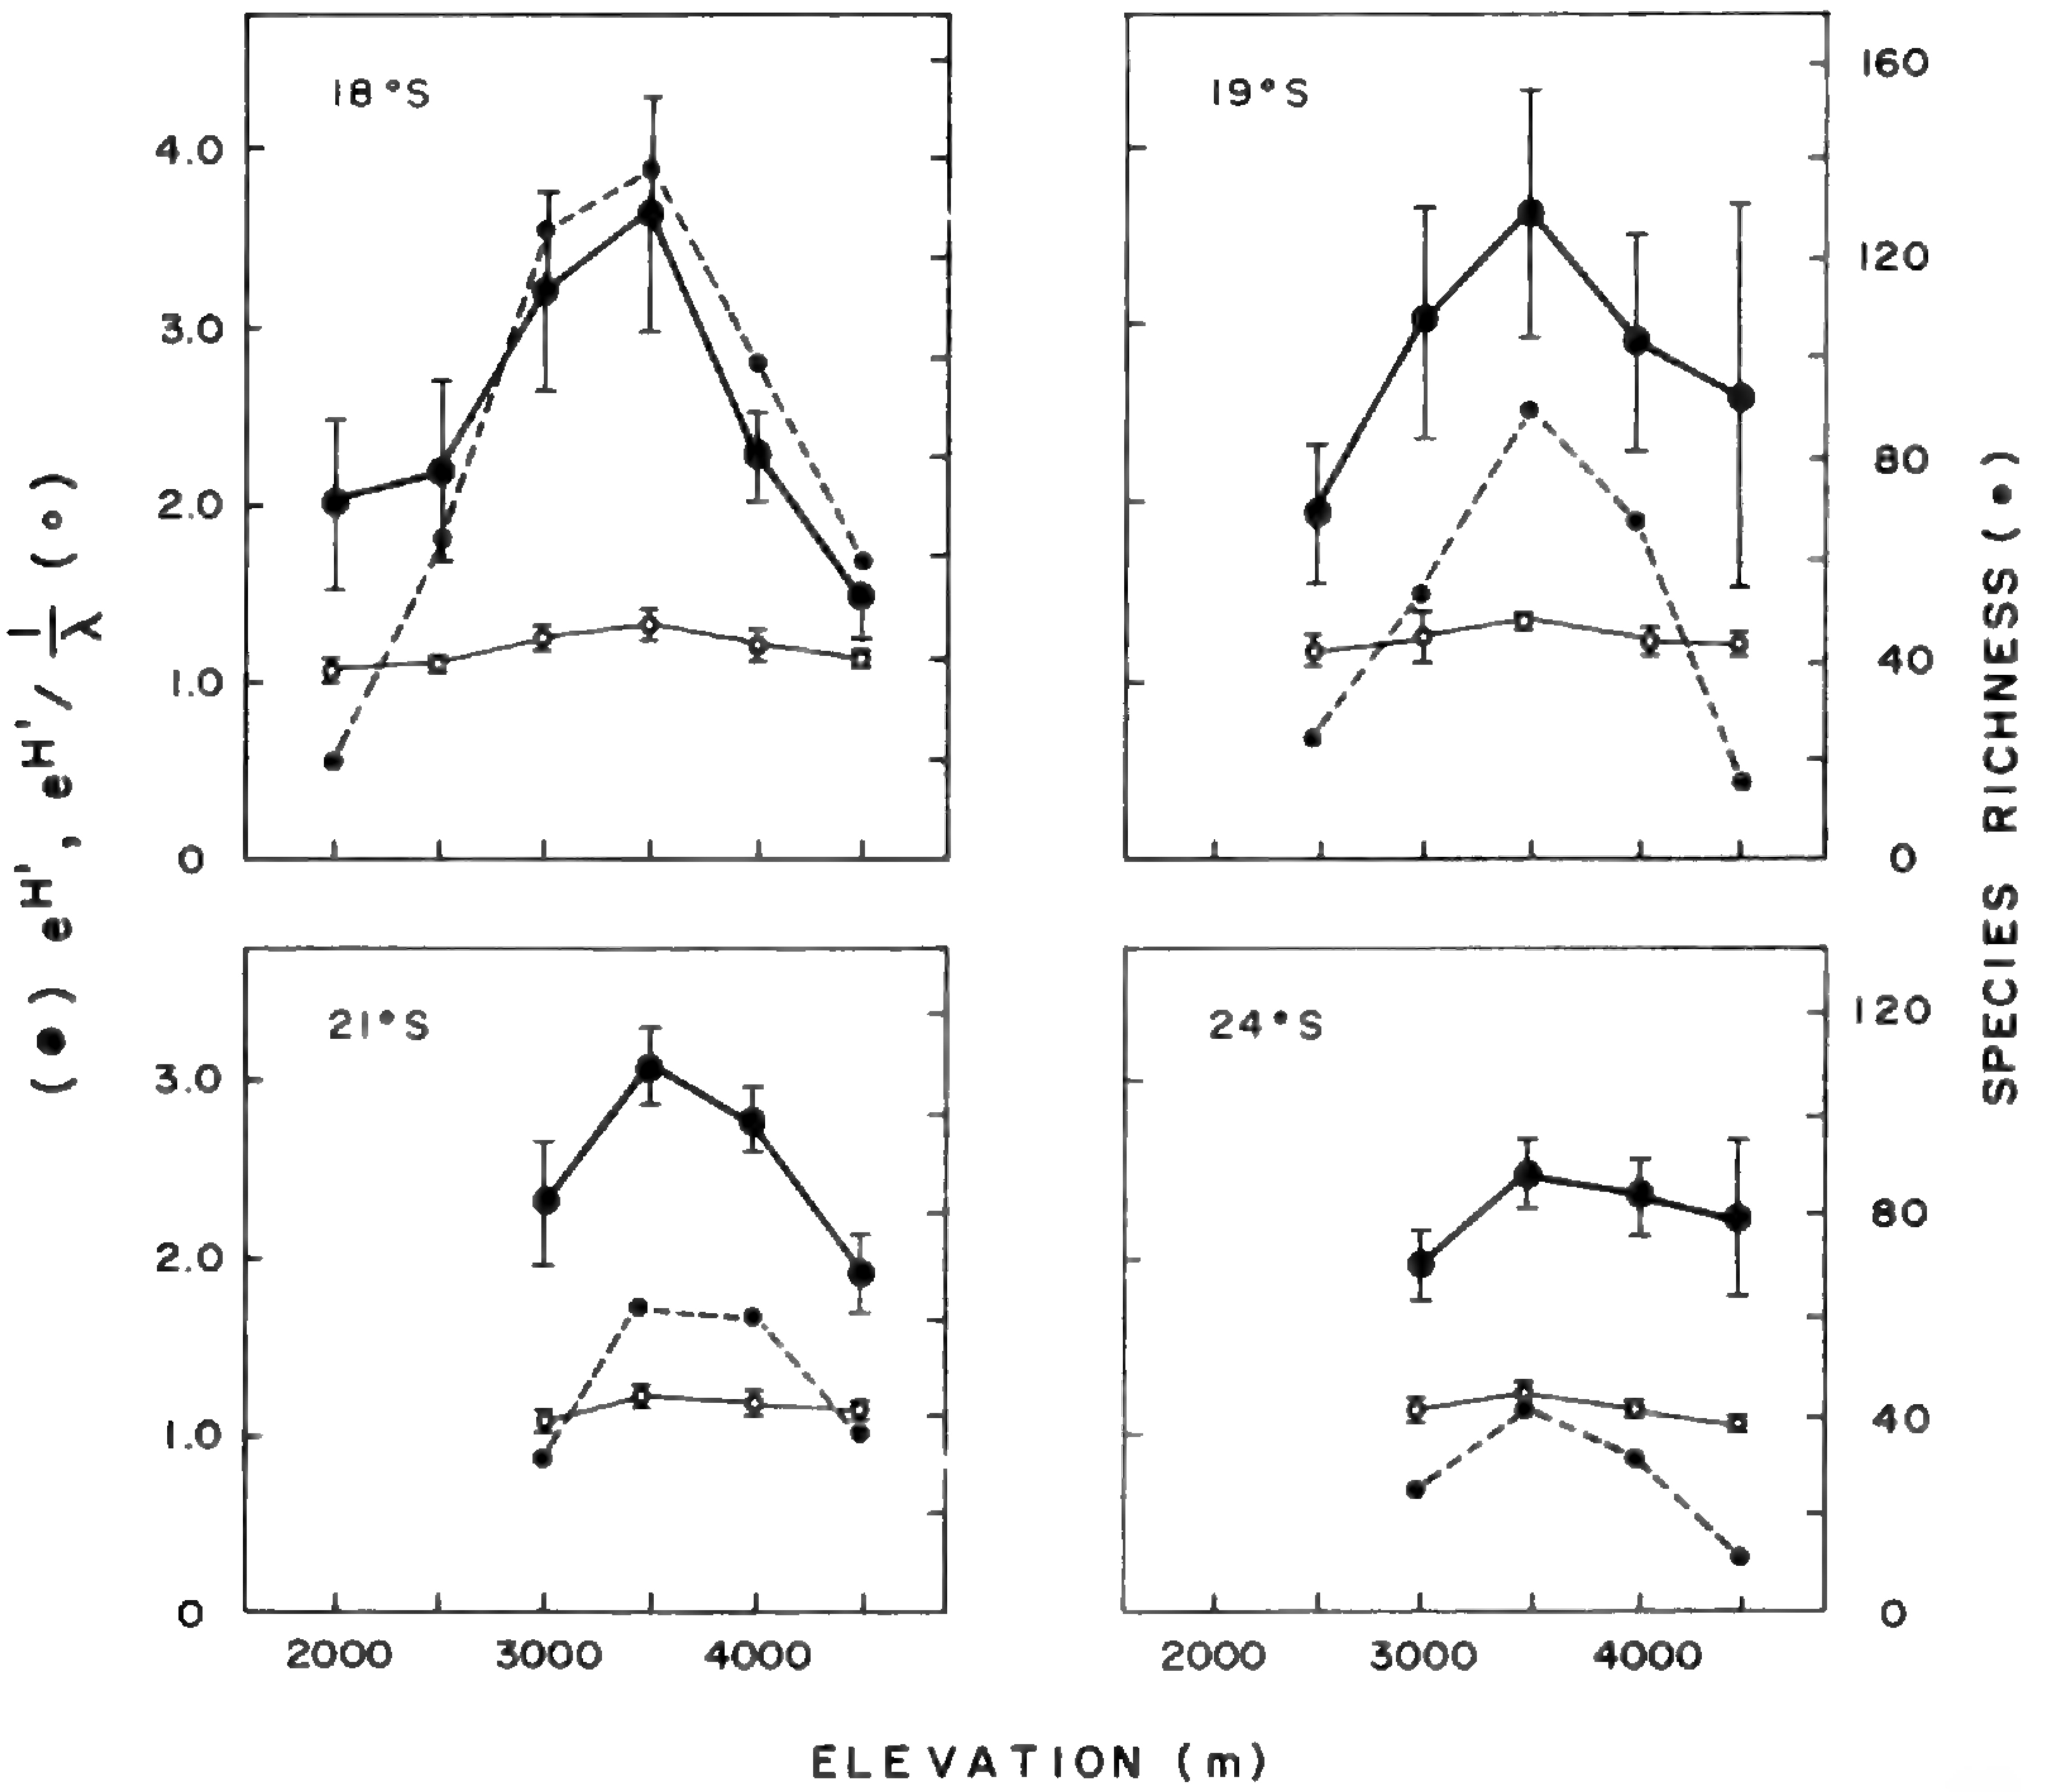

FIGURE 11. *Mean exp* H', *exp* H'/ (1/λ), *and species richness vs. elevation at different latitudes in the northern Chilean Andes. Lack of variation in exp* H'/ (1/λ) *indicates that diversity trends resulting from application of 1/λ as a diversity index are similar to those obtained using exp* H'. *Vertical bars are 95% confidence intervals for the means.*

from 1,500 m to the upper vegetation limit from 17°S to 28°S. This leads to an estimate of under 1,000 species per 10° latitude or the equivalent of less than one-fifth of the total Chilean flora (Marticorena & Quezada, 1985). This is only one-sixth more species present over 1° of latitude from 3,500 to 5,000 m in Parque Nacional Huascaran (8°S) in the northern Peruvian Andes (estimated by David Smith, pers. comm., to have 660 species). It is only just over three times the number above tree line (309 species) at 33°S (Arroyo et al., 1983) for an area similar to that sampled in the individual northern transects and in the paramos of Colombia (4°N; Rangel et al., 1983), where 321 species occur above tree line on an area covering much less than 1° of latitude. The Andes of Jujuy in northwestern Argentina (22°–24°S) immediately across the main divide, where it was seen that rainfall is much higher, support 622 species (Ruthsatz, 1977), in contrast to only 199 at 21° and 24°S on the Chilean side.

Areas least affected by aridity and cold temperature proved to be richest in species. Such areas also exhibit high community diversity. Highly stressed areas with low species richness, nevertheless, are relatively robust for community diversity. Any seasonal variation in annual growth, as along the desert edge, could greatly affect community diversity estimates. Revisits to the Andean highlands in from Arica (18°S) in a very wet year subsequent to vegetation sampling leave little doubt that annual cover at lower elevations there fluctuates widely. However, the trends above 4,000 m, where there are very few species of annuals, are unambiguous.

Maintenance of relatively high local levels of community diversity in the most arid areas will probably turn out to be the result of lowered dominance levels in the drier areas. Thus aridity, the very feature driving lowered species richness in the Andes from the outset, probably eventually reduces the rate at which local diversity declines. In this sense the not

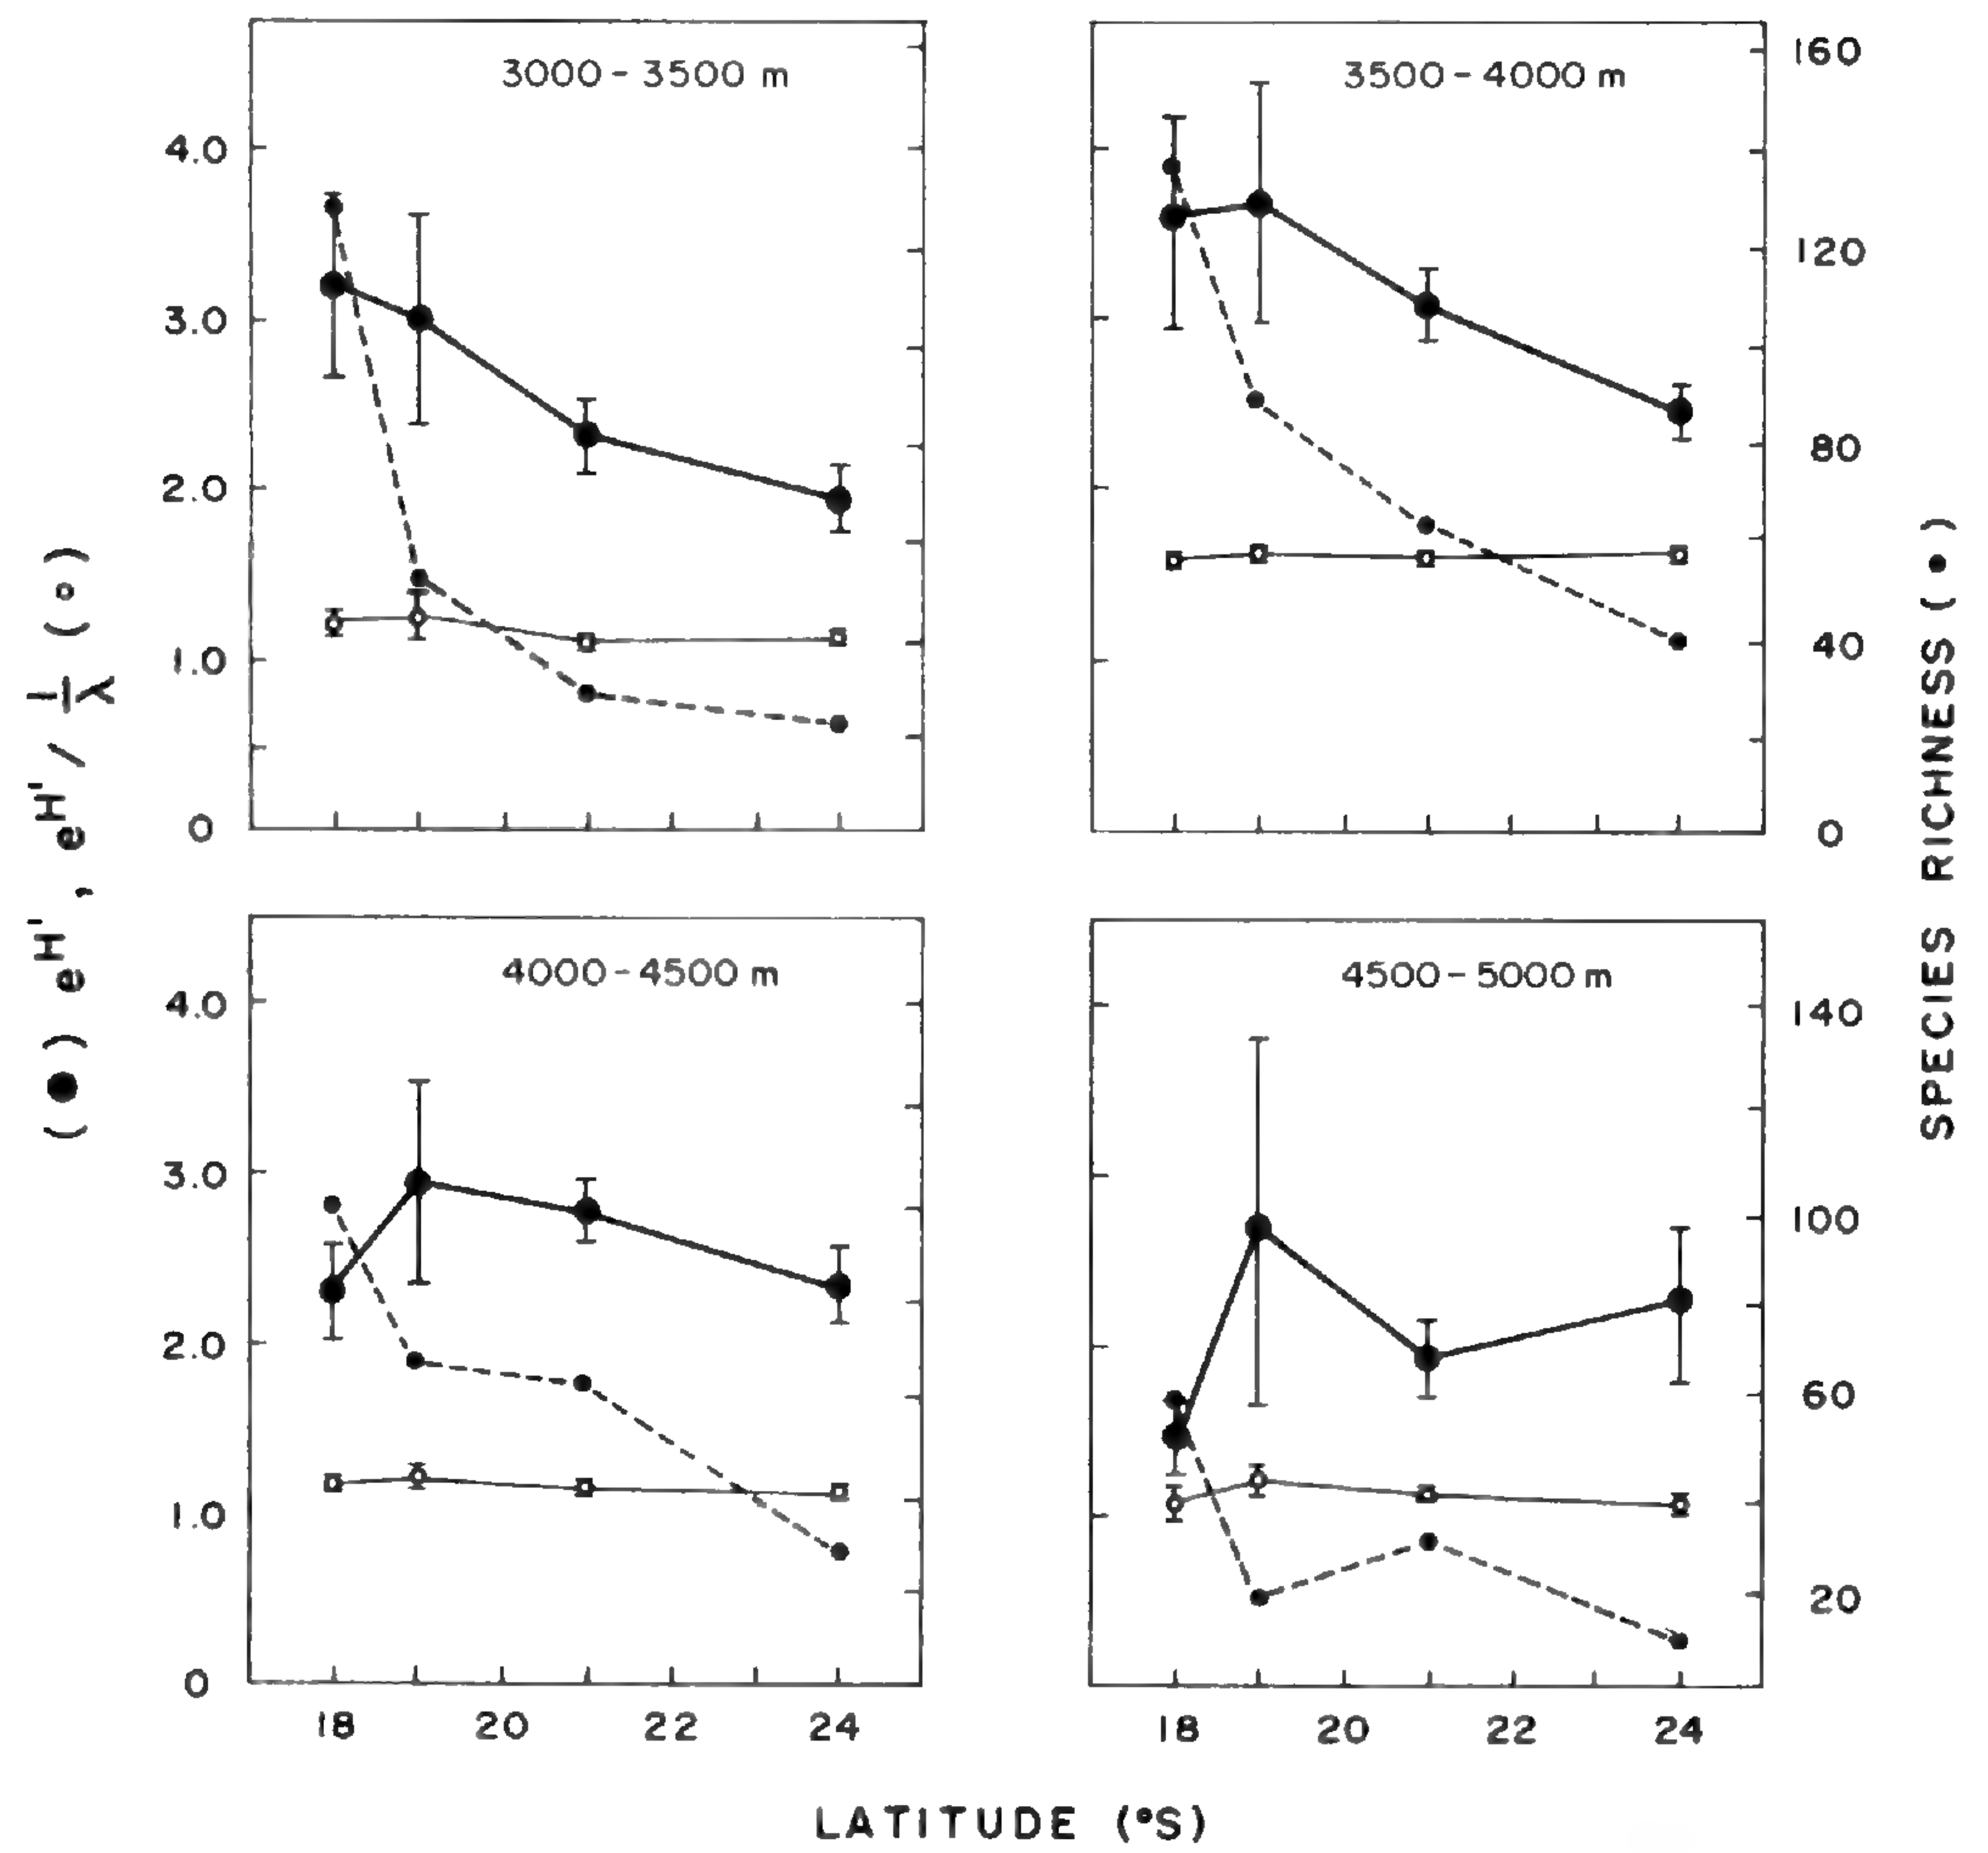

FIGURE 12. *Mean exp* H', *exp* H'/ $(1/\lambda)$, *and species richness vs. latitude from 18°S (maximum precipitation) to 24°S (minimum precipitation). strongly exponential drops in species richness with aridity should be recalled. They seem to indicate that loss of species richness has been counteracted to some extent. The life-form changes we have demonstrated must also be important here; however, it is far too early to sort out the relative contributions of different factors against species richness loss.

Stress-tolerant (e.g., annual life form) and stress-resistant (e.g., shrub life form) strategies are often considered as hierachically equivalent alternatives for harsh environments. Our results suggest that woody species gain prominence over annuals on the harshest of the Andean habitats. Significantly, moreover, some of the most successful "perennial herbs" from the driest areas of the Andes (e.g., *Sisymbrium philippianum, S. lanatum, Tarasa operculata*) have semiwoody stems. Thus the trend towards woodiness goes beyond simple reshuffling of the taxa present and is probably being actively selected for in some individual taxa.

Woody species are probably best adapted to extreme aridity through a combination of ecophysiological and demographic features. Root/shoot ratios for warm-desert species are usually around one, and there is relatively little vertical root growth (Barbour, 1981). In contrast, root/shoot ratios in excess of four have been reported for shrubs in cold North American and Eurasian deserts (Caldwell, 1985). This suggests that for cold arid areas, where growth is relatively slow, large long-lived species might be favored by being able to produce larger root systems that would reach deep into the soil over a prolonged growth season. Soils in the northern Chilean Andes are largely volcanic, hence surface water is probably always limited. Further, in the driest areas of the summer-precipitation zone, rain comes in light morning showers and is never abundant at any one time. We suspect that this factor favors shrubs in the driest areas and, as was mentioned earlier, explains why annuals are generally less frequent in the summer-rainfall zone.

Because they tend to be long-lived, woody species require less frequent establishment events (Schaffer & Gadgil, 1975). This should be highly advantageous in habitats where seed germination and seedling establishment are precarious, as is the case with strongly arid climates. Seed production is not only a function of pollination success and of resources allocated to reproduction, but also of the probability of an adult reaching reproductive maturity and its physiological state at that stage. Woody-stemmed shrubs are more likely to reach reproductive maturity than soft-stemmed herbs because of their greater resistance to drought. In spite of the fundamental nature of the question, as far as we know, to date there have been no attempts to appraise the relative importance of the physiological and demographic features of woody species in harsh environments.

The greater representation of woody species in the northern Andes might reflect the Andes being located some ten degrees of latitude closer to the equator than is the Great Basin. The floristic matrix out of which the Andean flora evolved, as a result, probably possessed a higher percentage of woody elements initially. Fossil floras for the Great Basin (Axelrod, 1979a, 1983) and as far south as the Chihuahuan desert (Wells & Woodcock, 1985) show North American desert floras emerging out of open woodland with many herbaceous elements. The radical climatic changes at each glacial/interglacial interface in the Andes should have further impoverished the herbaceous flora. These historical factors, apart from effects of present climatic characteristics, should have produced a gradual accumulation of woody elements in the northern Andes.

Heavy grazing in the Andes (alpaca, llama) has possibly influenced the broad intercontinental differences in life form. Interestingly, areas of the northern Andes in which woody species are most strongly represented today are least affected by grazing (e.g., 21°–24°S), while those with well-developed herbaceous floras can be heavily grazed (north of 19°S). Very plausibly, climatic and biotic factors have acted in concert to produce the intercontinental differences in life form.

Emphasis on the long-lived, woody life form, as seen in harsh environments in the northern Chilean Andes, is also a feature of tropical and other forests developed in abiotically benign conditions. For the tropics in particular, longevity is usually seen as a correlate of large body size resulting from selection for competition for light (Grime, 1979). Much woodiness in the tropics could equally bear relation to the demographic advantages of being long-lived, as was suggested for abiotically harsh habitats. In the tropics, seed predation (Ramirez & Arroyo, 1987) and fungal infections (Ramirez & Arroyo, 1984) can significantly lower successful seed germination. Additionally, juvenile mortality can be high due to strong intra- and interspecific competition for light and nutrients (Connell et al., 1984) and leaf predation (Clark & Clark, 1985). These features have direct parallels in the extremely arid Andean ecosystem, the difference being that in the tropics they are mediated through the biotic environment rather than the abiotic environment. Grime (1979) recognized that "stress" in productive environments arises mainly through competitive depletion of resources (the biotic environment). Yet he perhaps placed undue emphasis on longevity in tropical ecosystems as being a result of selection for direct competitive ability without paying much attention to the demographic advantages. As in arid environments, the role of longevity for tropical forests needs more critical assessment.

Diversity patterns in the kinds of "abiotically" harsh environments we studied and in "biotically harsh" tropical forest communities might also show convergent trends. Many tropical forests lack clear dominants—dominance is probably less well developed in the most arid environments we studied. Lack of dominance in tropical forests has been seen as an effect of reduced opportunities for coevolution resulting from low interspecific connectance sensu Pimm (1984) (Connell, 1980), or in Buckley's (1983) words, "in diverse, well-mixed communities individuals cannot predict their neighbours." Hubbell & Foster (1986) proposed a similar but not identical hypothesis: individual species are seen to reflect the temporal and spatial average of biotic selective conditions created by ever changing and diffuse competitors, leading to guilds of functionally equivalent generalists. Sustained biotic interactions are also seen to be limited in very arid environments. Wetter deserts like the Mohave and Sonoran provide some evidence of root competition between widely spaced individuals (Yeaton & Cody, 1976; Phillips & MacMahon, 1981). Gulmon et al. (1979), by contrast, concluded that limited opportunities for establishment lead to little competition between individuals of the long-lived *Copiapoa* (Cactaceae) in the Chilean coastal desert at 25°S, where ca. 25 mm of rain falls annually. This is tantamount to low connectance, the abiotic environment assuming the role of the biotic environment in a tropical forest.

We suspect that a suite of common features will be revealed for these two kinds of "harsh" environments for the organisms that inhabit them. Convergence could be expected in breeding system (e.g., levels of sexual dimorphism), seed size, and sexual selection. Some of these possibilities are presently being studied by us in cold alpine habitats in the Chilean Patagonia (e.g., Arroyo & Squeo, 1987).

PATTERNS OF SPECIES DIVERSITY IN ANURAN AMPHIBIANS IN THE AMERICAN TROPICS[1]

William E. Duellman[2]

ABSTRACT

The Neotropical Region has a greater species richness of anuran amphibians than any other region in the world. Approximately 44% of the total number of species of anurans of the world (3,533) occur in the American tropics, and many new species are discovered every year. Patterns of species diversity were determined by analyzing data from 48 sites—32 in the lowland tropics (11 Middle American, 21 South American), nine in montane cloud forests (four Middle American, five South American), and seven in supra-treeline regions of the Andes. Taxa also were noted as to their reproductive mode (site of egg deposition, site of larval development, and associated parental care, if any). As expected, for the entire anuran fauna, there are gradients from lower diversity in dry regions to higher diversity in wet regions, and from lower diversity at high elevations to higher diversity at low elevations. The greatest species diversity is in the equatorial region of the upper Amazon Basin. However, different patterns emerge when taxonomic groups (families, subfamilies, and large genera) are examined independently. Two factors contribute significantly to the different patterns observed: (1) the historical biogeography of different taxa, especially in relation to the separation of Central America from South America during most of the Cenozoic, and (2) reproductive modes of the taxa. Seventeen reproductive modes can be identified among anurans at the 48 sites. The generalized reproductive mode (eggs and tadpoles in lentic water) is characteristic of all lowland sites but is rare or nonexistent in montane regions where there are few ponds. Some reproductive modes involve terrestrial eggs and/or larvae that are dependent for their survival on high moisture content of the air; anurans having these modes are most diverse in regions having high humidity. Other modes necessitate the presence of high-gradient streams or aerial aquatic habitats (bromeliads) for the development of eggs and tadpoles. Sites having the highest species diversity also have the greatest diversity of reproductive modes; these sites are in lowland rainforest near the base of the Andes and in the Atlantic forest of southeastern Brazil at the edge of the Brazilian Highlands. Thus, although total species diversity in anurans is dependent on rainfall, patterns of diversity of component groups results partly from their geographic histories and partly from the consequences of the nature of their reproductive modes.

Despite the fact that most amphibians have rather narrow physiological tolerances and ecological distributions, in their successful attainment of independence from water and the colonization of the land they have undergone a remarkable adaptive radiation. The living amphibians exhibit a greater diversity of life histories than any other vertebrates. The nearly 4,000 living species of amphibians are grouped into three distinct orders—Caudata (salamanders), Gymnophiona (caecilians), and Anura (frogs and toads). The last is by far the largest, with 3,533 currently recognized species.

Anyone who has spent a rainy night in a neotropical rainforest is aware of the nocturnal cacophony raised by calling males of many species of frogs. The American tropics are especially rich in species of anurans; at one site in the upper Amazon Basin in Ecuador

---

[1] *The compilation of data from so many sites has been possible through the generosity of several colleagues who provided unpublished data on their own fieldwork; for their kind help I am grateful to Patricia A. Burrowes, Ronald I. Crombie, W. Ronald Heyer, John D. Lynch, Roy W. McDiarmid, Norman J. Scott, and Barbara L. Zimmerman. My own studies on neotropical anurans have been supported by the Museum of Natural History at The University of Kansas and by grants from the National Science Foundation and the National Geographic Society. Many persons have assisted me in the fieldwork, but I am especially indebted to John E. Simmons and Linda Trueb.*

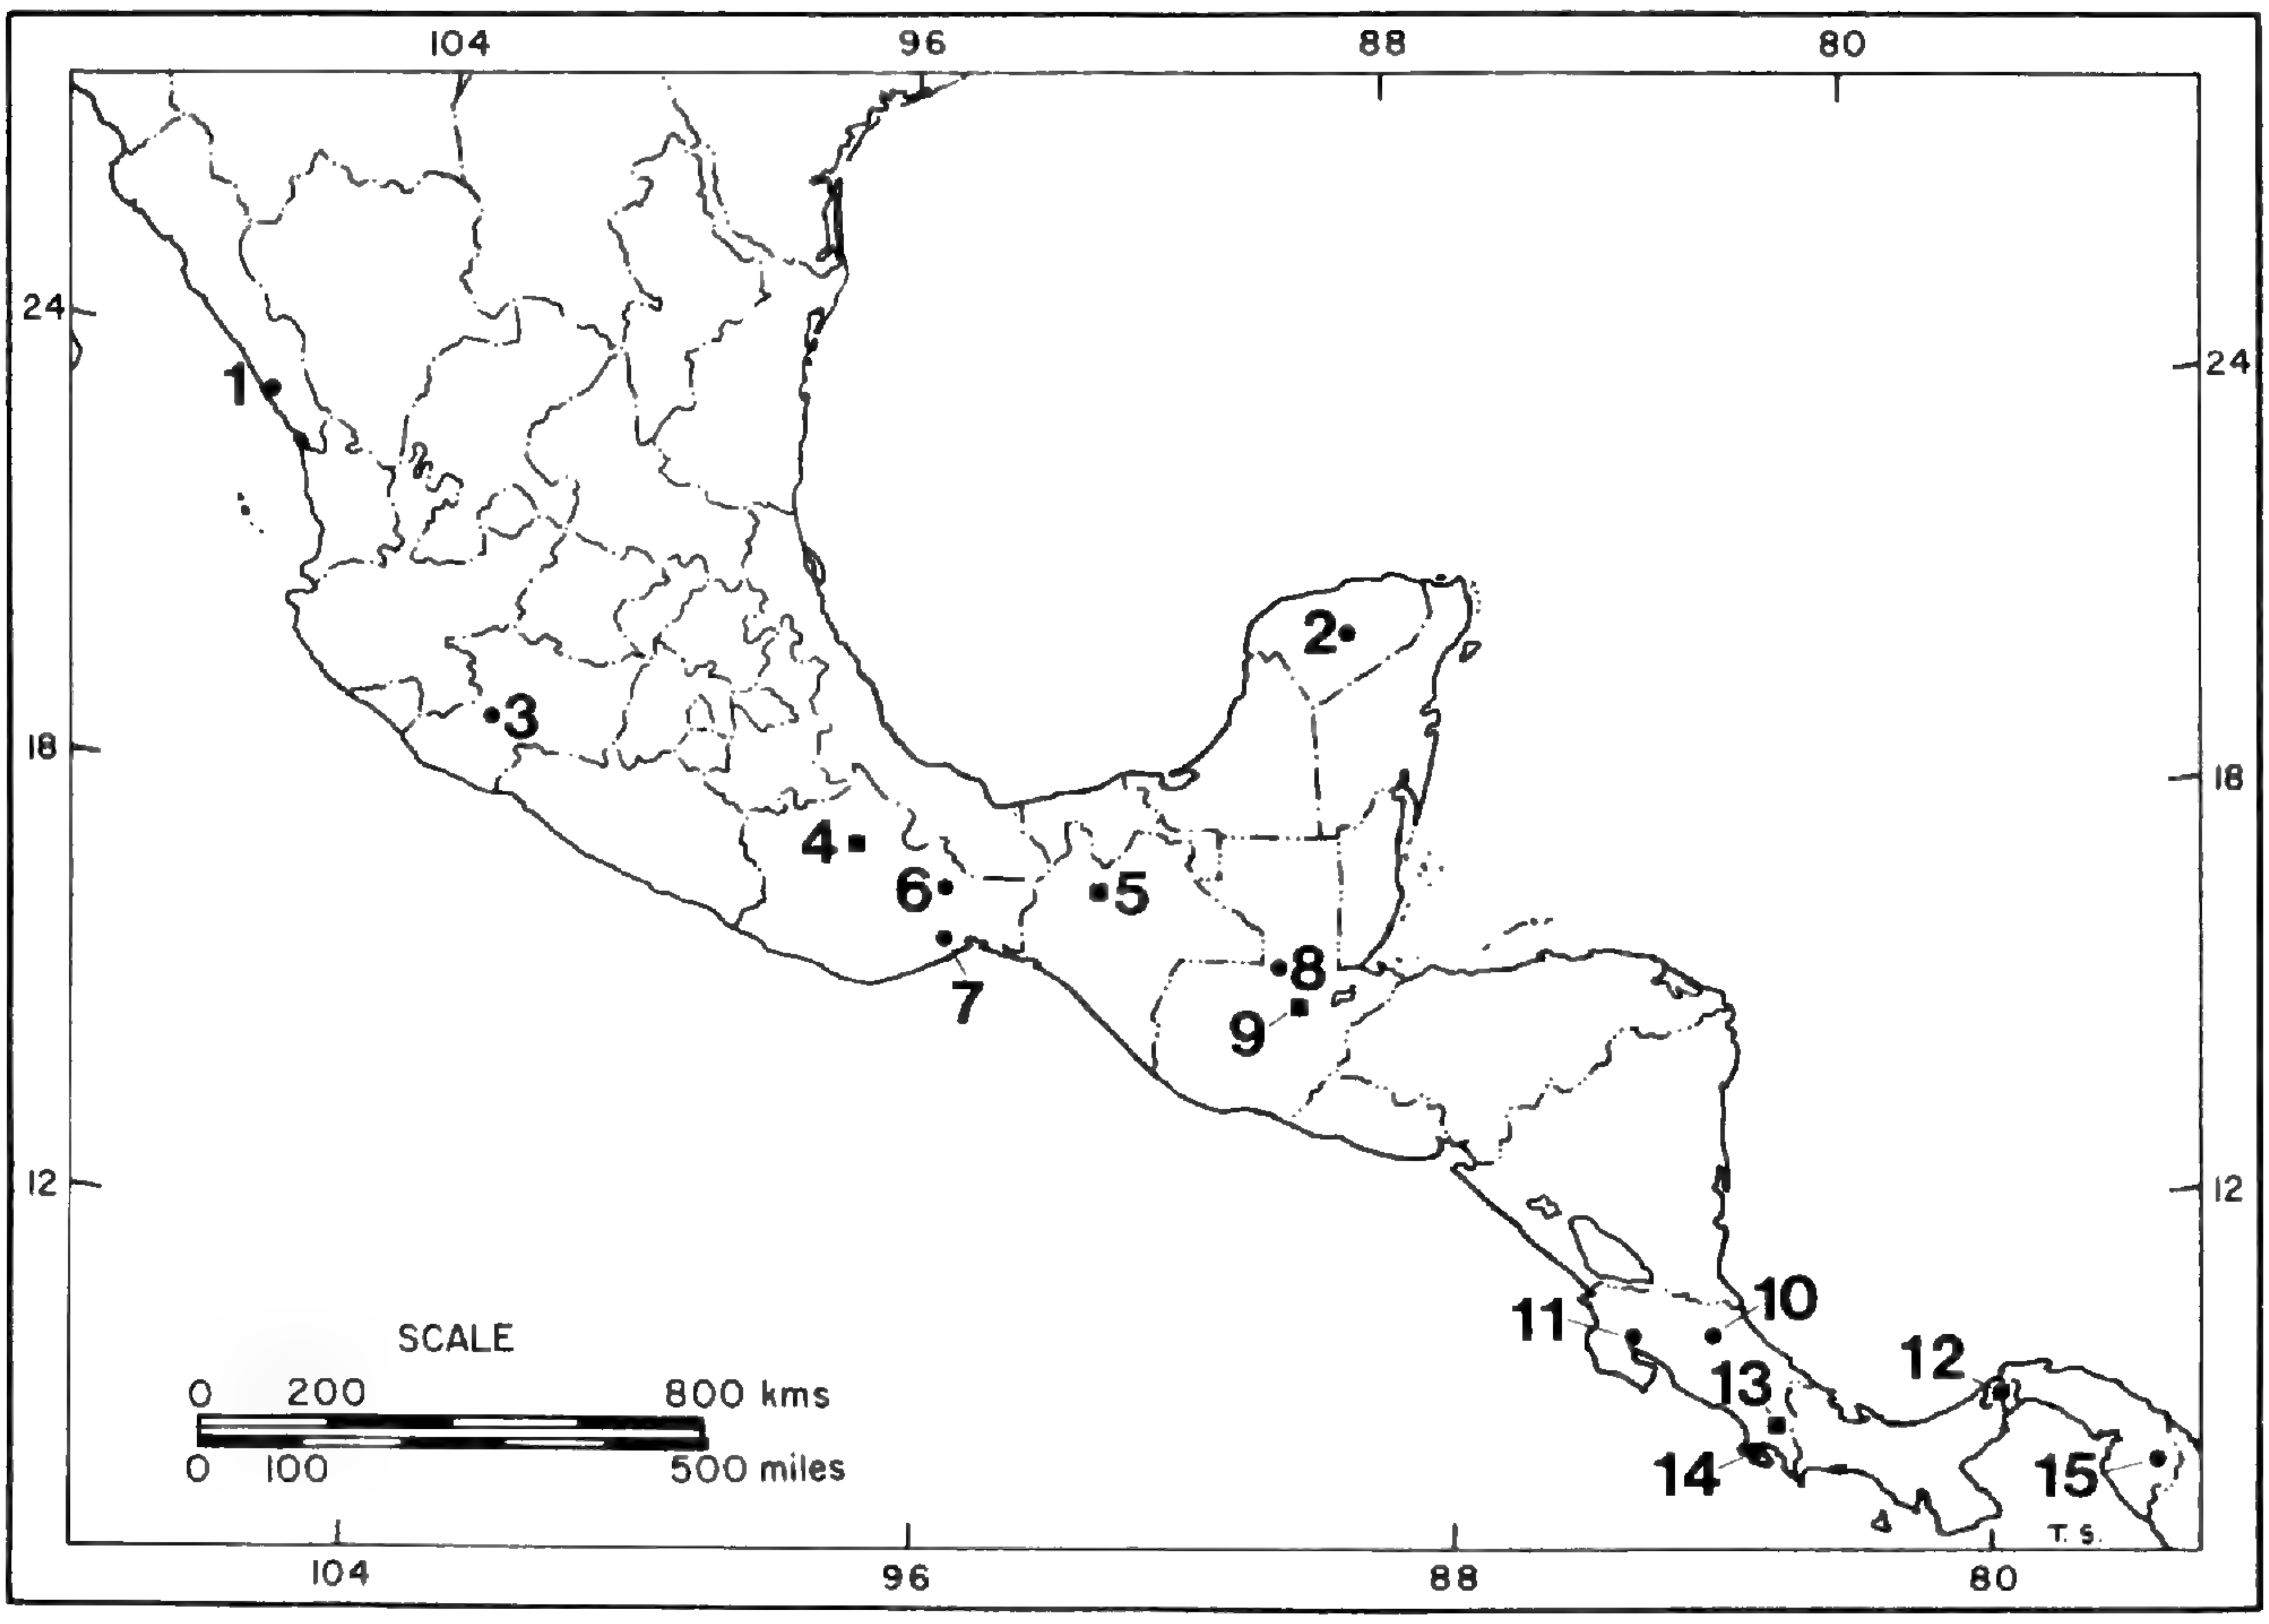

FIGURE 1. *Study sites in Mexico and Central America. Dots are lowland sites; squares are montane cloud forest sites. Numbers refer to the list of sites in the text: 1 = MAZA, 2 = PIST, 3 = APAT, 4 = VHER, 5 = RMES, 6 = SARA, 7 = TEHU, 8 = CHIN, 9 = PURU, 10 = LSEL, 11 = TABO, 12 = BCIS, 13 = CRUC, 14 = RINC, 15 = TUIR.*

there are more species of anurans than occur in all of the United States and Canada (Duellman, 1978). The diversity is much higher than on other Gondwanan continents—56.0 species/million km^2 in South America, as compared with 11.7 in Africa and 20.1 in Australia (Duellman, 1979a). Therefore, the American tropics represent an ideal region for investigation of patterns of species diversity in anuran amphibians. Salamanders and caecilians have been omitted because the former are poorly represented in South America and because the latter are too poorly known to be analyzed.

The purposes of this paper are to (1) summarize data on species diversity from many sites in the American tropics, (2) examine the patterns of species diversity, and (3) interpret these patterns in relation to present climatic patterns, historical biogeography, and reproductive modes. I consider the term species diversity to be synonymous with species density and species richness.

MATERIALS AND METHODS

For purposes of defining the anuran fauna of tropical America, I did not include any species confined to Argentina, Chile, or Uruguay, and I included no North American species that do not range into the tropical regions of Mexico. Lists of species of anurans were obtained for 48 sites in tropical South America, including the Andes (Figs. 1, 2); no sites were incorporated from the West Indies. Each site is a relatively small area, usually encompassing fewer than 10,000 hectares. I have worked at 30 of the sites.

In the following list of sites, each is identified by an abbreviation (used in tables), name, geographical coordinates, elevation, vegetation formation (Holdridge, 1964), and ref-

THE TROPICAL AMERICAN ANURAN FAUNA

Seventeen of the 46 family groups (families and subfamilies) of anurans occur in the American tropics; nine of these are endemic to the region and three others are extratropical only in southern South America. Of the 301 genera and 3,533 species of anurans known worldwide (figures updated from Frost, 1985), 107 genera (35.5%) and 1,545 species (43.7%) occur in the American tropics (Table 1). Ninety-six of the 107 genera are endemic to the American tropics.

Of the 1,545 species known from the American tropics, the majority (1,138) occur in South America; 64 of these also occur with an additional 261 species in Middle America (Mexico and Central America), and 146 species are known from the West Indies (Table 2). Thus, of the number of anurans known worldwide, 32.2% occur in tropical South America, 9.2% occur in tropical Middle America, and 4.1% occur in the West Indies.

Two families make the largest contribution to the anuran fauna of the American tropics. The Leptodactylidae (41 genera, 562 species) and the Hylidae (28 genera, 443 species) account for 72% of the 1,399 species of anurans on the mainland. Six endemic families (Allophrynidae, Brachycephalidae, Centrolenidae, Dendrobatidae, Pseudidae, and Rhinophrynidae) account for 14% of the mainland species. Four widespread families (Bufonidae, Microhylidae, Pelobatidae, and Ranidae) make up the remaining 14% of the fauna, with the Bufonidae (10 genera, 129 species) making the largest contribution. Two large genera—*Hyla* (Hylidae, 230 species) and *Eleutherodactylus* (Leptodactylidae, 308 species)—make up 38% of the anuran fauna of the mainland tropics.

PATTERNS OF SPECIES DIVERSITY

Patterns of anuran species diversity were determined from compilations of species from each of 48 sites in tropical America (Tables 3–7). For purposes of discussion these are divided into three categories: (1) lowland sites (N = 32) at elevations of less than 1,000 m, (2) montane cloud forest sites (N = 9) at elevations of 1,100–2,010 m, and (3) high Andean sites (N = 7) at elevations of 2,700–4,010 m. The patterns of species diversity are examined with respect to (1) climate and habitat, (2) taxonomic composition, (3) historical components, and (4) reproductive modes.

The comparisons reflect existing knowledge of the fauna at each of the sites. Disparity exists in the sampling effort at the sites. Thus, for sites that have been subjected to intensive study (e.g., Barro Colorado Island, Santa Cecilia), the species lists can be viewed as nearly complete. However, at other sites (e.g., Río Cuyuni, Rio Tapajós) sampling has been limited to short periods of time, and therefore additional species are expected.

CLIMATE AND HABITAT

In the lowlands of the American tropics, the greatest number of species of anurans is found in the equatorial part of the upper Amazon Basin. The greatest number of species known from one locality is 84 at Santa Cecilia in Amazonian Ecuador. Throughout the upper Amazon Basin in areas receiving more than 3,000 mm of rain per year and having only a limited dry season species diversity is high (55–84, $\bar{X}$ = 62.8, N = 6). Eastward

Totals	13	14	41	42	28	27

in the middle and lower parts of the Amazon Basin, species diversity is lower (32–59, $\bar{X}$ = 46.3, N = 4). In those parts of the basin rainfall is less than 3,000 mm annually, and there is a prolonged dry season of four to six months. The same climatic pattern exists in the Guianan Region, where anuran species diversity is even lower (29–35, $\bar{X}$ = 32.0, N = 2). The correlation of decreased anuran species diversity with lower rainfall and more prolonged dry seasons is reflected in the number of species of anurans in the Venezuelan llanos and the Chacoan scrub forests of Paraguay, where rainfall is less than 2,000 mm annually and the dry season is more than six months long. In the Chaco, species diversity is 22–29 ($\bar{X}$ = 25.3, N = 3), and in the llanos, 16–26 ($\bar{X}$ = 21.0, N = 2).

This pattern seems to hold for the Atlantic coastal forests of southeastern Brazil where at one site with rainfall exceeding 3,600 mm annually there are 65 species of anurans. Although rainfall is high (over 4,000 mm) and aseasonal in the Trans-Andean rainforest, however, species diversity (35–49, $\bar{X}$ = 42.6, N = 3) is slightly lower than that in the middle and lower Amazon Basin characterized by less rainfall and a distinct dry season.

The same general pattern holds in the lowlands of Middle America. In the wet forests, species diversity is higher (13–42, $\bar{X}$ = 27.5, N = 6) than in the dry forests (6–22, $\bar{X}$ = 14.4, N = 5). However, both figures are much lower than for comparable habitats in South America.

Although montane rainforests may not receive as much precipitation as many lowland rainforests, the montane forests are shrouded in fog almost daily. Moreover, because of lower temperatures and insolation, evaporation is lower. Thus, cloud forests provide a moist environment for anurans. Average anuran species diversity is higher in some South American cloud forests (20–39, $\bar{X}$ = 25.4,

N = 5) than in Middle American cloud forests (16–30, $\bar{X} = 20.5$, N = 4). Near the northern extent of both lowland rainforest and cloud forest in Mexico, the numbers of species of anurans are higher in the cloud forests than in the lowland rainforests. On the other hand, species diversity in South American cloud forests is considerably less than in lowland rainforests.

The high Andes provide a distinctive environment of supra-treeline habitats (páramo and puno). In these high-elevation sites anuran species diversity is low (5–15, $\bar{X} = 8.1$, N = 7). One of the sites (Abra Zamora, 2,700 m) is subpáramo; it has 15 species, whereas the other higher sites have 5–9 ($\bar{X} = 7.0$). Generally in the supra-treeline habitats in the Andes, the number of species of anurans diminishes from north to south (Duellman, 1979b; Péfaur & Duellman, 1980). This seems to be correlated at least in part with a decrease in the amount of moisture and an increase in the seasonality of precipitation.

The elevational gradient in anuran species diversity in the Andes has been discussed by Duellman (1979b, 1983) and by Lynch & Duellman (1980). This gradient is demonstrated well by an equatorial transect spanning the Andes and the lowlands on either side of the mountains (Fig. 3). Many species in cloud forests have rather narrow altitudinal ranges. Thus, although the number of species (17) at 2,600 m on the Amazonian slopes is not much fewer than that at 1,100 m (22 species), no species occur at both locations.

It is obvious that diversity generally decreases from wetter to drier regions and from lower to higher elevations. However, this explanation is simplistic and does not take into account some important aspects of the biology of anurans, such as reproductive mode.

TAXONOMIC COMPOSITION

Analysis of species diversity by taxonomic groups reveals a variety of patterns. Within the tropical lowlands, three family groups account for most of the taxa at any one site. Of these, the Hylinae and Leptodactylinae are present at all sites. Within the Amazon Basin, hylines are most numerous in the upper part of the basin, but they constitute a higher percentage of the anuran fauna in the middle and lower parts of the basin (Fig. 4). They are numerous in the Atlantic coastal forest of southeastern Brazil, but the hyline fauna is depauperate in the Chocoan and Central American rainforests. Likewise, the number of species of hylines diminishes in the dry forests of Middle America, the Chaco, and the Venezuelan llanos.

The leptodactylines present a different picture (Fig. 5). They are well represented throughout the cis-Andean lowlands and form a large part of the anuran fauna in the Venezuelan llanos (38–50%) and in the Chaco (36–44%). Leptodactylines constitute a much smaller part (3–15%) of the anuran fauna in the trans-Andean and Central American lowlands.

Telmatobiines contrast strongly with lep-

todactylines (Fig. 6). Telmatobiines (composed mostly of species of *Eleutherodactylus*) make up a significant part (21–35%) of the anuran fauna in the lowlands of the Chocoan region and lower Central America; this is about the same as their contribution (25%) to the anuran fauna of the Atlantic coastal forest in southeastern Brazil. In the Amazon Basin the number of species (and percentage contribution) diminishes rapidly from the equatorial part of the upper basin to the southern, middle, and lower parts of the basin. Telmatobiines are poorly represented in the Chaco and are absent from the Venezuelan llanos.

Although dendrobatids are represented by far fewer species, their pattern of diversity parallels that of the telmatobiines (Fig. 7). However, dendrobatids are absent from the Atlantic coastal forest in southeastern Brazil, the Chaco, and the llanos.

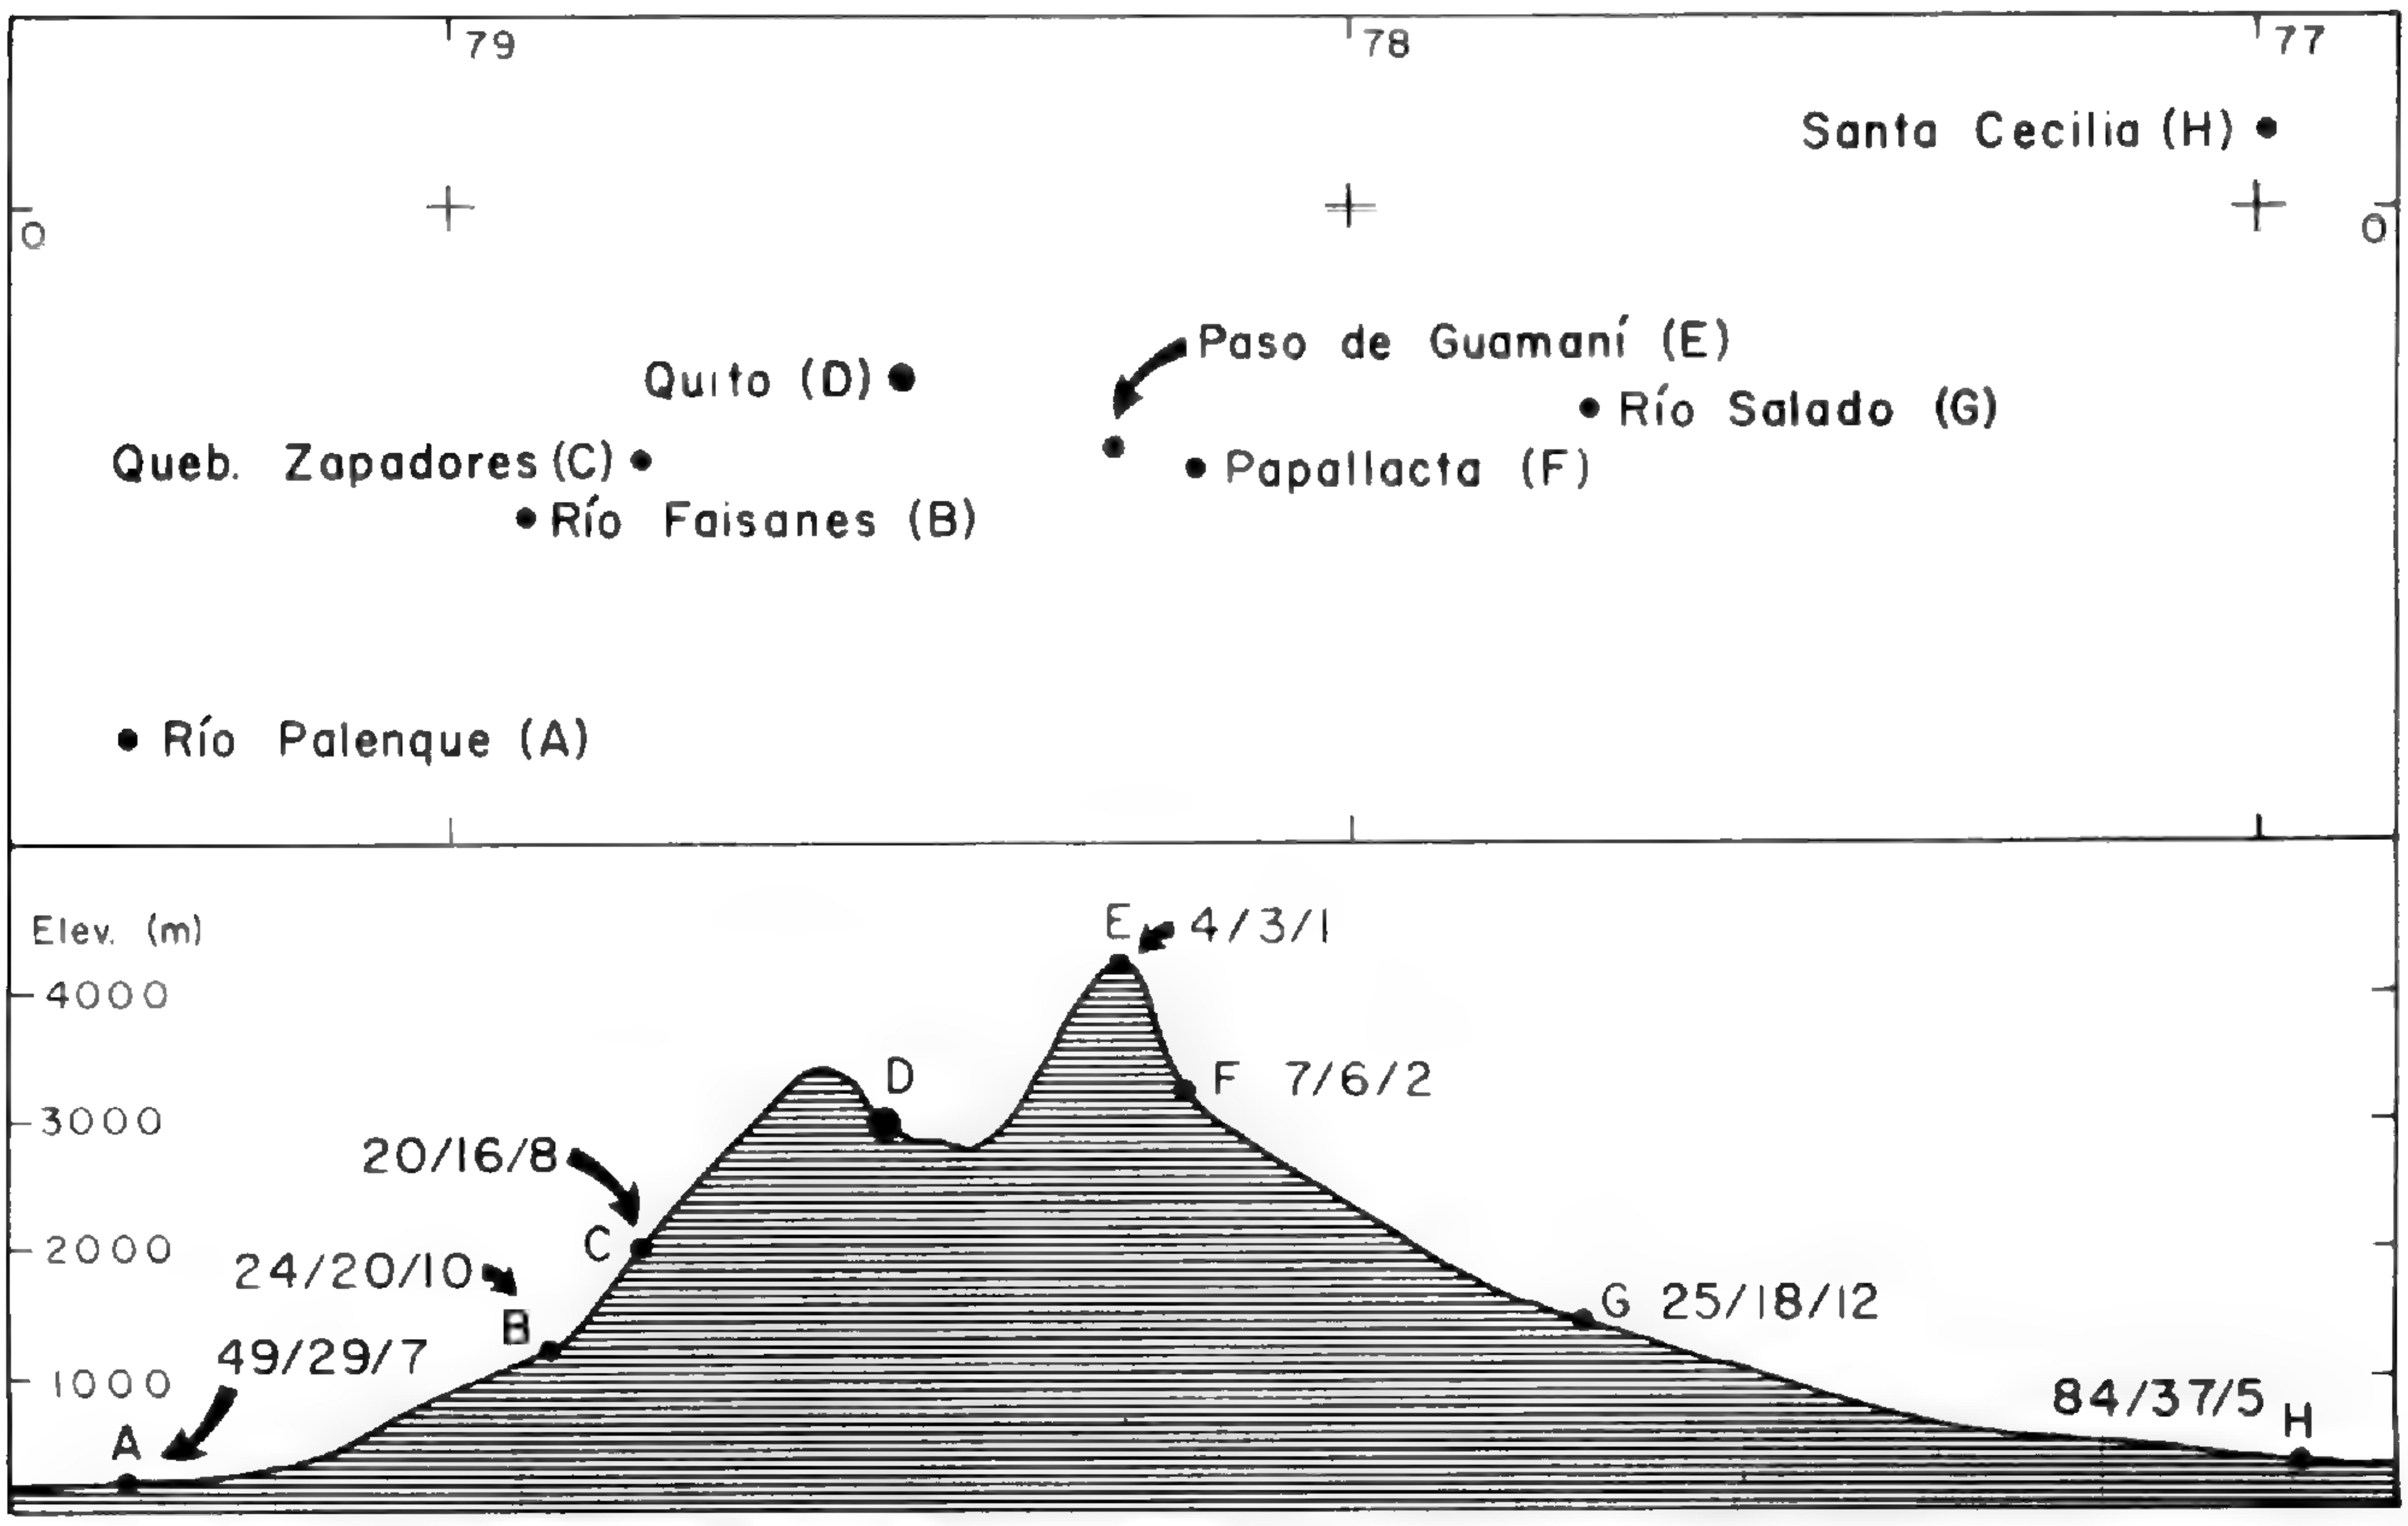

FIGURE 3. *Above, map of central Ecuador showing location of sites (A–H); below, equatorial transect of the Andes showing certain aspects of the anuran fauna at each site. Numbers are total number of species/percent with forest mode/percent with stream-dependent mode.*

FIGURE 4. *Hyline frogs in lowland sites in South America and lower Central America. Numbers are number of species/percentage of total at each locality.*

Bufonids are about equally abundant throughout the lowlands, but they tend to account for a higher percentage of the anuran fauna in the llanos (11–13%) and Chaco (3–9%) than elsewhere. Centrolenids make a large contribution to the anuran fauna in the Central American (10–17%) and trans-Andean (10–18%) lowlands; they are few in number or absent in the cis-Andean lowlands. Ranids are represented in South America by only one currently recognized species of *Rana*, which is absent from the southern and eastern lowlands. Pseudids are represented by only three species; these are restricted to the middle and lower Amazon Basin, the llanos, and the Chaco. Pipids are widespread in the cis-Andean lowlands and represented in eastern Panama by a single species. Three family groups have restricted distributions in the American tropics. The Allophrynidae occurs only in the Guianan forests. Brachycephalids and hylodines are restricted to southeastern Brazil, where they account for 1.5% and 6.2% of the anuran fauna, respectively.

In the Middle American lowlands, rhinophrynids and pelobatids make a minor con-

FIGURE 5. *Leptodactyline frogs in lowland sites in South America and lower Central America. Numbers are number of species/percentage of total at each locality.*

tribution to the anuran fauna in dry forests, and hylines and telmatobiines (mostly *Eleutherodactylus*) contribute significantly to the anuran fauna of the wet forests.

Taxonomic composition changes radically in the montane cloud forest and high Andean sites. A significant part of the anuran fauna in cloud forests is made up of telmatobiines (mostly *Eleutherodactylus*); these account for 28–56% ($\bar{X}$ = 38.8, N = 5) of the anuran fauna in South American cloud forests and 12–27% ($\bar{X}$ = 21.0, N = 4) in Middle American cloud forests. The most striking difference between cloud forests in Middle and South America is the number of species of hylines; in Middle America these make up 30–53% ($\bar{X}$ = 44.0, N = 4), as contrasted with 0–20% ($\bar{X}$ = 8.2, N = 5) in South America. Centrolenids are a major component of the anuran fauna in South American cloud forests (10–25%, $\bar{X}$ = 19.0, N = 5), whereas in Central America they account for no more than 10% of the fauna at any one site. Hemiphractines and dendrobatids each account for an average of 9% of the anuran fauna in South American cloud forests, whereas hemi-

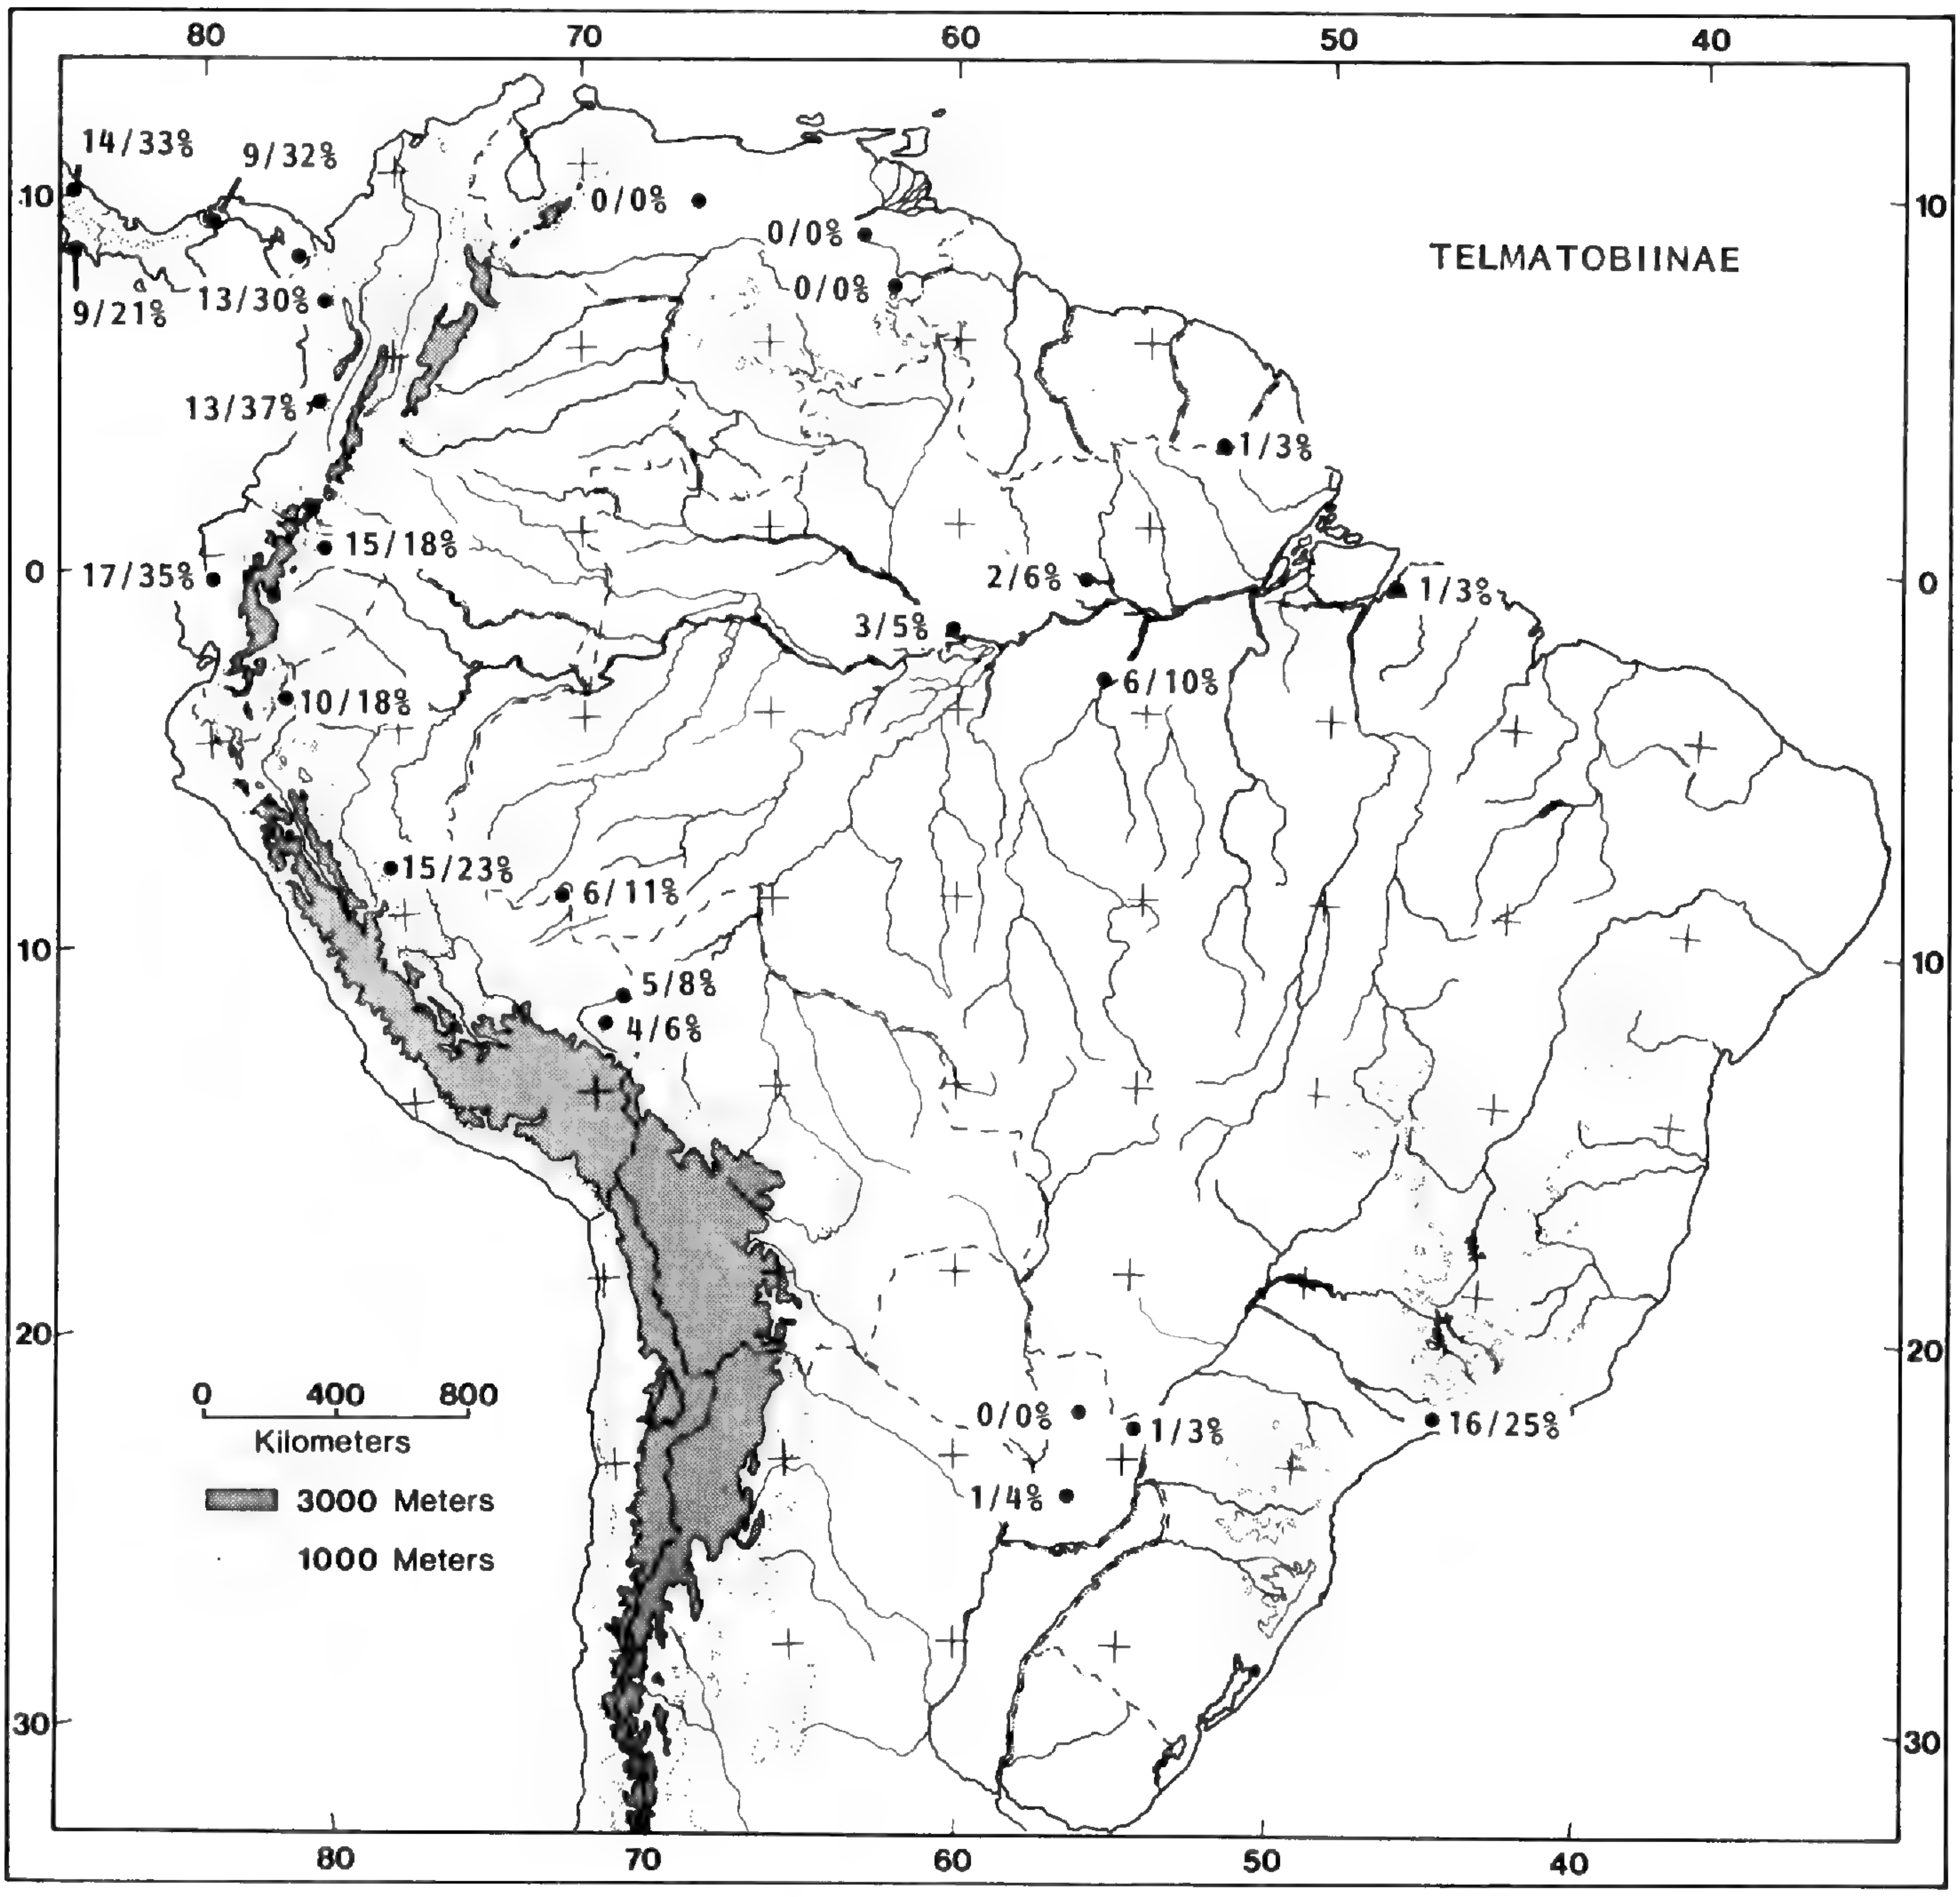

FIGURE 6. *Telmatobiine frogs in lowland sites in South America and lower Central America. Numbers are number of species/percentage of total at each locality.*

phractines are absent at all of the Middle American sites, and only one dendrobatid occurs at one of the sites. On the other hand, *Rana* makes up an average of 6.5% of the anuran fauna at Middle American sites, but the genus is absent in South American cloud forests.

In humid high Andean sites, telmatobiines (*Eleutherodactylus* and *Phrynopus*) account for the majority of the anuran fauna—45–74% ($\bar{X}$ = 62.0, N = 5). Bufonids are the other major component, accounting for as much as 22% of the fauna. The rest is composed mainly of dendrobatids (*Colostethus*) and hemiphractines (*Gastrotheca*). In the southern part of the Andes, aquatic telmatobiines (*Telmatobius*) and leptodactylines (*Pleurodema*) make significant contributions to the small anuran faunas.

From these data it is apparent that the patterns of diversity of various taxonomic components are not reflected in the overall diversity of anurans. This is especially noticeable in different patterns of diversity among taxonomic groups in Middle America and South America and suggests that the histories

FIGURE 7. *Dendrobatid frogs in lowland sites in South America and lower Central America. Numbers are number of species/percentage of total at each locality.*

of the family groups may play an important role in the geographic differences in species diversity.

HISTORICAL COMPONENTS

An overwhelming amount of data on plate tectonics and biogeography shows that (1) South America had a land connection with Middle America at the time of the Cretaceous–Tertiary boundary; (2) South America was isolated from other land masses throughout most of the Tertiary; and (3) the isthmian link providing a continuous land connection between Middle America and South America has persisted since the late Pliocene (Stehli & Webb, 1985). The early unification of the land masses provided an opportunity for interchange of Laurasian and Gondwanan biotas at the end of the Cretaceous. The interchange, followed by separation of the land masses, resulted in isolation of taxa in South America and Middle America and subsequent vicariance of taxa. Reunification of the land masses provided the opportunity for more recent dispersal.

The history of anurans with respect to the inter-American biotic exchange has been reviewed by Savage (1982) and by Vanzolini & Heyer (1985). Savage championed the idea of a Mesoamerican herpetofauna that evolved in isolation in Central America. Thus, the tropical American frog fauna is composed of three historical elements—North American, Mesoamerican, and South American (Table 8).

TABLE 9. *Biogeographic components of anuran faunas at 48 sites in the American tropics. Numbers in parentheses indicate number of sites. Numbers in columns are percentages.*

Trans-Andean forest (3)	59.2–74.3 (67.2)	12.2–29.5 (23.4)
Lower Middle American wet forest (4)	55.6–60.7 (57.9)	14.3–26.2 (17.5)
Upper Middle American wet forest (2)	23.1–35.7 (29.4)	—
Middle American dry forest (5)	0.0–20.0 (11.6)	—
Middle American cloud forest (4)	23.5–50.0 (35.9)	33.3–52.9 (45.9)
South American cloud forest (5)	61.0–92.0 (76.4)	28.0–43.5 (38.1)
Wet high-Andean sites (6)	57.1–100.0 (81.2)	12.5–33.3 (22.8)
Dry high-Andean sites (1)	20.0	20.0

The North American anurans make only a minor contribution to the tropical anuran fauna. These include pelobatids (two species of *Scaphiopus*), rhinophrynids (one species of *Rhinophrynus*), and ranids (21 species of *Rana*) in Middle America; of these, only one species of *Rana* occurs in South America. There is no evidence that any North American anurans entered South America during the connection with South America at the Cretaceous–Tertiary boundary.

On the other hand, during the Cretaceous–early Tertiary connection, members of five family groups dispersed into Middle America from South America. These include some groups of bufonids (*Bufo*), hylines (*Hyla*), phyllomedusines (ancestor of *Agalychnis* and *Pachymedusa*), telmatobiines (*Eleutherodactylus*), and microhylids (ancestor of *Gastrophryne* and *Hypopachus*). During their isolation in the Tertiary, these groups differentiated into many species. The "*Hyla*" vicariant presumably was ancestral to the Middle American genera *Anotheca*, *Plectrohyla*, *Pternohyla*, *Ptychohyla*, *Smilisca*, and *Triprion*, in addition to the numerous Middle American and Holarctic frogs currently placed in the genus *Hyla*. Likewise, the "*Eleutherodactylus*" vicariant presumably was ancestral to the genera *Hylactophryne*, *Syrrhophus*, and *Tomodactylus*, as well as the many species of Middle American *Eleutherodactylus* placed in the subgenus *Craugastor* by Lynch (1986).

With the closure of the Panamanian Portal in the late Pliocene, a few groups of Mesoamerican taxa dispersed into South America (principally the Chocoan region), and many South American taxa dispersed into Central America. Mesoamerican dispersalists into South America include only *Agalychnis*, *Smilisca*, *Eleutherodactylus* (members of subgenus *Craugastor*), and *Rana*. Only *Rana palmipes* is widely distributed in the cis-Andean lowlands, where *Agalychnis* is represented by one species in the upper Amazon Basin, as contrasted with three species in the trans-Andean lowlands.

Twenty-one genera included in ten family groups have dispersed from South America into Central America since the late Pliocene. Two genera of bufonids (some groups of *Bufo* and *Atelopus*) have reached Costa Rica, and *Atelopus* has differentiated in Central America. *Centrolenella* has dispersed to southern Mexico and has undergone extensive speciation in Central America. All three genera of dendrobatids have dispersed to Costa Rica (*Dendrobates* to Nicaragua) and have differentiated in Central America. Among hemiphractines, one South American species each of *Gastrotheca* and *Hemiphractus* have

FIGURE 8. *Reproductive modes of anurans at lowland sites in South America and lower Central America. Numbers are percentages of species with forest modes/stream-dependent modes.*

reached Panama, and another *Gastrotheca* has dispersed to Costa Rica. The hyline genera *Hyla* and *Ololygon* have dispersed to Mexico and differentiated in Middle America, whereas the South American *Phrynohyas venulosa* extends throughout the tropical lowlands of Middle America. *Phyllomedusa* has reached Costa Rica, where a distinct species occurs; another South American species extends into eastern Panama. Although leptodactylines are widely dispersed in Middle America, they have not differentiated from South American populations; one *Leptodactylus* reaches Texas, and four other species have dispersed shorter distances in Middle America. *Physalaemus* reaches southern Mexico and *Pleurodema* extends only to central Panama. South American *Eleutherodactylus* extends northward to Nicaragua. Three South American species of microhylids have dispersed to Panama and one to Costa Rica. Pipids are represented by a distinct species in eastern Panama.

When the anuran diversity at the 48 sites is examined with respect to the histories of the component taxa, we see that slight differences exist among the South American sites but that these are notably different from the Middle American sites (Table 9). Moreover, North American and Mesoamerican elements play a minor role in the South American fauna, whereas at Middle American sites, a significant contribution is made by South American elements. The recent dispersal of South American taxa into Central America accounts for the greater species diversity in lower Central American lowland forests than in those in Mexico.

REPRODUCTIVE MODES

Mode of reproduction is a combination of ovipositional and developmental factors, including oviposition site, ovum and clutch characteristics, rate and duration of development, stage and size of hatchling, and type of parental care, if any. Duellman & Trueb (1986) recognized 29 reproductive modes in anurans worldwide. At the 48 tropical American sites analyzed here, 17 modes occur. These modes and the taxa exhibiting them are:

1. Eggs and tadpoles in lentic water.—All allophrynids, ceratophryines, ranids, and pseudids; most bufonids, hylines, and microhylids; telmatobiines (*Proceratophrys*), and some leptodactylines (*Paratelmatobius, Pseudopaludicola, Pleurodema marmorata*).
2. Eggs and tadpoles in lotic water.—Bufonids (*Atelopus, Bufo haematiticus* group), hylines (*Hyla bogotensis, H. callipleura, H. larinopygion, H. circundata* groups and most Middle American cloud forest groups, *Plectrohyla, Ptychohyla*), hylodines, and telmatobiines (*Paratelmatobius, Telmatobius*).
3. Eggs and tadpoles in water in basins constructed by males.—Hylines (*Hyla boans* group).
4. Eggs and tadpoles in tree holes or bromeliads.—Some hylines (*Anotheca, Nyctimantis, Phrynohyas resinifictrix, Hyla astartea, H. bromeliacia*).
5. Eggs in streams; tadpoles on rocks in spray zone.—Telmatobiines (*Cycloramphus* and *Thoropa*).
6. Eggs in aquatic foam nest; tadpoles in ponds.—Most leptodactylines.
7. Eggs in terrestrial foam nest; direct development into froglets.—Leptodactylines (*Adenomera*).
8. Eggs embedded in dorsum of aquatic female; tadpoles in ponds.—Pipids (*Pipa arrabali*).
9. Eggs embedded in dorsum of aquatic female; direct development into froglets.—Pipids (*Pipa pipa*).
10. Eggs terrestrial; tadpoles in streams.—Centrolenids (*Centrolene*).
11. Eggs terrestrial; tadpoles carried to water by adults.—All dendrobatids.
12. Eggs terrestrial; direct development into froglets.—Brachycephalids, bufonids (*Osornophryne, Rhamphophryne*), telmatobiines (*Barycholos, Eleutherodactylus, Holoaden, Hylactophryne, Ischnocnema, Phrynopus, Phyzelaphryne, Syrrhophus, Tomodactylus*), microhylids (*Myersiella, Synapturanus, Syncope*).
13. Eggs arboreal; tadpoles in ponds.—Hylines (*Hyla leucophyllata* and *H. parviceps* groups) and all phyllomedusines except *Phyllomedusa cochranae* group.
14. Eggs arboreal; tadpoles in streams.—Centrolenids (*Centrolenella*), hylines (*Hyla albosignata* and *H. lancasteri* groups), and phyllomedusines (*Phyllomedusa cochranae* group).
15. Eggs in dorsal pouch of female; feeding tadpoles in ponds.—Hemiphractines (some *Gastrotheca*).
16. Eggs on dorsum or in dorsal pouch of female; nonfeeding tadpoles in tree holes or bromeliads.—Hemiphractines (*Flectonotus, Fritziana*).
17. Eggs on dorsum or in dorsal pouch of female; direct development into froglets.—Hemiphractines (*Hemiphractus*, some *Gastrotheca*).

Lynch (1979) and Duellman (1982) noted the fidelity of certain reproductive modes to tropical forest environments and designated forest and nonforest reproductive modes. In the foregoing list, numbers 10–17 are considered to be forest modes. In these modes the eggs (and in some cases the tadpoles) are exposed to the air as they develop on the ground, on vegetation, or on the back of the female. Thus, egg development is dependent upon high humidity.

Modes 2, 5, 10, 14, and 11 (in part, *Colostethus*) are dependent on the existence of high-gradient streams for the survival of the tadpoles. Of these, modes 10, 11, and 14 also are forest modes, for the eggs are deposited on the ground or on vegetation.

Analysis of the reproductive modes at the 48 tropical American sites reveals great disparities in the proportions of nonforest, forest, and stream-dependent modes (Fig. 8, Table 10). The highest proportions of forest modes are in the equatorial part of the upper Amazon Basin, the trans-Andean forests, the lower Central American wet forests, and the humid montane sites. In Middle American dry forests, the Venezuelan llanos, and the Chacoan dry forests, the proportion of forest modes is less than 12%. Reproductive modes dependent on streams are most common in the humid montane forests (28–53%), the trans-Andean forests (12–30%), the lower Central American wet forests (14–26%), and the coastal forest of southeastern Brazil (23%). Stream modes are uncommon in the Amazon Basin (6–8%) and absent in the Venezuelan llanos, Chacoan dry forests, and Middle American dry forests.

Thus, we find that there is a trend from a high proportion of forest modes in aseasonally wet lowland forests to low proportions (or absence) of these modes in dry forests and llanos. Stream-dependent modes are uncommon or absent in most lowland sites, and these make up a larger proportion of the anuran faunas in montane sites (Fig. 3). Likewise, most montane sites have a high proportion of species having forest modes of reproduction (Fig. 3).

DISCUSSION

When all of the factors (environmental, historical, and reproductive) are viewed as a whole in attempting to provide an explanation for the patterns of species diversity in neotropical anurans, we find that each factor influences species diversity to varying degrees in different areas. The combined effects of these factors result in the existing patterns of diversity.

In the cis-Andean tropical lowlands of South America, Mesoamerican and North American components play a minor role. No taxa of Mesoamerican origin are found there, and one northern group (Ranidae) is represented by a single species, *Rana palmipes*, at sites primarily north of the Equator. Some South American family groups have restricted distributions; thus, *Allophryne ruthveni* is restricted to the Guianan forests, and *Brachycephalus* and hylodines are restricted to the coastal forests of southeastern Brazil.

Within the cis-Andean lowlands there is a decrease in annual rainfall and an increase in the seasonality of rainfall away from the equatorial part of the upper Amazon Basin. This trend is reflected in the diminution in overall anuran species diversity from the equatorial upper Amazon Basin to the lower basin in the east, the Chaco in the south, and the llanos in the north, and a concomitant trend in the reduction in forest modes of reproduction. Thus, in the cis-Andean lowlands, climatic factors seem to have an important effect on overall anuran species diversity.

In the cis-Andean lowlands stream-dependent modes of reproduction are poorly represented, but in southeastern Brazil, where high-gradient streams are numerous, 23.1% of the anurans have stream-adapted reproductive modes.

Compared with other lowland sites, those in the trans-Andean Chocó and lower Central America (Costa Rica and Panama) have a high percentage (61.9%) of forest modes of reproduction and also a high percentage (20.0%) of stream-dependent modes. The presence of high-gradient streams provides the necessary habitat for the stream-adapted reproductive modes. Overall diversity at these sites is less than in the upper Amazon Basin, and the high percentage of forest modes of reproduction is correlated with the few species of pond-breeding hylids and leptodactylids as compared with the upper Amazon Basin. The principal differences between the lower Central American and Chocoan sites are the historical components of their anuran faunas.

At the Chocoan sites more than 90% of the taxa are South American, whereas at the Central American sites 55% of the species are Mesoamerican. One North American species (*Rana palmipes*) occurs in the Chocó; the same species occurs with two other species of *Rana* in lower Central America.

There is a gradient in decreased annual precipitation and increased seasonality from the lower Central American rainforests to those in northern Central America and Mexico. This is reflected in a decrease in overall anuran species diversity. Furthermore, in the northern forests there is an absence of stream-dependent reproductive modes, a decrease to only 7.1% of South American taxa, and an increase to 14.2% of North American taxa. These trends are continued in contrasting Mesoamerican dry forests with the northern rainforests. In the dry forests there are no stream-dependent reproductive modes, and only 11.6% of the species (all Mesoamerican in origin) have forest modes of reproduction. In the dry forests, 16.1% of the species are North American in origin.

Comparison of Middle and South American cloud forests with one another and with adjacent wet lowland forests reveals that overall diversity is much less in the cloud forests in lower Central America and in South America than in the adjacent lowlands; however, in northern Middle American cloud forests the overall diversity is only slightly less than that in the lowlands. The scarcity of ponds in the montane cloud forests is reflected in the few pond-breeding species of anurans at these sites; this is the single largest group of anurans having low diversity in the cloud forests. In contrast, all cloud forests have a high percentage of stream-breeding anurans (45.9% in Middle America and 35.9% in South America) and species with forest modes of reproduction (35.9% in Middle America and 76.3% in South America). The major genera having forest modes are *Colostethus*, *Centrolenella*, and *Eleutherodactylus*, and the first two also are stream-breeding taxa. On the other hand, in Middle American cloud forests, the major stream-breeding genera are *Hyla*, *Plectrohyla*, and *Ptychohyla*. All species in South American cloud forests are members of groups having a South American origin, but in Middle American cloud forests 33.3% of the stream-breeders and 28.3% of the forest modes are species of Mesoamerican origin. No North American groups are represented in South American cloud forests, and North American groups (species of *Rana*) constitute only 6.5% of the anurans at sites in Middle American cloud forest.

All of the taxa at the high Andean sites are South American in origin. The major reproductive modes at wet páramo sites are forest modes (76.3%) or stream modes (38.2%), some of which are included in the forest modes. The anuran fauna of the wet páramos has been derived from that of the adjacent cloud forests, whereas that of the drier puna habitats in the central and southern Andes, which is less diverse and contains about 60% pond-breeding species, has been derived from the Patagonian region (Duellman, 1979b).

Our knowledge of the anuran fauna of tropical America is fragmentary. Of the sites included herein, only those at La Selva, La Planada, Barro Colorado Island, Palenque, Santa Cecilia, and Belém can be considered to have been studied thoroughly enough to provide a reasonably complete list of species and knowledge of their reproductive modes. In order to refine the patterns of anuran species diversity presented here, more data need to be accumulated from many other sites.

I have emphasized the role of reproductive mode in understanding anuran species diversity. The diversity of modes seems to be correlated with humidity and with stream gradients. Accurate microclimatic measurements and data on the physiology of anuran eggs and larvae are needed in order to quantify and refine these presumed correlations.

Much of the anuran fauna in tropical America is disappearing at a rapid rate. The wet lowland rainforest at Santa Cecilia, Ecuador, that provided data for the largest assemblage of anurans in the world has been destroyed. Other tracts of rainforest and especially cloud forest are being eliminated before their biotas are inventoried. Fortunately, many tracts of forest are being set aside as preserves, and data from some of them have been incorporated into this review. However, the establishment of reserves usually is based on the known or presumed existence there of high diversity of birds or primates, with little or no attention given to more poorly known groups such as anurans.

MANAGEMENT OF HABITAT FRAGMENTS IN A TROPICAL DRY FOREST: GROWTH[1]

Daniel H. Janzen[2]

ABSTRACT

Tropical conservation biology is inescapably the biology of habitat fragments and has been focused on habitat decay. Habitat restoration is primarily the initiation, growth, and coalescence of habitat fragments. Management of a tropical wildland will become the art and science of arresting the decomposition of habitat fragments and promoting their growth and coalescence. Forces that determine accumulation of structure and species are significantly within human control. Today's management actions will determine the nature of wildland habitats for centuries to come. Tropical dry forest is the most threatened of all the major lowland tropical forest habitats, simply because it has always occupied some of the lands most easily farmed in the tropics, and because it is so susceptible to fire. When dry forest and fields are abandoned and therefore allowed to return to dry forest, there are two principal kinds of forest initiation (assuming that there are nearby seed sources). a. When large pastures are downwind of a relatively intact forest, the initial invasion is primarily by individuals of large wind-dispersed trees that will persist and characterize the site for hundreds of years. However, these tree species are a minority of the total flora. Such forests of wind-dispersed trees are relatively inhospitable to animals, highly deciduous, and relatively species-poor. b. When there is any kind of attraction for animals in an abandoned open area, they may perch in it or rest below it while crossing the open area. This results in accumulation of an entirely vertebrate-dispersed forest patch. Such patches may grow and coalesce to form a forest type as artificial as is a wind-generated forest. Vertebrate-generated forests contain more food items of interest to animals, are more species rich, and are more evergreen than are wind-generated forests. As large areas of abandoned low-grade farm and ranch land are returned to dry forest, the manager of national parks or other wildlands is confronted with the difficult decision of just which of the above, or other, forest types is to be promoted. The same will apply to rainforest when its restoration becomes a focus of concern.

Tropical conservation biology is inescapably the biology of habitat fragments. There are two kinds of fragments. First, much of what is worthy of conservation has already been broken into *decomposing habitat fragments* that are refugia and remnants. Even a large national park that is a solid block of pristine forest is a fragment. The biology of the decomposition process of these fragments is of intense contemporary interest to conservation planners and managers (e.g., Lovejoy et al., 1986; Diamond, 1986; Janzen, 1986a, c; Wilcove et al., 1986; Uhl & Buschbacher, 1985; Newmark, 1987). Second, habitat restoration is primarily the initiation and coalescence of *growing habitat fragments*. Management of a tropical wildland therefore becomes the art and science of arresting decomposition of habitat fragments and promoting their growth and coalescence. In such an arena, today's management actions will determine the nature of wildland habitats for centuries to come; forces that determine accumulation of structure and species are significantly within human control.

Here I examine the biology of habitat initiation and growth in a Costa Rican tropical dry forest. Dry forest is the most threatened of all the major lowland tropical forest habitats. It once covered more than half of the world's tropics (e.g., Brown & Lugo, 1982; Murphy & Lugo, 1986) but now supports a diverse array of breadbaskets, cotton fields, and pastures. In Pacific Mesoamerica, for example, less than 0.1% of the original tropical dry forest, which once covered an area the size of France (equal to five Guatemalas in area), has conservation status, and there

1985	0	0	0	3	99	211	154	169	214	436	119	26	1,431

are no remaining large areas of even relatively pristine dry forest (Janzen, 1986a). This dry forest area exists almost entirely as habitat fragments and degraded patches, all of which are still shrinking if not in conserved areas. If there is ever to be a Pacific mesoamerican dry forest national park large enough to truly maintain the animals, plants, and habitats that greeted the Spaniards in the early 1500s, it will have to be grown rather than decreed (Janzen, 1986a).

The study site is the 108-km^2 Santa Rosa National Park and its immediate surroundings, the site of the proposed 800-km^2 Guanacaste National Park (GNP) (Janzen, 1986a). GNP is an approximate rectangle of variably damaged dry forest in northwestern Costa Rica, lying between Volcán Orosí and Volcán Cacao on the east and the Pacific Ocean to the west, with the Interamerican Highway cutting through the middle. From the ocean to the tops of the 1,500-m volcanoes is a moisture and elevational gradient that ranges from the driest part of Costa Rica (the sea level tip of the Santa Elena Peninsula, with less than 1 m of rainfall during its 5–6-month rainy season, Table 1) to seasonal rainforest on the volcano sides to ever-wet cloud forest on the volcano tops. The dry forest discussed here grows primarily within 10 km of the Administration Area of Santa Rosa National Park and is a mosaic of pristine forest, 0–400-year-old woody succession, and abandoned pastures of an introduced African pasture grass (jaragua, *Hyparrhenia rufa*). The Santa Rosa dry forest contains about 700 species of plants (Janzen & Liesner, 1980), 115 species of mammals (Wilson, 1983), 170 species of resident birds (Stiles, 1983), and 13,000 species of insects (including about 3,000 species of moths and butterflies, Janzen, 1988a, b).

The essay presented here is based on processes observed within the area of the proposed Guanacaste National Park. Space does not permit review of the pertinent literature from other habitats, but this will be done in a later publication.

WHAT ARE THE TRAITS OF THE TWO PRINCIPAL KINDS OF HABITAT FRAGMENTS?

DECOMPOSING HABITAT FRAGMENTS

As logging, burning, and clearing for pastures and agriculture have whittled away at Guanacaste Province's dry forest in northwestern Costa Rica (e.g., Uhl & Buschbacher, 1985; Janzen, 1986a), the large and multi-habitat dry forest expanses have been reduced to fragments ranging in size from a few hundred hectares to areas containing only a single remaining tree. Species richness in these fragments is decaying to substantially lower equilibrium densities than once existed, but many decades will pass before a stable equilibrium level is reached (if ever). The rate and depth of decay depends on at least three major variables:

1. How directly prejudicial is the forest fragmentation process to the organisms in the remaining fragments? This aspect of fragmentation cannot be separated from the simple effects of reducing the size of the habitat (and thus the sizes of the constituent populations). Except in experiments (e.g., Lovejoy

et al., 1986) and massive logging or resettlement schemes, habitat is almost never reduced in area as if a giant cookie-cutter had cut out a small relict piece in one fell swoop. For example, the fragmentation and decomposition of dry forest by repeated fires has a quite different effect on its species composition than if some of the forest is left standing and some is bulldozed for cotton fields that are then allowed to change to brushy pastures.

2. Are there other areas that continually generate incoming individuals? In other words, is the population of any given species in a habitat fragment maintained by internal recruitment, colonists, or both? Incoming individuals may originate in the same or different kinds of habitat as the recipient habitat (e.g., Janzen, 1986e).

3. What proportion of the species have what population decay rates and individual life spans? A tree species whose individuals have a 400-year life span may persist in a habitat fragment long after that fragment can support a breeding population of the species, while an insect population might well disappear within weeks of the time when its population no longer achieves recruitment. Whether the observer is left with a feeling of pending doom as a dry forest is increasingly fragmented depends in great part on which kinds of organisms are censused as indicators. Agroecosystems based on what once was tropical dry forest are especially rich in the living dead—individuals living out a physiological life span but no longer occupying a habitat in which recruitment occurs (Janzen, 1986b).

GROWING HABITAT FRAGMENTS

The second kind of habitat fragment is very different from the shrinking relict mentioned above. In the long view of tropical conservation, growing habitat fragments are extremely important and complex; while shrinking habitats may even be accepted as they stand, growing habitats require management technology and choices. As more tropical restoration projects take root, there will be more efforts at initiating habitats, reconstructing habitats from fragments, and even reinstalling species from distant habitats and geographies. Restoration will often initiate growing habitat fragments that accumulate species richness to equilibrium levels as yet unknown. As they grow and coalesce, the three variables mentioned above will generally apply, but with different relative importance.

1. The selection of ecological processes (e.g., fire, hunting, grazing) to be stopped will determine the species richness, life forms, and habitat structure. Stopping hunting but allowing fire to continue yields a very different kind of habitat fragment than does allowing hunting but stopping fires. Stopping anthropogenic fires has a very different effect than does stopping natural fires. While the site may initially have had an equilibrium array of species, for all practical purposes and for many centuries it can sustain many different kinds of habitats during the restoration phase. Which habitat occurs will depend on the initiation and management processes.

2. Proximity of source areas for incoming species, as measured by the ability of individuals of species to arrive, establish, and recruit once present, will be very important in determining whether a growing fragment quickly or slowly rises to an equilibrium value. Since different groups of organisms have extremely different abilities to colonize, and since the chance of establishment in a habitat depends at least on what species have colonized earlier and the environmental traits of the habitat, I expect the rate of species buildup to be very irregular, with long periods of relative stasis.

3. Species will appear in a fragment long before they have attained a density at which their population can survive through recruitment and/or persistence within the habitat. That is to say, the species richness of a growing habitat fragment can easily be greater than the equilibrium density for a fragment of that size and set of conditions.

Study of the decay of species richness within a fragment requires either actual or inferential knowledge of reference or benchmark habitat. This is becoming extremely difficult in dry forest because this forest type has already been thoroughly fragmented for decades or even centuries. On the other hand, there are numerous opportunities to study species accumulation in growing habitat fragments, even if there are not enough species in the region to completely restore the habitat.

INITIATION AND GROWTH OF HABITAT FRAGMENTS

The manner of initiation and growth of habitat fragments in Santa Rosa's dry forest is a novel process in the evolutionary and ecological history for these habitats and for this fauna and flora (just as it would be for other tropical restoration projects). Even though much of Santa Rosa has been cleared to bare ground by volcanic activity in the past, habitat restoration (primary succession) on such a site is different in many ways from the secondary succession that occurs when habitats are initiated and grow in old fields, abandoned pastures, or repeatedly burned forest. However, be they novelties or otherwise, understanding the biology of growing fragments is critical to survival and maintenance of Santa Rosa's tropical dry forest.

Growing habitat fragments in Santa Rosa are most commonly initiated in abandoned pastures. Even if land is lumbered or cleared for fields, it is usual for such areas to be converted to pastures before the restoration process is allowed. Most Santa Rosa pastures are almost pure jaragua (*Hyparrhenia rufa*) with a sprinkling of native herbs, though a few pastures of native grasses remain on the poorest, driest, and/or rockiest soils (e.g., Santa Elena Peninsula and Cerro El Hacha), and pastures of other introduced grasses occur on the moister volcanic slopes. The abandoned or lightly used pastures in Santa Rosa range from grass patches of less than a hectare to several km^2 in area.

Abandoned pastures initially range from virtually lacking trees and treelets to quite rich in sucker shoots from old and large root systems. Santa Rosa pastures are also dotted with the occasional seedling or sucker shoot from a sapling tree or treelet. The numbers, sizes, and kinds of large woody plants in a newly abandoned pasture depend on its age, frequency and timing of burning, timing of pasture "cleaning," proximity to forest (e.g., Purata, 1986), kind of livestock, stocking density, and numerous other variables (just as is the case in extratropical invasion of abandoned fields and pastures by forest, e.g., Olsson, 1984, and included references). All of the initially present woody plants are potential starting points for dry forest habitat initiation (see "nuclear trees" discussed below) and add to the composition of a growing habitat fragment without having to arrive by dispersal.

Expanding and filling habitat fragments range from being totally isolated to being expansions of an existing forest into an adjacent pasture. Placement of these fragments is not haphazard and often has clear relationships to fire patterns, wind direction, animal availability, soil moisture and contour, kinds of nearby forest, and other factors.

TWO PRINCIPAL KINDS OF HABITAT INITIATION

Almost all fires were stopped in abandoned pastures in Santa Rosa's dry forest through an active fire control program initiated in the 1984 dry season. All modern fires in the Santa Rosa area are set by humans or arrive as free-running wildfires that were set by humans. In some of the park pastures, fires even stopped at the time of park establishment in 1972 (or later, 1972–1983) because they were sufficiently isolated that only deliberately set fires got to them. There are even some old pastures or pasture remnants in the park that have not been burned for many decades because woody succession isolated them from the pastures that traditionally burned. As a general rule in Santa Rosa, when woody succession has proceeded to the point where the overstory canopy shades out the grasses and herbs, the forest does not carry a fire (though there are special circumstances, to be described elsewhere, in which enough dry forest can burn to initiate a return to grassland).

When livestock were finally removed from Santa Rosa in 1978–1979, an important ecological process was altered. Livestock had maintained the jaragua at a low level through heavy grazing. Grass fires had relatively little fuel, and a conspicuous equilibrium was maintained between forest/pasture edges; in dry years or when the fire was late in the dry season, it nibbled away the margins of the forest. In wet years or when there was an early burn, the forest margins moved slightly into the pasture. When the cattle were removed, the jaragua formed dense stands 1–2 m in height within a single rainy season. These stands shade woody plant seedlings and provide enough fuel to support very hot and thorough fires at any time in the dry season (such stands even support fires during droughts in the rainy season). This initiated a rapid decline in the area and quality of dry forest fragments surviving in the abandoned pastures and on their margins. This decline stimulated the fire control program initiated in the 1984 dry season.

The two processes of forest initiation described below are occurring in fire-free and cattle-free contemporary Santa Rosa. Were the park to be returned to either cattle-rich, fire-rich, or cattle- and fire-rich status, the details of these processes would undoubtedly be different.

Habitat establishment through seed dispersal by wind.

In many of Santa Rosa's abandoned pastures free of cattle and fire, a distinctive set of woody species has appeared as the forest moves into the pasture. At least 90% of the trees and treelets have wind-dispersed seeds. The vertebrate-dispersed initial colonizers, such as *Cecropia obtusifolia*, *Piper* spp., *Trema micrantha*, *Muntingia calabura*, *Spondias mombin*, and *Bursera simaruba*, are almost entirely absent. For example, the oldest explicit regeneration plot (CT Regeneration Plot, on soils derived from a flat, volcanic welded ashflow) in the park was last swept by fire in the 1979 dry season (it was a jaragua pasture that had been frequently burned pasture of some kind for several hundred years). Today (end of the 1986 rainy season), the following 12 species constitute at least 90% of the 5,000-plus individuals and biomass of trees and treelets in the 3-ha plot (all trees of all sizes in the plot are registered and mapped): *Ateleia herbert-smithii*, *Acosmium panamensis*, *Lysiloma auritum*, *Dalbergia retusa* (Leguminosae); *Rehdera trinervis* (Verbenaceae); *Cordia alliodora* (Boraginaceae); *Luehea speciosa* (Tiliaceae); *Swietenia macrophylla* (Meliaceae); *Tabebuia rosea* and *T. ochracea* (Bignoniaceae); *Cochlospermum vitifolium* (Cochlospermaceae); and *Hemiangium excelsum* (Hippocrateaceae). All plants in this plot arrived by their own means, and the vegetation was not manipulated.

All these species have wind-dispersed seeds. However, Santa Rosa has a native tree and treelet flora of 215 species (Janzen & Liesner, 1980) of which 25% are wind dispersed; 64% are vertebrate dispersed. More than 100 species of vertebrate-dispersed trees and treelets maintain breeding populations within 200 m of the CT Regeneration Plot. It is clear that habitat initiation in this plot is based on an ecologically distinctive subset of the species pool (cf. Beyer, 1975, for a curiously similar extratropical example).

There is one major reason why vertebrate-dispersed species are scarce in this restoration site. Among the many seed-dispersing vertebrates in the park, only white-tailed deer (*Odocoileus virginianus*) and coyotes (*Canis latrans*) encounter resources in a pure stand of jaragua. A deer sometimes uses it for cover when resting and spits out *Spondias mombin* (Anacardiaceae) and *Byrsonima crassifolia* (Malpighiaceae) nuts when chewing its cud (Janzen, 1985). Coyotes hunt there for cotton rats, *Sigmodon hispidus*, and defecate tree seeds such as *Manilkara chicle* (Sapotaceae) and *B. crassifolia*. Other vertebrates that disperse trees and treelets (e.g., collared peccaries (*Tayassu tajacu*), coatimundis (*Nasua narica*), magpie jays (*Calocitta formosa*), and tapirs (*Tapirus bairdii*)) only defecate in the pasture when they happen to cross it on their way from one forest to another; in addition to the two plants listed above, these animals have dispersed a few individuals of *Enterolobium cyclocarpum* and *Acacia collinsii* (Leguminosae), *Genipa americana* and *Alibertia edulis* (Rubiaceae), and *Annona reticulata* (Annonaceae) into the CT Regeneration Plot. This particular abandoned pasture did not have a tree that served as a nuclear tree (see below) though the single old *Acrocomia vinifera* palm could have served that role. Also, animal-rich forest only occurs along one side of the plot and so there is little reason for animals to cross it.

There are many places in Santa Rosa where patches of wind-generated forest have recently been initiated as major protrusions into abandoned pastures. Examination of these forest fragments (or peninsulas) over the past few years allows a number of generalizations:

1. Not only is an abandoned jaragua pasture initially unattractive to seed-dispersing animals because the grass usually does not represent food or other resources, but the growing forest made up predominantly of wind-dispersed trees offers no food for frugivory (by monkeys, bats, coatis, tayras, tapirs, peccaries, deer, numerous birds) compared with a forest fragment containing a more balanced mix of seed dispersal types. Since the wind-dispersed trees are first to colonize the site, they physically and numerically dominate it for many decades as they live out their life spans. While the site does offer shade and some foliage and seeds, it still lacks a major class of food.

2. The wind-dispersed initial colonizers are large trees (attaining heights of 15–25 m) and live for 50 to several hundred years. There is no wave of early successional, short-lived, and comparatively small species. It is even tempting to suggest that a wind-dispersed colonizing tree has to be tall in dry forest, or it won't be tall enough to have its seeds blow over the canopy and into tree falls and other gaps in the canopy. Put another way, in a climatic regime that grows a tall forest, only canopy-level or emergent trees (and high-climbing vines) will successfully colonize that forest via wind-dispersal or evolve wind-dispersal.

3. Not only does a wind-dispersed dry forest lack fruit, but all its seeds are well protected against vertebrate postdispersal seed predators. The species with big seeds in conspicuous fruits or other dispersal units (e.g., *Lonchocarpus* spp., *Acosmium*, *Swietenia*, *Hemiangium*, *Ateleia*) have very toxic seeds (e.g., Janzen, 1986d). Those with edible seeds (e.g., *Cochlospermum*, *Rehdera*, *Luehea*) have very small seeds that easily escape by self-burial in the litter.

4. As the first wave of wind-dispersed trees reaches maturity and begins bearing seeds, the dispersal process in the fragment does not change. By contrast, in a site that is invaded by vertebrate-dispersed tree species, the pattern of the dispersal process will change as the trees come into reproductive maturity and begin to attract animals. Some of these animals (e.g., agoutis (*Dasyprocta punctata*)) play no part in initiating the forest fragment. This attraction will increase the rate of accumulation of plant species in the habitat fragment.

5. The majority of the large trees in Santa Rosa (many with fruits eaten by vertebrate dispersal agents) require at least as much sunlight as is made available when a tree falls to grow into saplings (the evergreen *Manilkara chicle* is the only obvious exception). Once the habitat fragment is occupied by large wind-dispersed trees, the species composition of the canopy will not significantly change its composition until these wind-dispersed trees begin to die of senescence (and create tree falls) many decades later, even if there is a very heavy flow of vertebrate-dispersed seeds into the site during intervening years.

6. A wind-dispersed forest does not expand into a pasture from all compass directions. A pasture on the downwind side of a forest of mixed dispersal types receives a heavy inoculum of wind-dispersed seeds, but a pasture upwind of forest receives none. This process is especially critical to restoration efforts if the upwind margin of the pasture borders

on a park boundary with agricultural land, ocean, or other nonforest habitat. Vertebrate-dispersed seeds in a pasture may have come from any direction. In Santa Rosa, the dry season winds blow almost invariably from northeast to southwest; rainy season winds blow in many different directions, but there are no wind-dispersed trees or treelets that mature their seeds at this time (see 10 below).

7. The only parents of wind-generated fragments in pastures are trees near the forest–pasture interface. Even a few tens of meters of forest thoroughly filter out wind-borne tree seeds (e.g., Augspurger, 1986). On the other hand, the vertebrate-dispersed seeds falling into a growing habitat fragment in an abandoned pasture may have passed through forest expanses hundreds to thousands of meters wide.

8. Wind-dispersed seeds at Santa Rosa move up to about 200 m into pastures, but a more common distance is 0–100 m. The seeds move greater distances if the parents are maximally tall individuals that have grown up in competition with other forest trees (i.e., near forest margins) rather than shorter isolated trees in open pastures. This means that wind-generated growing habitat fragments will always be near another forest with adult trees in it.

9. Wind-generated seed shadows are often dense and very uniform compared with vertebrate-generated seed shadows (which have conspicuous heterogeneity associated with perches, waterholes, trails, shade, steep contour, tourist presence, and other factors). If there is one member of a wind-dispersed species of tree maturing in a growing habitat fragment, there are likely to be numerous others (unique individuals of vertebrate-dispersed trees are commonplace in growing habitat fragments, see below).

10. Forests of wind-dispersed species bear no ripe fruits or seeds throughout the rainy season (no Santa Rosa species of wind-dispersed tree or treelet ripens its fruits in the rainy season). Associated with this, the wind does not blow with equal intensity and pattern throughout the year. The highest average wind velocity occurs during the first half of the dry season (December through early March). The days with the strongest wind occur in late December and January. During the dry season the most intense winds occur during the central part of the day (when it is driest and fruits are most likely to be shed or broken off, and fruits are most likely to dehisce). During the rainy season, there are many nearly calm days, and winds often occur during rainstorms (when a wind-dispersed fruit or seed would have little or no chance of dispersal). Another barrier to wind-dispersal during the rainy season is that wind-dispersed units of dispersal lose weight at maturity by drying out, which does not occur readily in the rainy season.

Along the same lines, almost all wind-dispersed seeds at Santa Rosa appear to germinate within a few weeks of being wetted by the first rains. There is a major pulse of seedling appearance with the first rains (from seeds accumulated during the dry season) followed by no further seedling input or site colonization during the six-month rainy season. Vertebrate-dispersed seeds in Santa Rosa display many kinds of dormancy and new seedlings of many species appear at different times during the rainy season. Since many of these seeds are dispersed during the rainy season, a habitat fragment can be initiated at this time of year from dispersing seeds or from seeds in the soil.

Habitat establishment through seed dispersal by vertebrates.

Vertebrates play a much more complex role than does wind in initiation and growth of habitat fragments. This is because:

a) There are nearly three times as many species of vertebrate-dispersed than wind-dispersed trees and treelets in Santa Rosa, and they bring with them more life forms and kinds of ways to occupy a site than are found among the wind-dispersed species.

b) There are many more kinds of vertebrate-generated seed shadows than wind-dispersed seed shadows in Santa Rosa.

c) The pattern of forest initiation depends on the biology of the animals as well as on the biology of the plants. The wind has not evolved and coevolved with plants, and the plants can only evolve, not coevolve with the wind.

Here, I focus on one particular kind of vertebrate-generated forest initiation in Santa Rosa pastures, that which is associated with nuclear trees.

A nuclear tree is a single tree that appears in a pasture and is then attractive to animals that defecate or otherwise drop seeds in its vicinity (see McDonnell & Stiles, 1983; Beckwith, 1954; Debussche et al., 1982, for ornithological extratropical examples). The animals go to the tree as a perch, for shade, to eat its fruits, to mark ranges, and other reasons. Whether a nuclear tree and its associated seed rain actually becomes a growing fragment of forest habitat depends on numerous environmental variables ranging from the rate and kind of seed rain to the depth of the grass, soil conditions, species of nuclear tree, fire regime, and other factors. For example, many of the best contemporary examples of vertebrate-generated growing habitat islands in Santa Rosa are centered on guanacaste trees (*Enterolobium cyclocarpum*) on small rocky outcrops that protected the sapling from low grass fires (in the heavily grazed pastures). Within a few years after cattle were removed from Santa Rosa, the high grass fires swept across these small fragments and obliterated many of them and their nuclear guanacaste trees.

Representative nuclear trees in Santa Rosa are guanacaste, cenizaro (*Pithecellobium saman*, Leguminosae), guacimo (*Guazuma ulmifolia*, Sterculiaceae), jobo (*Spondias mombin*, Anacardiaceae) and figs (*Ficus* spp., Moraceae), but many other species can serve this function (some are remnant wind-dispersed trees standing as the sole survivors of a dwindled forest fragment).

A growing dry forest fragment that has been generated by vertebrates around a nuclear tree in the center of an abandoned pasture has a number of distinctive traits:

1. Wind-dispersed species of trees and treelets are absent (unless they were present as persistent suckers at the time of fragment initiation). That is to say, the species pool from which the fragment is potentially drawn is some subset of the 138 species of vertebrate-dispersed trees and treelets in Santa Rosa.

2. Certain vertebrate-dispersed species are missing because they are usually dispersed by vertebrates that either never cross pastures or are very unlikely to carry one of these seeds when they do. For example, agoutis and monkeys are very unlikely to carry the large seeds of guapinol (*Hymenaea courbaril*, Leguminosae), panamá (*Sterculia apetala*, Sterculiaceae), and tempisque (*Mastichodendron capiri*, Sapotaceae) across a pasture.

3. The species and age of the nuclear tree will influence the species composition of arriving seeds. If it bears edible fruits (which is very likely since wind-dispersed nuclear trees are almost nonexistent in large pastures), the species composition of the seed rain during fruiting will be strongly influenced by the assortment of animals attracted to its fruit. Additionally, different species of trees offer different kinds of perches and shade, which likewise will influence animal visitors and their seed cargoes.

4. The species and age of the nuclear tree will influence the survival of the seedlings below it through differential shade effects on grasses and woody seedlings, protection of seedlings from fire through shading out grasses and keeping the soil moist, and the duration of its deciduousness during the dry season.

5. The trees accumulating around a nuclear tree are usually smaller and shorter than the nuclear tree because they are younger than it and because they compete with it. The canopy is therefore dome-shaped with the nuclear tree near the center rather than flat-topped (as is the case in wind-generated habitat fragments).

6. The understory of a vertebrate-generated habitat fragment often contains reproducing treelets and shrubs, e.g., *Chomelia spinosa*, *Alibertia edulis*, *Psychotria* spp.

(Rubiaceae); *Piper* spp. (Piperaceae); *Erythroxylon havanense* (Erythroxylaceae); *Malvaviscus arboreus* (Malvaceae), *Hirtella racemosa* (Chrysobalanaceae); *Ximenia americana* (Olacaceae); *Casearia* spp. (Flacourtiaceae); *Ocotea veraguensis* (Lauraceae); and *Annona reticulata* (Annonaceae). Reproducing small plants are generally missing from the understory of a wind-generated forest fragment.

7. Owing to the larger species pool and area from which the species are drawn, species richness of trees and treelets is substantially greater in growing vertebrate-generated habitat fragments than in wind-generated ones. However, if there is frequent animal movement through a wind-generated habitat fragment, the sum of the wind-dispersed species and the animal-dispersed species gives the most species-rich habitats of all.

8. Except for the very large seeds that are not carried out into a pasture (see 2 above), all sizes of seeds arrive at a vertebrate-generated habitat fragment. However, there should be some sorting with distance as fragments get so far out into a pasture that small frugivorous birds are less likely to go to them. In contrast, a wind-generated growing forest fragment should also display sorting whereby the species with lighter seeds move further downwind in the initial invasion.

9. A vertebrate-generated habitat fragment can grow in any direction, rather than downwind as does a wind-generated habitat fragment; and a vertebrate-generated fragment can range from a distant island to a peninsula, while a wind-generated fragment is usually a peninsula from an established forest.

10. The seeds in a vertebrate-generated habitat fragment may come from as far as many thousands of meters from the fragment, and from any compass direction. The tree species in the fragment are thus likely to represent a much greater portion of their respective populations than is the case with a wind-generated patch (which is derived from the immediately adjacent forest). Associated with this process is the fact that vertebrate-generated habitat fragments often contain isolated representatives of a species; whether these individuals can reproduce (through long-distance pollination or by being self-compatible) varies with the species. However, it is quite likely that such species occasionally exceed the species carrying capacity of the fragment, since if it does not maintain itself in the fragment, it is not present in some senses.

11. Since there are some vertebrate-dispersed tree species in fruit throughout the year in Santa Rosa, there are likewise trees and treelets in fruit throughout the year in the vertebrate-generated growing habitat fragments.

12. As a habitat fragment grows by vertebrate input of seeds (and by internal recruitment), its margins become less likely sites of seed deposition. The rate of expansion of a habitat fragment noticeably declines as it becomes more than about 0.5–1 ha in area.

DISCUSSION

I have briefly described two prominent kinds of forest habitat initiation and growth in abandoned pastures in Santa Rosa's dry forests. There are also many other kinds of habitat initiation occurring in this park at present. It is evident that the initial processes in habitat initiation will determine the species composition and structure of the forest for many centuries on these sites. It is equally evident that the actions of park managers will determine the kinds of habitat initiation that occur. If the park is left completely to itself, one kind of mosaic will occur. If livestock are used to depress the grass in certain areas, a different kind of mosaic will occur. If nuclear trees are planted far out into pastures or seeded there in the dung of cattle (as occurs with guanacaste and cenizaro trees if the cattle have access to fruit crops), a third kind of mosaic will occur. If native timber trees are seeded in by air or hand, and then natural succession is allowed to continue (as an example for those who want to know how to return worthless dry forest pastures to timber production), the resultant forest will depend in great part on the particular species of timber trees used (fleshy fruit-bearing versus wind-dispersed, evergreen versus deciduous, fast- versus slow-growing). Pastures near forests rich in seed-dispersing mammals and birds will initiate quite different kinds of forest than will those in areas relatively free of vertebrates due to poaching, heavy tourist use, or experimental removal.

It is clear that the managed fate of the entire area of tens of km^2 of pasture in Santa Rosa or several hundred km^2 of pasture in Guanacaste National Park should not be the same from area to area. But whatever kinds of management of habitat fragment initiation and growth are to be applied, it will require basic research into the multiple pathways that secondary succession can follow in this species-rich situation. Whether these pathways will finally converge on a single kind of vegetation for any given site is almost irrelevant, since this will take thousands of years to occur and we have to deal with the situation at hand.

How broadly applicable is the philosophy espoused in this essay? Rainforest restoration has not been explicitly tried, but it is an integral part of traditional shifting agriculture in some areas and has occurred throughout the wet tropics where farms and homesteads have been abandoned when farmers have been relocated out of an area slated to become a rainforest national park. The details of rainforest restoration will obviously be different from those in dry forest, but there will be many similarities.

One difference is apparent even at this early stage of understanding. When a clean pasture is abandoned next to a pristine rainforest, the rate of rainforest tree and treelet movement into it appears to be much slower than in seemingly equivalent cases in dry forest. This is the case even in the wetter eastern end of Guanacaste National Park as compared with the central drier part. There are at least three possible causes. First, rainforest vertebrates may be even more reluctant to enter rainforest pastures and use nuclear trees, for example, than are dry forest vertebrates. Second, the general lack of strong directional winds in rainforest may impede movement of wind-dispersed species into pastures. Third, and I suspect the most likely case, a seedling from a dry-forest seed dispersed into a dry-forest pasture finds itself in a much more foreign environment than does a seedling from a rainforest seed dispersed into a rainforest pasture. The heat, sun, wind, dryness, and fluctuations of an open pasture are much more similar to the rigors of dry forest than they are to the understory of a rainforest (even in a tree fall). Additionally, dry-forest pasture soils are rich in spores of endomycorrhizal fungi while rainforest pasture soils are generally very poor in them (D. Janos, pers. comm.). Certainly at Santa Rosa there is no indication that the physical conditions of open pasture habitat are lethal to tree seedlings, even when they are species commonly associated with relatively moist habitats (e.g., *Hymenaea courbaril*, *Manilkara chicle*).

Blydenstein (1967) described the mosaic of Venezuelan grazed pasture and forest patches as the result of a dynamic interaction between dryness and fire, just as occurred in Santa Rosa before the fire and cattle were eliminated. In some ways, this dynamic is a fine-scale version of the global balance between the dwindling tropical wildlands and restoration systems such as that occurring in Santa Rosa National Park and the proposed Guanacaste National Park area. At present we are in a continuous drought and fire phase, with the forest patches shrinking very, very rapidly. If the dynamic is to have any significant balance, forest restoration is going to have to start up throughout the tropics. It must start not only in places like Guanacaste National Park, where remnants of the plants, animals, and habitats are still present, but also in the large expanses of the tropics where there is virtually nothing left. For example, in countries like Costa Rica, virtually all rainforest parks are on hilly to mountainous soils, with the true flatlands either cleared or almost cleared. The real challenge is whether with fencerow populations, woodlot populations, and living dead (Janzen, 1986f) one can put back together even a first approximation of the flatland rainforests that once stood on the enormous acreages of low-yield rainforest fields and pastures.

The question has been raised as to why Guanacaste National Park needs to be as large as 800 km², especially since about 90% of the habitat has been partly homogenized through partial destruction. The traditional answer is that a large area is needed to maintain even minimal populations of the wide-ranging large animals and the big trees. A less traditional, but nonetheless compelling, answer is that the area must be large to maintain intact wildlands *and* be extremely accessible to tourists, researchers, managers, and school groups; these are the people whose votes and long-term use will keep GNP alive. But there is also a less conventional biological reason that is especially pertinent to dry forest. Intact dry forest is a very complex mosaic of many small fragments of habitat types nestled in amongst each other, generated by soil type, drainage, wind exposure, slope, and rainfall. This mosaic of conditions and species is largely responsible for the many pathways that may be taken by secondary succession in an abandoned pasture; two pastures with identical conditions may easily be positioned next to two quite different source areas for the species that will colonize it. A given animal or plant species exists as a population supported by one or more of these habitat types, but the support base is highly fragmented. A dry forest wildland must be big so that the total area contains enough pieces of a given habitat type (e.g., dry ridges) to support healthy populations of the species that are supported by that habitat type. Yes, there are 800 km² of dry forest in GNP, but, for example, less than 100 km² supports the endemic population of the tree *Ateleia herbert-smithii*, the only legume in the world that is known to be wind-pollinated (Janzen, 1988c).

This worry applies to rainforest as well. Yes, it all appears to be just a sheet of green, but as soon as it is necessary to find any tree species, or any constellation of species, the biologist learns to search for the subtle differences in drainage, soil, and other factors that lead to the highly localized target. When the professional conservationists tell us that X% of the rainforest still remains, and that Y% of X is disappearing daily, it is imperative to remember that 0% of many of the habitat types of tropical rainforest remain. Furthermore, that Y% is not spread proportionately over the remaining types, giving us an equal amount of time to crusade for what remains. It is critical to identify those rainforest habitat types that are as threatened as is the tropical dry forest and focus restoration projects on them. The battle for mesoamerican tropical dry forest conservation should have been fought in the year 1800; don't wait until the year 2000 to begin to fumble with the rainforest pieces worth restoration.

FACTORS CONTROLLING SPECIES DIVERSITY: OVERVIEW AND SYNTHESIS

Jared Diamond[1]

ABSTRACT

Factors controlling species diversity are usually presented as a laundry list without organization—for instance, "The tropics have more species than the temperate zones because of greater stability and *reduced seasonality* and *higher productivity* and *more diverse resources* and . . . ." *This paper instead proposes a fourfold grouping of factors, termed the QQID approach. Q = resource quality, consisting of the habitat and resource factors that determine the "number of niches." Q = resource and consumer quantity, consisting of factors determining the quantity of resources (i.e., area and productivity), and factors determining the number of consuming individuals (especially body size) that divide those resources. I = species interactions, which may boost or lower species diversity through effects on individual numbers or individual fitnesses. D = dynamic processes (e.g., extinction, immigration, and speciation), which affect species diversity in both equilibrial and nonequilibrial situations. I illustrate this approach by applying it to understand the famous gradients of species diversity over altitudinal and latitudinal gradients. A major problem for the future involves seeking generalizations as to which factors are likely to be most important under which circumstances. Another problem is to convert this empirical fourfold grouping into a natural hierarchy of factors, possibly based on a hierarchy of processes in space and time.*

INTRODUCTION: THE QQID APPROACH

This article aims to provide an overview of the many factors controlling species diversity. My minimum goal is to construct a simple, four-step checklist for analyzing the determinants of species diversity in any given case (Table 1). I shall also briefly suggest an approach by which this checklist, designed for practical purposes, might be converted into a natural hierarchy of the determinants of species diversity. My examples will be drawn mostly from the other papers of this symposium.

At the outset, let us be clear why the problem of understanding species diversity is complicated. In the first place, species diversity is surely not determined in all cases by the same single factor but is the outcome of many contributing factors. Secondly, while one can formulate "rules" about species diversity, each rule has many exceptions. For example, island species diversity usually increases with island area, but there are more frogs on little Barro Colorado Island than on the much larger Cuba (Duellman, this volume). Island species diversity generally decreases with distance from the mainland, but one of the world's most remote archipelagoes, Hawaii, has more species of *Drosophila* than do continents. Species diversity as one ascends a mountain generally decreases with altitude, but along the western slopes of the Andes above Chile's Atacama Desert it increases from middle to high elevations (Arroyo et al., this volume). Small-bodied species are generally more diverse than large-bodied species, but whale diversity exceeds insect diversity in the open ocean. These exceptions to rules based on single factors arise in part for the obvious reason that species diversity is the outcome of many factors, so that the effect of one factor may be overridden by others. Partly, too, the reason is that some of the determinants of species diversity, such as predation, herbivory, disturbance, seasonality, and environmental predictability, control diversity in a nonmonotonic way, so that an increase in those factors may yield either an increase or a decrease in diversity.

Do the factors controlling species diversity just constitute a laundry list, a catalog without organization? Discussions of the latitudinal

TABLE 1. *The QQID formulation of factors controlling species diversity.*

Q = Quality

1. Diversity of niches or resources
    - E.g., habitat structural complexity, habitat diversity, resource species diversity, temporal variability, and diversity of consumer strategies.

Q = Quantity

2. Number of consumer individuals, N
    - $N = R/R_0 = AP/R_0$
    - where R = available quantity of resources
    - R_0 = resource requirements per individual (increases with body size)
    - A = area
    - P = productivity per unit area

I = Interactions

3. Species interactions
    - Effects on N
        - Increase of N
            - Predation or herbivory on competing species
        - Decrease of N
            - Resource competition
            - Predation or herbivory on the consumer itself
    - Effects on individual fitness
        - Increase of fitness
            - Mutualism
        - Decrease of fitness
            - Interference competition
            - Parasitism
            - Disease

D = Dynamics

4. Species dynamics
    - Effects of dynamics at equilibrium
        - Effects of extinction rates (decrease with N, etc.)
        - Effects of immigration rates (increase with proximity, vagility, larval settling rates, etc.)
        - Effects of speciation rates (decrease with vagility, etc.)
    - Nonequilibrium situations
        - Pulse disturbance
            - Transiently depressed species diversity
        - Recent pulse decrease in area
            - Transiently elevated species diversity

gradient in species diversity often read that way: "The tropics have more species than the temperate zones because of greater stability *and* reduced seasonality *and* higher productivity *and* more diverse resources *and* . . . ." In fact, life is full of multi-determined phenomena (e.g., whether to declare war, whom to marry, how many children to bear) that at first appear to be influenced by innumerable factors, but for which the factors actually prove to fall into just a few groupings. In some cases, the groupings may even define a natural hierarchy or decision path of factors.

For example, suppose you want to know what determines the number of children in any given candy store. The number obviously depends on the quality or variety of candy to be seen in the window. It is also heavily influenced by the quantity of candy or the size of the store. A little reflection also shows that the number of children in the store depends on interactions, such as those with attractive fairy godmothers beckoning at the door, or with bullies or hungry lions inside. Finally, there is also some role of dynamic or nonequilibrium factors, such as how long ago the doors opened, or how large is the pool of children available for colonizing the store, and where the store is (particularly relative to a school). Thus, the numerous determinants of the number of children in the store sort out into four sets of considerations: quality of resources, quantity of resources, interactions, and dynamics.

It seems to me that species diversity as well is determined by the same four sets of factors—quality, quantity, interactions, and dynamics (Table 1). As a simple mnemonic, I shall abbreviate this accounting as "QQID."

Q. Discussions of species diversity usually start out with an analog of the quality or variety of candy: namely, the diversity of niches or of resources. Hence my first, simplest approach will consider just the diversity of niches without taking into account the quantity of resources or the number of consumer individuals or species interactions. We shall pretend that the environment is constant and without temporal variation, that the world is at equilibrium, and that species dynamics are nonexistent or irrelevant.

Q. Next, I shall take account of the quantity of resources, which partly determines the number of consumer individuals.

I. Thirdly, I shall add consideration of species interactions.

D. Finally, I shall incorporate consideration of dynamics and shall allow for the possibility of nonequilibrium.

Q: Resource Quality

The ecological equivalent of the variety of candy is the number of niches or of resources. One of the basic findings of ecology is that species diversity increases with niche or resource diversity, as expressed in the statement that each species must occupy a distinct niche. This ubiquitous generalization is the outcome of two facts. First, any given genotype can do certain things (e.g., harvest certain resources by a certain method) better than other things. Second, a single gene pool (i.e., one species) can comprise only a certain diversity of genotypes because of the constraint that the individuals carrying those genotypes must be reproductively inter-compatible in order to remain members of the same gene pool. The combination of those two facts has the consequence that each species occupies a certain "niche," however defined, and that species diversity increases with niche or resource diversity.

Many familiar predictors of species diversity fall under this heading of niche diversity. Among the many examples of predictors that could be cited, I shall discuss five that are well illustrated by the papers of this symposium.

Habitat structure.

It is commonly found that habitats with a more complex or variegated structure contain more species than do simpler habitats. Thus, within any given group of taxa there are generally fewer species in a rock desert than in an adjacent grassland, fewer in the grassland than in an adjacent savanna, and fewer in the savanna than in an adjacent tropical rainforest. The symposium papers by Gentry, Erwin, and Duellman emphasized that peak diversities of plants, beetles, and frogs are achieved in tropical rainforest. For birds a rough quantitative measure of habitat structural complexity that serves to predict species diversity is the habitat's foliage height diversity: that is, a diversity measure of how foliage is distributed among different vertical layers of the habitat (MacArthur et al., 1966).

Habitat diversity.

Another expression of niche specialization is that a particular species tends to occur only in certain habitats and not others. Thus, as one proceeds along a habitat gradient, one accumulates more and more species, and the accumulated number of species increases with the diversity of habitats encountered. Familiar examples are that species accumulate as one goes along an elevational gradient on a mountain, a depth gradient in the sea, or a horizontal sequence of habitats on land or in the intertidal zone. One example from this symposium is that most neotropical wet forest tree species are confined to a single forest type or soil type (Gentry, this volume). Another example is that 83% of the beetle species at Manaus, Brazil, are similarly confined to a single forest type (Erwin, this symposium).

Species themselves as niches or resources. Species may constitute niches or resources for exploitation by other species. Thus, diversity of consumer species tends to increase with diversity of resource species. For instance, there are more stenophagous herbivorous beetle species in tropical rainforest than in a temperate woodland because the rainforest has many more tree species. An example is that many neotropical rainforest beetle species are confined to a single tree species; some may even be confined to the interface of a particular pair of tree species (Erwin, this symposium).

Temporal variability. Time also serves as a niche dimension that can be partitioned, so that temporal variability provides opportunities for differentiation absent in an environment that is constant with time. For example, the 24-hour solar cycle permits differentiation between nocturnal, crepuscular, and diurnal species exploiting similar resources in the same habitat. The annual cycle permits species to specialize by adopting various seasonal strategies, as exemplified by the coexisting insect species with different overwintering strategies, or by bird species that coexist in the breeding season but segregate in winter as a result of some being migratory, others resident. Still longer cycles in a variable environment permit the differentiation of *K* strategists from *r* strategists. A striking example from this symposium is the 97% turnover of beetle species in a single tree species of Barro Colorado Island between the wet season and dry season (Erwin, this symposium).

Consumer strategies. Species that harvest similar resources in the same habitat may coexist by employing different foraging techniques, or by adopting differing life-history strategies. Here, too, this symposium has provided a striking example: the 28 alternative reproductive modes by which frogs solve the common problem of producing offspring while protecting them from desiccation (Duellman, this volume).

These five sets of examples do not exhaust the axes along which coexisting species may segregate. Readers will undoubtedly be able to think of further biologically significant ways in which differences in resources or in other niche parameters are exploited by different species.

QQ: Quantity of Consumer Individuals or of Resources

In the preceding discussion we have ignored consideration of the quantity of resources. We have pretended that a resource is either present in sufficient quantity to support a species, or else the resource is absent. However, resource quantity is obviously important because species are packaged in discrete units (i.e., individuals), and a population consisting of too few individuals cannot survive. There is no hard rule as to how many constitutes "too few," but a population consisting of one individual of a species practicing sexual reproduction is clearly doomed to extinction within one generation, a population size of two (one male, one female) is extremely precarious, and only populations with an effective size above 500 are considered reasonably safe even in the short run (Frankel & Soulé, 1981; Soulé, 1986). Thus, the species diversity of any given group of taxa generally increases with the group's total population size.

However, population size, the number of consumer individuals, does not depend only on quantity of resources. More generally, population size equals the total quantity of resources available, divided by the quantity of resources required to sustain one individual. Resource quantity in turn equals the product of area times productivity per unit area, while quantity of resources required per individual increases with body size. Thus, the second "Q" in our "QQID" formulation groups three factors: the increase in species diversity with area, productivity, and decreasing body size.

Area.

The most familiar generalization of island biogeography is that species diversity on islands, mainland habitat patches, or arbitrarily defined mainland census plots increases with area. This species/area relation arises partly from the increase in habitat diversity with increasing area sampled, but also from the direct proportion between area on the one hand and resource quantity and thus consumer population size on the other hand. An example from this symposium is Janzen's (this volume) comment that conservation areas in Costa Rican dry forest should be at least 500–1,000 km^2 in extent, because smaller areas would contain too few individuals of important species to sustain their populations.

Productivity.

Productivity increases with increasing rainfall or temperature, hence with decreasing latitude or altitude. Since number of consumer individuals increases with productivity, species diversity also increases with productivity. This symposium has provided three clear examples. First, plant species diversity on the western slope of the Andes rising out of the Atacama Desert of Chile increases with rainfall (Arroyo et al., this volume). Second, neotropical plant species diversity, collectively or else of each life form considered individually, increases with rainfall up to an asymptotic value (Gentry, this volume). Finally, neotropical rainforest beetle species diversity is much higher in the forest canopy than in lower vertical strata, because the canopy intercepts most of the solar energy and is the most productive stratum (Erwin, this symposium). (Note that these arguments implicitly assume a more or less uniform increase in productivity across the resource spectrum. If production of only certain resources is increased, as in a eutrophic pond, the outcome may be reduction rather than increase in species diversity, because those consumer species specializing on the increased resource type will thrive and may eliminate other species by preempting their resources.)

Body size.

The product of area times productivity equals the total quantity of available resources, but the body sizes of the consumers determine among how many individuals those resources may be apportioned. Thus, for a given resource quantity and hence given consumer biomass (ignoring second-order effects from the variation in metabolic rate per gram of tissue with body size), consumer population size decreases with body size. Hence, all other things being equal (which they often are not), there tend to be more species of small-bodied animals than of large-bodied animals. In the canopy, Erwin (this symposium) encountered thousands of species of beetles but not of elephants. The whole neotropical region contains only 1,545 species of frogs (Duellman, this volume), a number exceeded by the beetle species in a single tree canopy (Erwin, this symposium). Even among beetles, species diversity is highest in Erwin's smallest size class of beetles.

All these examples illustrate that species diversity increases with the quantity of resources and, more generally, with consumer population size.

QQI: SPECIES INTERACTIONS

In our discussion of resource quality and quantity so far, we have ignored species interactions and have implicitly lumped all resource species together simply as "food." However, species interactions may boost or lower species diversity in comparison with the value that one would predict by ignoring species interactions. Some of these effects of species interactions on species diversity are mediated by effects of species interactions on population numbers (the second "Q" of "QQID"), while other effects require instead consideration of individual fitnesses.

Effects on number of individuals.

A familiar example of how species interactions may lower species diversity is that certain consumer species may competitively lower diversity of other consumer species at the same trophic level by preempting resources and hence lowering the population sizes of their competitors. An example of resource competition on a gigantic temporal and spatial scale is that the evolutionary history of vascular plants has involved a parade of successive dominants, starting with the rhyniophytes and proceeding through pteridophytes and gymnosperms to the angiosperms. The rhyniophytes disappeared completely, but the pteridophytes and gymnosperms continue to survive today, albeit represented by many fewer species than formerly. The most likely explanation is that each new evolving group of vascular plants preempted resources that would otherwise have been utilized by previously evolved groups, thereby reducing their numbers of individuals and consequently of species, or even driving them to extinction (Knoll, 1986; Niklas, this volume).

Species interactions may have the opposite effect—boosting species diversity by boosting the quantity of available resources, these supporting greater numbers of consumer individuals. This situation arises when predators or herbivores reduce the numbers of individuals of their prey or plant species, thereby making more resources available for other consumer species at the same trophic level and thus increasing the numbers of individuals and hence species diversity of those other consumers (Paine, 1966). However, predators or herbivores can also reduce species diversity of consumer species by greatly reducing numbers of individuals. Thus, predation and herbivory can either increase or decrease species diversity, depending on circumstances such as the intensity of predation or herbivory. By analogy with the intermediate disturbance hypothesis, one might speculate that a community's species diversity initially increases with increased community-wide intensity of predation or herbivory, then decreases with further increase in intensity. (The intermediate disturbance hypothesis proposes that low levels of physical disturbance also increase species diversity by removing some consumer individuals, thus reducing competition for resources, while an increase in disturbance that more severely reduces consumer population sizes decreases species diversity. (See Yodzis (1986) for further discussion.)

Effects on individual fitness.

The species interactions of interference competition (e.g., physical aggression), parasitism, and disease tend to decrease species diversity by decreasing individual fitness. Conversely, the species interaction of mutualism tends to increase species diversity by increasing individual fitness. Effects on fitness merge into effects on population size as the effects on fitness become strong enough to kill individuals or else to permit them to survive where they otherwise could not.

QQID: DYNAMICS

Our discussion so far has ignored dynamic considerations. The final step in our QQID analysis takes species dynamics into account. We first retain the implicit assumption of equilibrium that we have made up to this point. Even at equilibrium, consideration of dynamics predicts trends in species diversity that one could not interpret without considering dynamics. We shall then relax our assumption of equilibrium and thereby encounter still further trends in species diversity. There are three dynamic processes underlying species diversity: extinction, which tends to decrease species diversity; immigration, which tends to increase it; and speciation, which also tends to increase it.

Effects of dynamics at equilibrium.

Effects of extinction dynamics. All else being equal, the probability (per unit time) of extinction increases with decreasing population size, hence with decreasing area. That inverse dependence of extinction rates on area provides the major reason why species number on islands increases with area. In this instance, dynamic considerations do not predict a new trend in species diversity that we have not already considered; instead, they provide the basis of a trend that we had already noted.

Effects of immigration dynamics. The second rule of island biogeography, after the species/area relation, is that species diversity tends to be higher on islands close to a colonization source than on distant islands, even if the close and distant islands are identical in area and in resources. In this case the phenomenon cannot be discussed at all without reference to dynamic considerations: immigration rates from the mainland source to a nearby island are higher than to a distant island, with the result that equilibrium species diversity is higher on the nearby island. Another consequence of immigration dynamics is that species groups with high immigration rates (high dispersal ability) are represented on islands by a higher fraction of the mainland species pool than are species groups with low immigration rates. Thus, compared with mainlands, oceanic islands have more species of birds and bats than of flightless mammals. As a final example of the effects of immigration dynamics on species diversity, high larval settling rates increase the diversity of barnacles, coral reef fish, and other marine organisms with planktonic dispersal (Roughgarden, 1986).

Effects of speciation dynamics. Anything that increases speciation rates will tend to increase species diversity. Speciation rates depend on numerous factors, such as frequency of chromosomal rearrangements, ease of developing reproductive isolation, and dispersal rates. I shall provide a few examples involving dispersal, which is important in speciation since reproductive isolation is more likely, even over shorter distances, for taxa with poor dispersal ability than for others with great dispersal ability. In part for that reason, there are many more species of flightless beetles and land snails than of tardigrades, which are readily wafted in the aerial plankton and are virtually panmictic and cosmopolitan. Because tropical species of birds and possibly of other taxa tend to be more sedentary than temperate species, considerations of dispersal and speciation rates also contribute to the higher species diversities in the tropics. Note that dispersal has opposing effects on species diversity: with increasing dispersal, the fraction of the regional species pool that reaches a given site increases (increasing the species diversity at that site), but the frequency of speciation and thus the size of the regional species pool itself decreases.

This symposium provided several examples of the sensitivity of species diversity to dispersal through its effects on immigration and speciation rates. As an example of the effect on immigration rates, the plant diversity and composition of Costa Rican dry forests depend on the relative opportunities for seed dispersal by wind and by animals (Janzen, this volume). As an example of the effect of dispersal on speciation rates, the roles of biotic vectors both for pollination and for seed dispersal were a decisive factor in the diversification of angiosperms (Niklas, this volume). Biotic vectors can carry out pollination between conspecific individuals separated by a much greater distance than can be effectively bridged by wind, thus permitting angiosperms to live at much lower population densities than other plants and hence to evolve high diversities of relatively rare species. Biotic seed dispersal permits angiosperms to reach sites accessible only with greater difficulty to other plants.

Nonequilibrium situations.

All out discussions so far have referred to species diversity at equilibrium. However, it is a debated question whether it is frequent or exceptional for species communities to be at equilibrium. There is no doubt that many communities have species diversities below equilibrium values, while other communities have species diversities above equilibrium values (Janzen, this volume). Subequilibrial diversities are a transient result of pulse disturbances, while supraequilibrial species diversities are a transient result of pulse decreases in area.

Pulse disturbances leading to subequilibrial species diversity. If populations or resources are decreased or wiped out by disturbance at a site, species diversity at the site will transiently be below the equilibrium value until the resources are restored, or until the consumer populations are restored by immigration or by speciation. The time constants or relaxation times for species communities to recover from disturbance vary enormously. It may be a few months or years after a storm batters a coastline until resources have been replenished and consumer species have returned. When a volcanic explosion destroys the biota of an island, as happened on Krakatau, it may be decades or centuries before immigration has restored the original species diversity. As a result of Pleistocene glaciations that backed populations of many northern European tree species against the Alps and exterminated them, tree species diversity in Europe today, 10,000 years after the end of the Pleistocene, is still below North American levels. It will presumably take much longer than 10,000 years for European tree species diversity to be restored by a combination of immigration and speciation. Finally, for many millions of years after an asteroid collision caused mass extinctions at the Cretaceous/Tertiary boundary—if indeed there was such a mass extinction, and if it was caused by an asteroid—species diversity of large terrestrial vertebrates remained low until it was eventually restored and surpassed by speciation of mammals.

Pulse decrease in area, leading to supraequilibrial species diversity. Because equilibrial species diversity tends to increase with area, a decrease in area eventually leads to a decrease in species diversity. However, the greater the area after the pulse decrease, the slower the "relaxation time" required for species diversity to decay to the new lower equilibrial value (because "relaxation time" depends on extinction rates which are inversely proportional to area according to Diamond, 1972). Immediately after the pulse decrease in area, species diversity equals that prevailing at the site immediately before the pulse decrease in area. If one looked at the site immediately after the pulse area decrease and did not know that there had been such an area decrease, one would be puzzled to find species diversity higher than the site would support if it had not just suffered such a pulse area decrease. This "supersaturation effect" lasts only for a century or so in the case of birds in a forest fragment of one km^2, but lasts for many millenia for birds or mammals on large land-bridge islands such as Java and Borneo, or on a large mountaintop with Pleistocene habitat connections to other mountaintops, such as the mountains rising out of the Great Basin (Brown, 1971; Diamond, 1984). Islands that lie today in shallow water near continents were connected to those continents at Pleistocene times of lower sea level by land bridges and were finally severed from those continents 10,000 years ago by rising sea levels. The larger land-bridge islands, which include Trinidad, Sri Lanka, Fernando Po, and Formosa, as well as Java and Borneo, are still supersaturated with bird and mammal species (Terborgh, 1974). It will presumably require many tens of thousands of years before their species diversities have declined back to the equilibrial values appropriate to their modern areas.

These considerations of how relaxation times of supersaturated habitat fragments increase with area have interesting implications for understanding continental biotas. Relaxation times for birds and mammals on islands of a few thousand square kilometers, and for insects, lizards, plants, and other species living at higher population densities than birds and mammals on still smaller islands, are in excess of 10,000 years. We must therefore expect that relaxation times for the world's continents are far longer, perhaps hundreds of thousands of years. As the continental tropical rainforests expanded in concert with Pleistocene climatic fluctuations, rainforest species diversity must also have tended to expand and contract. However, the expanses of rainforest in South America, Africa, or Asia are so large that species relaxation times for the rainforest biota may be longer than the interval between Pleistocene climatic optima. Thus, when the continental rainforests contracted during dry periods of the Pleistocene, the rainforest biotas may still have been supersaturated at the time when the next wet phase arrived. Species diversity on the major continents may never have a chance to decline to "equilibrium values" and may be chronically supersaturated.

The decreases in species number after habitat fragmentation, and their relaxation times, are of great significance in the worldwide extinction spasm that is now under way. This accelerating extinction wave is due partly to the habitat fragmentation and reduction in habitat area that humans are producing by destroying natural habitats. The habitat fragments thus created start off with their pre-fragmentation species diversity and are gradually losing populations at rates that depend on their area. We have already launched a process that, if it is not miraculously reversed, must result inevitably in a massive extinction wave, even though the wave itself has not yet reached massive proportions. Some economists ignorant of biology question those extinctions that have already occurred, note that massive extinction has not yet occurred, and on this basis belittle predictions of an impending extinction spasm. This reasoning reminds me of the story of the man who fell off the top of the Empire State Building and who had a friend working on the 20th floor. The worker on the 20th floor looked out the window, saw his friend plunging past, and shouted out in concern, "My God, what is happening?" to which the falling man shouted back as he plunged past, "Nothing much is happening, everything is okay so far." As stewards of the world's biota, we have already pushed most of the world's species off the top of the Empire State Building. Those who deny the impending extinction crisis demand to see bodies smeared on the pavement before they will discuss erecting a safety net.

SPECIES DIVERSITY GRADIENTS ALONG ENVIRONMENTAL GRADIENTS

Discussions of species diversity often focus on the famous changes of diversity over environmental gradients, such as habitat gradients, altitudinal gradients, and especially latitudinal gradients. All too often, ecologists seek to identify "*the* cause" of such a gradient. We should be suspicious of any such attempt. Since species diversity depends on many factors, diversity changes over such gradients are also likely to arise from gradients in multiple controlling variables. What we should seek instead is to provide a quantitative *partitioning* or *accounting* to tell us how the various factors that control species diversity vary along the environmental gradient and to tell how much each of the factors contributes to the species diversity gradient. Even along a given environmental gradient, the accounting will surely differ for different groups of species. For example, the form of the latitudinal gradient for birds is very different from that for salamanders, and these two gradients must be explained by different mixes of contributing factors.

To illustrate how the "QQID" approach provides a checklist of factors that may contribute to species diversity gradients, let us consider two of these famous gradients: the altitudinal gradient and the latitudinal gradient.

Altitudinal gradients in species diversity.

As one ascends from sea level towards the summit of a high mountain, species diversity tends to decrease with elevation, as exemplified in this symposium by the decrease in Andean tree species diversity (Gentry, this volume) and frog species diversity (Duellman, this volume) with altitude. However, this pattern is by no means universal. For example, the diversity of plant species along the western Andean slopes of northern Chile is extremely low at sea level, increases from middle to high elevations, and decreases only from high elevations onwards (Arroyo et al., this volume). In the Mediterranean zone of California the species diversity of birds reaches a maximum at middle elevations (Cody, 1975). How can we account for any one of these gradients, and why does the form of the gradient differ from case to case? Consideration of the QQID checklist suggests at least three important contributing factors that vary along the altitudinal gradient, one of them involving resource quality, the other two involving resource quantity.

Changes in habitat structural diversity. Habitat physiognomy varies dramatically along an altitudinal gradient. For example, in the moist tropics habitat structural complexity decreases monotonically along the altitudinal gradient, from tropical rainforest at the base through montane forest and then alpine elfin scrub at higher elevations, to alpine grassland and eventually rocky slopes and glaciers at the highest elevations. This continuous decrease in habitat structural complexity and consequently in "number of niches" contributes to the continuous decrease in plant and frog species diversity with elevation in the wet tropics. In the Mediterranean zone, however, scrub formations such as chaparral at sea level yield to forest at higher elevations before finally yielding to alpine habitats on the highest summits, and this intermediate maximum in habitat structural complexity contributes to the intermediate maximum in species diversity.

Productivity gradient. Temperature generally decreases with increasing altitude, while the altitudinal gradient of rainfall (and hence of productivity, which depends both on rainfall and temperature) varies from site to site. In the moist tropics, productivity decreases with elevation, or there may be a slight increase in productivity from sea level up to a gentle maximum at medium-low elevations, followed by a decrease in productivity thereafter. This productivity gradient reinforces the effect of the gradient in habitat structural complexity and also contributes to the decrease in species diversity with altitude in the moist tropics. However, in the Mediterranean zone of California and in the Atacama Desert there is a marked maximum in productivity at middle elevations (owing to the marked maximum in rainfall there), and this contributes to the species diversity maximum at middle elevations.

Area gradient. The distribution of available area with altitude depends on the form of the mountain. On conical mountains, area decreases continuously with altitude, tending to cause a monotonic decrease in species diversity with altitude. However, Tibet and the Peruvian/Ecuadorean Andes have a more trapezoidal shape, with a broad plateau at high elevations, so that the maximum area may actually be at high elevations rather than at sea level. These area considerations may contribute to the fact that species diversity at high elevations on the Tibetan Plateau and on the Andean Altiplano is much higher than in structurally similar habitats of New Guinea, whose mountains more nearly approximate steep narrow ridges with only tiny areas at high elevations. Quantitative analysis of the altitudinal distribution of area contributes to understanding the relative numbers of montane and lowland bird species on various islands of the Solomon Archipelago (Mayr & Diamond, 1976).

Thus, to account for the altitudinal gradient of species diversity in any particular case, one should at minimum consider that site's altitudinal gradient of habitat structural complexity, productivity, and area. Terborgh (1977) has shown that the quantitative accounting falls out differently for different trophic groups of birds (insectivores, frugivores, and nectarivores) along the altitudinal gradient of the Peruvian Andes. The same three variables—habitat structural complexity, productivity, and area—are also likely to be major contributors to species diversity gradients along horizontal habitat gradients such as the gradients of desert, grassland, scrub, and woodland in the Mediterranean zone, as illustrated by Cody's (1975) analysis.

Latitudinal gradients in species diversity. No discussion of species diversity would be complete without consideration of the latitudinal gradient. Species diversity of most broadly defined groups of plants and animals is maximal in the tropics and decreases towards the poles. Examples considered in this symposium are the high tropical diversity of plants (Gentry, this volume), beetles (Erwin, this symposium), and frogs (Duellman, this volume). In the analysis of plant species diversity in northern Chile by Arroyo et al. (this volume), a steep species diversity gradient arising from the rainfall gradient is superimposed on a gentler species diversity gradient associated with latitude itself. However, some plant and animal groups, such as sandpipers and Old World salamanders, do not exhibit a diversity peak in the tropics. Again using the QQID checklist, we can identify at least five factors with major contributions to the latitudinal gradient. Two of these factors involve resource quality, one involves resource quantity, and two involve dynamics.

Habitat structural diversity. Habitat structural diversity tends to decrease from the equator to the poles, the extreme ends of the gradient being equatorial tropical rainforest as contrasted with the polar ice caps. This environmental gradient contributes to the polewards decline in species diversity.

Gradient of resource types. The variety of resources, or of resources available year-round, tends to decrease with latitude. For example, the proportion of insect species with very large bodies decreases polewards, with the result that bird species (e.g., coucals) specializing on very large insects are mainly tropical. Nectar and fruit are available year-round in the tropics but not in the Arctic, contributing to the decrease in diversity of obligately frugivorous and nectarivorous bird species with latitude.

Productivity gradient. Productivity on land tends to decrease with latitude, reinforcing the polewards decline in species diversity. This latitudinal gradient in productivity is less regular in marine environments, because latitudinal effects of temperature changes in productivity are overridden by effects of nutrient upwelling in some high-latitude marine areas.

Disturbance gradient. One reason often proposed for the latitudinal gradient in species diversity is that disturbances on a geological time scale are supposedly more violent and produce more extinctions at high latitudes than at low latitudes. In particular, glaciations have periodically wiped out species diversity at high latitudes. This argument, if valid, would involve a contribution of species dynamics to the latitudinal gradient of species diversity. In recent years there has been increased appreciation of the historical importance of environmental disturbances in the supposedly stable tropics. The Pleistocene involved alternate wet and dry periods that caused large-scale habitat changes in the tropics. It is nevertheless probably still true that environmental changes over geological times have been more devastating of habitats and more destructive of species diversity at high than at low latitudes.

Gradient in dispersal and speciation rates. Tropical species of birds, and possibly of some other taxa, tend to be much more sedentary than temperate species. Practically all bird species of North America and Europe are known to have crossed water gaps of at least several miles in modern times, while most species of the continental tropics apparently do not cross water gaps (Diamond, 1976; Diamond & Gilpin, 1983). These low dispersal rates in the tropics may have contributed to tropical species diversity by making it possible for formerly conspecific populations to achieve reproductive isolation over shorter distances, and thus by enhancing speciation rates.

Thus, the latitudinal gradient in species diversity involves multiple factors, but these factors are not infinite in number. What is now required is to attempt to partition the contributions of these various factors to latitudinal gradients of species diversity in particular cases.

SUMMARY AND OUTLOOK

We have seen that determinants of species diversity can be grouped into four sets of factors that may be remembered by the mnemonic "QQID": (resource) quality, (resource) quantity, (species) interactions, and dynamics. This is not to say that all four sets of factors are equally important in explaining species diversity of different taxa, or at different sites. For example, an interesting interpretation of neotropical tree diversity within tree guilds dispenses almost entirely with considerations of niche differentiation and segregation by resource utilization, and instead stresses the dynamics of speciation, immigration, and extinction (Hubbell & Foster, 1986). A general explanatory theory of species diversity must ultimately tell us under what sorts of circumstances each factor is likely to be important and what factors contribute to species diversity gradients along various environmental gradients. At present, I doubt there is a single case where we have an adequate accounting that considers all four possible sets of factors for a given group of taxa at a given site. Thus, we shall have to obtain such analyses for many individual cases before we can begin to compare those cases and arrive at generalizations about species diversity. I view the gathering of such accountings as one of the two major tasks for future studies of species diversity.

The other major task is to attempt to convert empirical groupings of factors controlling species diversity, such as the one that I have proposed, to natural hierarchical groups. The QQID grouping is offered just as a convenient empirical checklist; it does not necessarily correspond to any scheme in nature. Must we always content ourselves with such an arbitrary laundry list, or is there any natural organization to the laundry list? I suggest that it may be possible eventually to account for species diversity by a hierarchy of processes in space and in time. The spatial hierarchy would begin or end with an understanding of species diversity at a single point in space, then within a single type of habitat (so-called alpha diversity), then diversity from end to end of a habitat gradient (species turnover along this gradient being termed beta diversity), and finally species diversity over areas large enough to permit geographic replacement (gamma diversity), or over whole biogeographic regions, or over the whole world. A hierarchy in time might begin with the rapid increase in species diversity during recovery from a storm, then the much slower increase following a glacial period with its attendant fluctuations in sea level, and finally the slow generation of species over geological/evolutionary time scales. In this way, it may eventually be possible to obtain not just a convenient checklist, but a natural explanation for the number of biological children in the world's candy store.

A CONTRIBUTION TO THE POLLEN MORPHOLOGY OF NEOTROPICAL LAURACEAE[1]

Bhoj Raj[2] *and Henk van der Werff*[3]

ABSTRACT

The present study is a pollen-morphological investigation of 80 species belonging to 17 of the 22 known neotropical genera of Lauraceae. Observations were made with light and scanning electron microscopes. An ultrastructural study of the pollen wall of 11 genera was also undertaken by transmission electron microscopy. The pollen grains of most of the genera are easily identifiable by their sizes and by the number and organization of spinules. The pollen grains of all the species investigated are apolar, spheroidal, and inaperturate. The exine is very thin and coherent due to loosely or densely packed globular to variously shaped bodies. The surface of exine is scattered with pointed or blunt, monomorphic or dimorphic spinules. The spinules are made up of numerous tightly woven strands; their bases are encompassed by a thick, circular, cushionlike form. The intine was found to be the dominant layer of the pollen wall and to show varied composition and structural details. It is remarkable that a similar type of intine has been encountered in the inaperturate pollen grains belonging to such disparate genera as Canna, Heliconia, Hernandia, *and* Palmeria. *The taxonomic implications of the palynological observations are discussed.*

TAXONOMIC REVIEW AND CLASSIFICATION

Lauraceae form a large, predominantly tropical family of trees and shrubs. The sole exception is the genus *Cassytha*, which consists of leafless, twining parasites much like *Cuscuta* (Convolvulaceae). *Cassytha* is sometimes treated as a separate family, but since it differs only in habit from the woody Lauraceae, we maintain it in the Lauraceae. Centers of species richness are tropical Asia and tropical America. Lauraceae are rather poorly represented in Africa, are rather diverse in Madagascar, and occur in Australian rain forests, the Pacific Islands, and in New Zealand (two species).

The family is easily recognized by its flowers. The perianth consists of two cycles of three tepals each, which are usually equal. By far the most common flower colors vary from white to green or yellowish; very rarely does one encounter reddish flowers (*Kubitzkia*). The stamens are also arranged in cycles of three each, and in principle there are four staminal cycles. The fourth or innermost cycle is nearly always reduced to staminodes or is entirely lacking. Three cycles are usually present but can be reduced to two or one fertile cycle in some genera. The three stamens of cycle three have nearly always two glands attached at or near their base. In the genus *Pleurothyrium* these glands become greatly enlarged and surround all nine fertile

---

[1] *We wish to thank the Directors of the Missouri Botanical Garden, St. Louis, and the Royal Botanic Gardens, Kew, for generously providing polliniferous material for the present study. We would like to extend our special thanks to Miss Pia Bro Christensen, Botanical Institute, Aarhus, Denmark, for undertaking the onerous task of calculating the number of spinules of all the species investigated, and to Dr. Gamal El-Ghazaly, University of Qatar, Qatar, for helping with light microphotography. Our warm thanks are due to Mrs. Elisabeth Grafström, Palynological Laboratory, Stockholm, for her kind help in embedding and sectioning material for transmission electron microscopy. We appreciate the critical comments and suggestions by Dr. John Rowley, Botanical Institute, Stockholm, Dr. I. K. Ferguson, Royal Botanic Gardens, Kew, and Dr. R. Keating, Southern Illinois University, Edwardsville, Illinois. Finally, we wish to express our sincere thanks to Dr. J. Praglowski, Palynological Laboratory, Stockholm, for his constant help and valuable comments during the course of this study. The authors gratefully acknowledge the financial support from Missouri Botanical Garden, which enabled us to undertake TEM studies.*

stamens. The ovary is superior (except in the monotypic African *Hypodaphnis*), has one locule, and develops into a drupe, which may be subtended by the enlarged floral tube. The flowers can be perfect or unisexual.

Although the Hernandiaceae and Monimiaceae are frequently mentioned as close relatives of the Lauraceae, flowers of Lauraceae are rarely confused with other families.

The Lauraceae are of considerable economic importance. *Persea americana* is widely cultivated for its edible fruit, the avocado. Most species of Lauraceae possess varying amounts of aromatic oils, some of which are economically important. Examples are camphor oil from *Cinnamomum camphora*; rosewood oil from *Aniba rosaeodora*; and Brazilian sassafras oil from *Ocotea odorifera*.

The bark of *Cinnamomum verum* yields cinnamon. Leaves of *Laurus nobilis* and *Umbellularia californica* are used as spices (bay leaves); in Central America, *Litsea glaucescens* is used for the same purpose. Several other species are used on a local basis, for instance *Sassafras albidum* for the preparation of root beer and *Dicypellium caryophyllatum* (now supposedly very rare due to excessive exploitation) for its spicy fruits. The wood of many species of Lauraceae is valuable. Some species have unusually hard or decay-resistant wood used for construction, and the wood of other species is excellent for making furniture (Richter, 1981).

CLASSIFICATION

A workable generic classification of the Lauraceae does not yet exist. Several reasons lie behind the poor understanding at generic level. The most important reason is that, with very few exceptions (*Cassytha*, *Hypodaphnis*), the genera do not have exclusive characters, that is, characters restricted to one particular genus. As a consequence, the genera are separated by combinations of characters. Very often both floral and fruit characters are used, and, because specimens only rarely have flowers and fruits (fruits usually require one or two months to mature), keying specimens to genus is frequently impossible. A second difficulty is that in some cases the characters separating genera are weak or difficult to interpret. Thus, even perfect specimens cannot always be unambiguously assigned to a genus.

Results of these difficulties are that many generic identifications are suspect and that species are frequently transferred between genera or described in incorrect genera. It seems that the Lauraceae are the only family in which every botanist who seriously worked on the family has redescribed an already published species in a genus different from the one in which it was previously described.

Tables 1, 2, and 3 present three recent generic classifications of Lauraceae. Tables 1 and 2 are abbreviated versions of classifications by Kostermans (1957) and Hutchinson (1964) based on flower and fruit characters. Table 3 shows Richter's (1981) generic groupings and is based on studies of secondary xylem and bark. *Cassytha*, not being woody, is excluded from Richter's groupings.

Kostermans (1957) recognized five tribes in the woody Lauraceae, which are separated on inflorescence and cupule characters. One tribe consists solely of the African *Hypodaphnis*, which has an inferior ovary. The other four tribes occur in the New World. They are the Perseae (inflorescence exinvolucrate, cupule lacking), subdivided into two subtribes; the Cinnamomeae (inflorescence exinvolucrate, cupule present), likewise subdivided into two subtribes; the Litseae (inflorescence with decussate bracts, cupule present), subdivided into two subtribes; and the Cryptocaryeae (inflorescence exinvolucrate, drupe fully enclosed in floral tube), also subdivided. The subdivisions in each of these four tribes are based on numbers of anther cells.

Kostermans (1957) postulated an evolutionary trend in the Lauraceae from genera with a very shallow floral tube, where the fruit is not subtended by a cupule (tribe Perseae), through genera with a deeper floral tube, where the mature fruit is subtended by a cupule up to one-third the size of the fruit

TABLE 1. *Classification (after Kostermans, 1957) of the neotropical genera of Lauraceae.*

	Subfamily Lauroideae
Tribe	**Perseeae**. Inflorescence paniculate, exinvolucrate. Cupule absent.
Subtribe	Perseineae. Anthers four-celled.
Genera	*Persea, Phoebe, Caryodaphnopsis*
Subtribe	Beilschmiediineae. Anthers two-celled.
Genera	*Beilschmiedia, Mezilaurus*
Tribe	**Cinnamomeae**. Inflorescence paniculate, exinvolucrate. Cupule present.
Subtribe	Cinnamomineae. Anthers four-celled.
Genera	*Ocotea, Nectandra, Pleurothyrium, Sassafras, Umbellularia, Dicypellium*
Subtribe	Anibineae. Anthers two-celled.
Genera	*Aiouea, Aniba, Endlicheria, Licaria, Urbanodendron, Kubitzkia, Phyllostemonodaphne*
Tribe	**Litseae**. Inflorescence involucrate with decussate bracts. Cupule present.
Subtribe	Litseineae. Anthers four-celled.
Genus	*Litsea*
Subtribe	Lauriineae. Anthers two-celled.
Genus	*Lindera*
Tribe	**Cryptocaryeae**. Inflorescence paniculate, exinvolucrate. Fruit fully enclosed in flower tube.
Subtribe	Eusideroxylineae. Anthers four-celled.
Genus	*Eusideroxylon* (not neotropical)
Subtribe	Cryptocaryineae. Anthers two-celled.
Genus	*Cryptocarya*
Tribe	**Hypodaphneae**. Ovary inferior.
Genus	*Hypodaphnis* (African)
	Subfamily Cassythoideae
Genus	*Cassytha*

(tribe Cinnamomeae), and through genera with a deep floral tube, where the fruit is fully enclosed in the floral tube (tribe Cryptocaryeae), to the tribe Hypodaphneae, where the fruit is fully enclosed in and becomes fused with the floral tube. This is a stimulating theory, although it is not certain whether it is phylogenetically accurate, that is, whether the Perseae are indeed the most primitive tribe. The position of the Litseae, recognized by their inflorescence type, is not clear in this theory.

Hutchinson (1964) also recognized five tribes of woody Lauraceae but defined his tribes quite differently. His Apollonieae are characterized by exinvolucrate inflorescence, two-celled anthers, and fruit not fully enclosed by floral tube. His Cryptocaryeae are as his Apollonieae except for the fruit being enclosed by the floral tube. Tribe III, the Sassafrideae, is of doubtful value; its single New World species, *Sassafridium veraguense*, has been placed by nearly all botanists during the last century in *Ocotea*. This tribe is characterized by having all anthers with introrse cells. The Cinnamomeae (exinvolucrate inflorescence, at least one anther row extrorse, all anthers four-celled) differs from the Sassafrideae only in having some anthers extrorse. *Hypodaphnis* is placed in this tribe. The fifth tribe, the Litseae, is also separated based on its involucrate inflorescence.

The third recent classification of Lauraceae (Richter, 1981) is not based on floral or fruit characters, but on wood and bark. It should therefore not be surprising that it differs in several features from Kostermans's and Hutchinson's classifications. Richter recognized three main groupings of genera without giving them taxonomic status. Each group includes primitive and more advanced genera (as defined by wood and bark characters). Ancestral genera from which these groups were derived are not yet known. The first group includes mostly palaeotropical genera—from this group only *Beilschmiedia*,

TABLE 2. *Classification of Lauraceae—Hutchinson (1964), neotropical genera.*

- Tribe 1. **Apollonieae**. Inflorescence exinvolucrate; anthers two-celled; fruit not or partly enclosed by cupule.
  - Flower bisexual.
    - Fertile stamens 9; calyx usually persistent.
      - *Beilschmiedia, Kubitzkia, Aniba, Nobeliodendron, Urbanodendron*
    - Fertile stamens 6–3.
      - *Aiouea, Licaria, Phyllostemonodaphne, Misanteca, Mezilaurus*
  - Flowers dioecious or polygamo-dioecious.
    - *Aniba, Endlicheria*
- Tribe 2. **Cryptocaryeae**. Inflorescence exinvolucrate; anthers two-celled; fruit enclosed in floral tube.
  - *Cryptocarya*
- Tribe 3. **Sassafrideae**. Inflorescence exinvolucrate; anthers four-celled; all anther cells introrse.
  - *Sassafridium* (now included in *Ocotea*)
- Tribe 4. **Cinnamomeae**. As tribe 3, but at least one row of anthers with extrorse cells.
  - Flowers bisexual.
    - *Nectandra, Persea, Phoebe, Pleurothyrium, Caryodaphnopsis, Synandrodaphne* (= *Rhodostemonodaphne*)
  - Flowers bisexual or polygamous
    - *Ocotea, Dicypellium*
- Tribe 5. **Litseae**. Inflorescence involucrate; flowers umbellate or solitary within the involucre.
  - Anthers four-celled.
    - *Litsea, Umbellularia*
  - Anthers two-celled.
    - *Lindera, Laurus*
- Tribe 6. **Cassytheae**. Parasitic, leafless herbs.
  - *Cassytha*

Caryodaphnopsis, and *Cryptocarya* are represented in the New World, albeit with few species. The second group includes most of the genera occurring in the subtropics of the Northern Hemisphere (*Persea* is the exception), but several of the genera are best represented in tropical areas. This group is represented in the New World by *Litsea*, *Lindera*, *Sassafras*, and *Umbellularia*. The third group includes all other (15 or 16) neotropical genera plus a few paleotropical segregates of *Persea* and *Phoebe/Cinnamomum* (*Alseodaphne*, *Dehaasia*, *Neocinnamomum*, and *Nothaphoebe*). Within this group, *Persea*, *Cinnamomum*, *Phoebe*, and allies can be separated from the remaining endemic neotropical genera (*Ocotea* is also present in Africa and Madagascar), but the remaining genera do not fall in distinct groupings based on wood or bark characters.

The classifications by Kostermans and Hutchinson show that our knowledge of the relationships among the genera of Lauraceae is still limited. Essentially, these classifications are only keys to genera, often based on readily observable but artificial characters such as the number of fertile stamens and number of anther cells on the stamens. The genera, defined with the help of these characters, often include species that do not possess the required characters but are placed in a certain genus due to general resemblance to other

TABLE 3. *Genera groups according to Richter (1981), neotropical genera.*

Group I	Group III
Beilschmiedia	*Persea*
Cryptocarya	*Phoebe*
Caryodaphnopsis	*Pleurothyrium*

Group II	*Aiouea*
Lindera	*Nectandra*
Litsea	*Ocotea*
Umbellularia	*Urbanodendron*
Sassafras	*Kubitzkia*
	Dicypellium
	Licaria
	Aniba
	Anaueria
	Mezilaurus
	[*Rhodostemonodaphne*]

species in that genus. Needless to say, this frustrates the efforts of the botanists who are not familiar with the group but try to key specimens to genus. A good example of these problems is found in the genus *Persea.* One of its characters is the presence of nine four-celled anthers and three staminodes. However, Kopp (1966), who monographed the genus, included in *Persea* also species with six four-celled anthers and six staminodes, and Kopp included species with some or all anthers two-celled, largely because of similarities in fruit and vegetative characters. In *Persea* the staminal configurations seem to be constant for a given species, but there are a few cases where the number of anther cells varies between flowers of the same inflorescence (*Aiouea lundelliana, Kubitzkia macrantha*). Normally, when flowers have both two- and four-celled anthers, the outer six anthers are always of one type and the inner three anthers the other; for instance, in *Endlicheria anomala* the outer six anthers are two-celled, the inner four-celled, while in *Phoebe* subg. *Heteranthera* the outer six are four-celled and the inner three are two-celled. Mez (1889) realized this and restricted the couplet in his generic key "anthers 4-celled or anthers 2-celled" to the outer six anthers. This greatly reduced the number of species that did not fit in any of the genera and made identifications easier. It is regrettable that this has been overlooked by later workers.

The differences in treatment of the genera with two-celled anthers show the lack of understanding of the generic relationships. In Hutchinson's classification, two-celled anthers characterize two tribes, the Apollonieae and Cryptocaryeae; the Cinnamomeae consist of four-celled genera, and the Litseae include both two- and four-celled genera. Thus, Hutchinson regarded the difference in number of anther cells as very important. Kostermans considered this difference as secondary, as all of his tribes include both two- and four-celled genera (except the monotypic Hypodaphneae), and accepted that the transition from four-celled to two-celled genera occurred several times. Richter found that wood and bark characters do not support the idea that genera with two- and four-celled anthers form distinct groups, and it seems likely that the two-celled genera have been independently derived from four-celled genera. This theory is strengthened by the observation that in some two-celled neotropical genera the upper two cells have been lost, while in other genera the lower pair has disappeared. There are also indications that some two-celled genera (*Aiouea, Endlicheria*) are not monophyletic, but contain groups of species that were independently derived from four-celled ancestors; on the other hand, other two-celled genera of comparable size (*Aniba, Licaria*) seem to be monophyletic.

In addition to the differences in treatment of the two-celled genera, the three classification systems differ in many other details. Hutchinson and Richter recognized some neotropical genera that Kostermans did not accept. Examples are (from Hutchinson): *Sassafridium,* now accepted as belonging in *Ocotea*; *Nobeliodendron* and *Misanteca,* both now included in *Licaria* (Kurz, 1983); and *Synandrodaphne,* included in *Ocotea* by Kostermans (1957), also frequently included in *Nectandra* but recently recognized as *Rhodostemonodaphne* by Rohwer & Kubitzki (1985). Richter also recognized several genera that Kostermans had treated as synonyms: *Caryodaphnopsis, Nectandra, Pleurothyrium,* and *Anaueria.* More differences exist in the placement of the genera, largely because Kostermans and Hutchinson used different characters to define their tribes. For instance, Hutchinson placed most two-celled, exinvolucrate genera in the tribe Apollonieae, whereas in Kostermans's system these genera are divided between the Perseae and Cinnamomeae. Kostermans's Perseae are divided between Hutchinson's Apollonieae and Cinnamomeae. Although both classifications need to be modified, incorporating results from Richter's work, it seems that Kostermans's system needs fewer changes and has the major groups better defined than Hutchinson's system.

Both Kostermans's and Hutchinson's classifications are essentially keys and aimed at easing the identification of specimens to generic level. Information needed for an understanding of the phylogeny was (and is) not available. As has been mentioned earlier, workable keys to the genera are still not available and a large obstacle is that both floral and fruit characters are important for the definition of the genera although rarely specimens include flowers and fruits. This difficulty is not likely to be solved in the near future. It is possible to write a generic key based on floral characters with which most specimens can be identified. Fruiting material can be recognized either by cupule shape or leaf venation; cupules are likely to offer important characters for defining phylogenetically sound genera.

Difficulties in resolving the phylogenetic relationships should be viewed as distinct from difficulties involving identifications. Analyses of flower and fruit types have shown an extensive reticulate pattern of variation within the Lauraceae, and it is not known which taxa are primitive and which are derived, nor where the family originated. Raven & Axelrod (1974) postulated that, based on present patterns of distribution and endemism and on the fossil record, in the New World some taxa migrated from South America northward, while others, of Laurasian origin, were present in North America and moved southward. Gentry (1982) supported the hypothesis that the Lauraceae are a tropical Gondwanaland family. Richter's (1981) work on wood and bark anatomy has shown that the mostly small genera found in temperate and subtropical parts of the Northern Hemisphere (*Apollonias, Laurus, Lindera, Litsea, Sassafras,* and *Umbellularia*) have a similar wood structure. Because these genera occur in different continents, and because two other genera, now largely represented in the tropics, also occur in northern subtropical/temperate areas (*Ocotea* in the Canary Islands; *Persea* in North America and the Canary Islands), it is tempting to regard the Lauraceae as a Laurasian family that has very successfully spread into the tropics. The fact that *Ocotea* is much better represented in the tropics than in the temperate zones does not imply a tropical origin. Accepting the dioecious species as derived from species with hermaphrodite flowers, one should note that most *Ocotea* species in the South American lowlands are dioecious, whereas nearly all Central American *Ocotea* species and most Andean species have perfect flowers. Further, in Central America *Ocotea* is much more weakly separated from its closest allies (*Nectandra, Phoebe*). These observations do not support the view that in the New World *Ocotea* and its allies originated in South America and moved north, but rather the reverse (Rohwer, 1986).

Much more information is needed for making secure claims about the phylogeny of the Lauraceae. First of all, our knowledge about the distribution of the genera is incomplete. Recently *Caryodaphnopsis,* previously known as an Asian genus of seven species, was found in South America (van der Werff & Richter, 1985); recent collections show that this genus includes six to eight neotropical species and occurs in Costa Rica, Panama, Colombia, Ecuador, Peru, and Brazil. Also during the last few years, four genera previously not known from Central America have been discovered there (*Aniba, Caryodaphnopsis, Mezilaurus,* and *Pleurothyrium*; pers. obs.).

Characters beyond flowers and fruits should be investigated. An excellent example is the work by Richter (1981) on wood and bark anatomy; studies of pollen, such as here reported, are very promising, and a study of leaf venation (Klucking, 1987) will appear soon. Other areas worthy of investigation are the chemical constituents and the structure of the cuticles. Results of such studies will be of much help in assessing the importance of the various morphological characters and in determining which characters should be used to define monophyletic genera and which are important on the species level.

PALYNOLOGICAL REVIEW

Extensive palynological investigations have been few. These were based mostly on observations with light microscopes. Pollen-morphological studies have been made by classical and by recent workers. The former generally included information on pollen as a matter of secondary importance.

The history of pollen descriptions probably began with Kölreuter (1811), followed by Purkinje (1830), Fritzsche (1832), Mohl (1834), Schnizlein (1843–1870), Berg & Schmidt (1858), Griffith & Henfrey (1875), Edgeworth (1877), Mez (1888), Knell (1914), Armbruster & Oenike (1929), Wodehouse (1932, 1965), Zander (1935, 1937, 1941), Cranwell (1942, 1953), Selling (1947), Kasapligil (1951), Erdtman (1952), Veloso & Barth (1962), and Pal (1976). The general descriptions given by the said authors is that the pollen grains are devoid of furrows and pores. Likewise, the sculpture spoken of by Wodehouse, as well as Mez, Knell, Zander, and Selling, to mention a few, are matters of controversy.

Short pollen descriptions and illustrations have also found a place in many regional floras: see Cranwell (1942, 1953), Ikuse (1956), Zinderen Bakker (1956), F. H. Wang (1960), J. L. Wang (1962, 1969), Rao & Lee (1970), Heusser (1971), Huang (1970, 1972), Markgraf & D'Antoni (1978), Lieux (1980), and Lewis et al. (1983).

Casual reference to pollen morphology mainly from an embryological standpoint has also been made by Schroeder (1952), Sastri (1958, 1962), Mitroiu (1970), and Pal (1975).

Recent noteworthy palynotaxonomic and phylogenetic studies are those of Agababian (1969, 1973), Ghosh (1977), Suryanarayana & Deodikar (1978), and Datta & Chanda (1980).

Of late the specialized wall structure of pollen grains has attracted the attention of many workers such as Takeoka (1965), Walker (1976), Rowley & Vasanthy (1980), Kubitzki (1981), Hesse & Kubitzki (1983), Hesse & Waha (1983), and Sohma (1985). The pollen wall is characteristic because of the extreme thinness of exine and the massive nature of the intine. A similar type of sporoderm stratification has been encountered in Cannaceae, Heliconiaceae, Hernandiaceae, Strelitziaceae, and Monimiaceae (Erdtman, 1952; Kress et al., 1978; Kress & Stone, 1982, 1983a, b; Stone et al., 1979, 1981; Stone, 1987; Rowley & Skvarla, 1974, 1975, 1986; Foreman & Sampson, 1987).

There is a scanty pollen record of fossil lauraceous genera. The few recorded are those of Macko (1959) and Macphail (1980). It is interesting that Selling (1947) stated that it is not "as if it [lauraceous pollen] had been overlooked, nor do I think that the possibility of the pollens being easily destroyed and therefore rarely preserved in peat (as was suggested by Rudolph 1936, p. 297, with regard to the pollens of this family) is of importance for the interpretation of their absence."

The present study is a broadly based pollen-morphological investigation of the apparently eurypalynous family. The aim is to present detailed morphological descriptions based on light microscopy (LM) and scanning electron microscopy (SEM), as the previous works are limited to very brief, sometimes incorrect accounts, depending mostly on light microscope observations. The complicated exine structure, sculpture, and ultrastructural details can be adequately studied with scanning electron microscopy and transmission electron microscopy (TEM) only.

The present investigation is aimed not only at giving a better understanding of pollen morphology but also at determining the correctness of the grouping of different genera under different tribes, subtribes, and their subfamilies respectively. The deflections of the palynological compass needle, at times oversimplified, have been taken into account to see whether it points towards better grouping, rearrangement, affinities, or evolutionary tendencies among the genera investigated.

MATERIALS AND METHODS

Polliniferous material of all the species investigated (except one sample each of *Kubitzkia mezii* and *Mezilaurus navalium*, obtained from Kew) was collected from the herbarium of the Missouri Botanical Garden

(MO), St. Louis, Missouri, U.S.A. Permanent slides were made from unacetolyzed, fuchsine-stained pollen grains. Acetolysis easily disintegrates the pollen grains because of the extreme thinness of exine (Erdtman, 1943).

A total of 80 species belonging to 17 out of the known 22 neotropical genera have been investigated. The LM studies were made using a Leitz Wetzlar Dialux microscope with apochromatic oil immersion objective (×100, N.A. 1.32) and periplan eye pieces (GF ×10). Measurements were made under oil immersion and are based on 30 or more pollen grains per species. Exine thickness was measured in the center of mesocolpia of pollen grains lying in equatorial view and includes spinules and other exinous excrescences. The maximum and minimum numbers of spinules per species were calculated using a programmable computer (Texas Instruments II Programmable 59; for details see Christensen, 1986) and and are presented in Table 1.

Pollen descriptions are based on LM and SEM observations. A general description is given for each genus, followed by a TEM description of the taxa sectioned. Pollen morphological data of the species are compiled in Table 1. The classification and order of genera follows that of Kostermans (1957), and the species are arranged in alphabetical order. The arrangement of photographs is according to the classification.

For scanning electron microscopy, unacetolyzed pollen grains were suspended in a drop of absolute alcohol and transferred to brass stubs. The pollen grains were coated with gold palladium for seven minutes using a Fine Coat ION Sputter JFC-1100. Scanning micrographs were taken with a Jeol JSM 25S-II microscope using Ilford FP4 film.

For transmission electron microscopy, unacetolyzed anthers were fixed in TAG solution (Rodewald & Karnovsky, 1974), buffered in sodium cacodylate buffer, postfixed in osmium tetroxide, and embedded in Spurr. Ultrathin sections were cut with a diamond knife using an LKB ultratome and poststained with uranyl acetate and lead citrate. The terminology follows that of Erdtman (1969).

GENERIC DESCRIPTIONS

The pollen grains of all the species investigated are inaperturate and spheroidal. The exine consists of an extremely thin, continuous or interrupted layer with an ornamentation consisting of pointed or blunt spinules made up of numerous twisted strands or of minute processes of varying shape (except *Cryptocarya*, where the exine is thin and smooth). The thinness of the exine makes it exceedingly difficult to distinguish the sexinous layer from the nexinous layer. Ultrastructural study of the pollen wall leads to the conclusion that the exine is totally ectexinous. The dominant massive layer is the intine. It is stratified, and its composition can be fibrillar, lacunar, lamellated, or granular. The intinous nature of this layer has been verified by acetolysis. It is uniformly thick throughout and does not show special thickenings that indicate possible germinal exits or germinative zones at any place. Instead, the entire wall may be equally suited for pollen tube egress.

Persea. Figure 1.

Diameter of pollen grains 29–44 μm. Exine 0.5–1.5 μm thick, scattered with spinules 1–3 μm apart of faintly discernible twisted strands. Spinules < 0.5–ca. 1 μm long, pointed or blunt, monomorphic or dimorphic with a basal cushionlike form of irregular shape; spinule surface devoid of processes but surrounded by a ring of densely spaced processes of varying shape and size. Intine 3–4 μm thick, appearing homogeneous.

In *P. americana* and *P. mutisii* the spinules are dimorphic; blunt and pointed spinules are intermingled. In *P. caerulea* and *P. schiedeana* the pollen grains are dimorphic; one type of pollen grains has monomorphic spinules and the other dimorphic. In *P. veraguasensis* neither the pollen grains nor the spinules are dimorphic.

Persea fulva. Figure 1C. TEM observation: pollen wall 4 μm thick, its outer, very thin electron-dense layer consisting of globular elements or in places baculalike elements

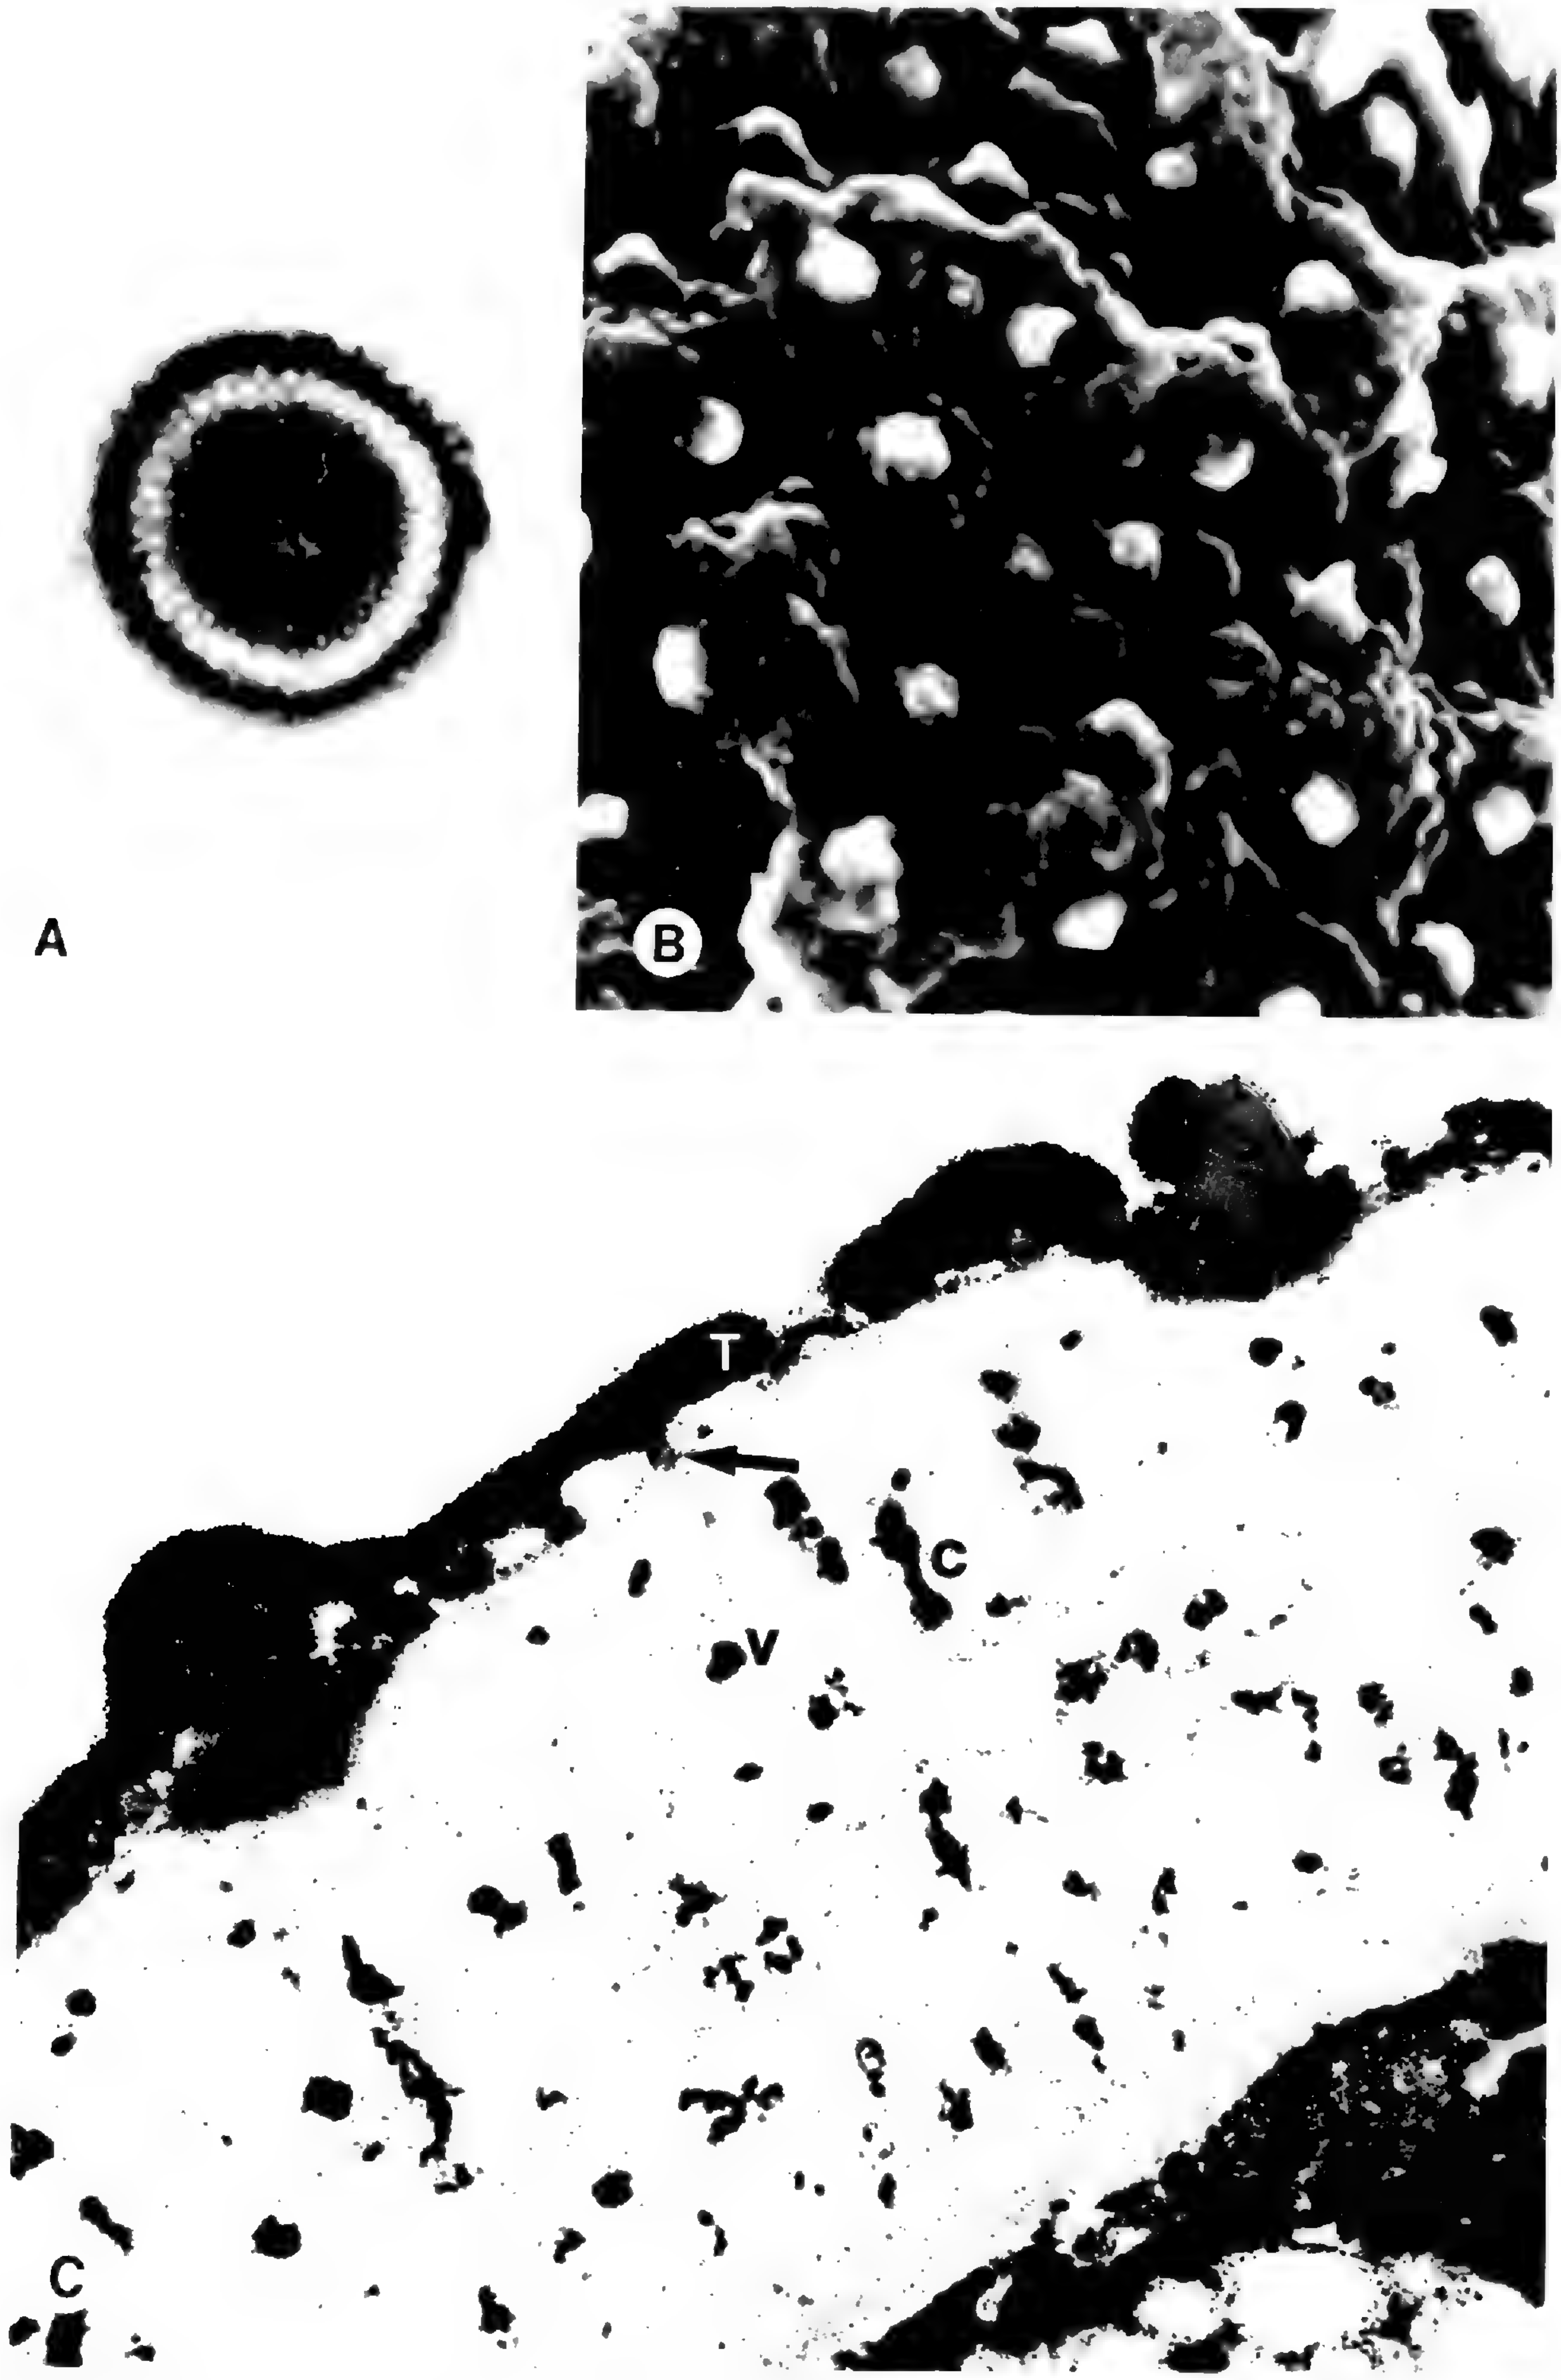

FIGURE 1. *A, B.* Persea americana.—*A. Entire pollen grain; spinules appear as white dots in the peripheral region; at a lower focus in the middle they appear as dark dots. LM ×1,000.—B. Part of exine showing spinules and the cushionlike bases studded with minute processes. supporting a discontinuous tectum and minute, pointed, solid spinules 3 μm apart, with a prominent, circular basal cushion intruding into the intinous layer, surrounded by densely spaced globular elements. The spinules and exinous surface covered with a "fuzzy coating" of granular composition. The underlying massive intinous layer distinguished into an outer, thick fibrillar layer with irregularly oriented narrow channels and vacuoles filled with osmiophilic material and into an inner, thin, electron-dense granular layer with a slightly undulating inner margin.

Phoebe. Figure 2.

Diameter of pollen grains 21–33 μm. Exine 1–2 μm thick, scattered with spinules 1–2.5 μm apart of easily discernible twisted strands. Spinules < 1–2 μm long, pointed, with a prominent basal, circular, cushionlike form. These cushionlike forms densely spaced, their surface and the general surface of exine scattered with sparsely spaced, minute, granular processes.

Phoebe helicterifolia. Figure 2D. TEM observation: pollen wall 5 μm thick, differentiated into an outer, thin, electron-dense ornamented exinous layer composed of closely packed granular elements and minute, pointed, spinules 2 μm apart, with a distinct, circular basal cushion intruding deeply into the intinous layer and making its distal surface distinctly undulating. Spinules and exinous surface covered with a "fuzzy coating." The underlying massive intinous layer distinctly demarcated into an outer, relatively thick, distally undulating layer beset with usually radially oriented cavities, these partly filled with osmiophilic material, and into an inner, unevenly thickened, electron-dense fibrillar layer, its inner margin uneven. The outer and inner layers of intine clearly separated by a thin, discontinuous electron-dense commissural line.

Caryodaphnopsis. Figure 3.

Diameter of pollen grains 27–33 μm, rarely 41 μm. Exine 2 μm thick, scattered with simple spinules 2–3 μm apart (rarely the spinules show faintly discernible twisted strands). Spinules about 1.5 μm long, pointed, with a basal cushionlike form, this circular to irreg-

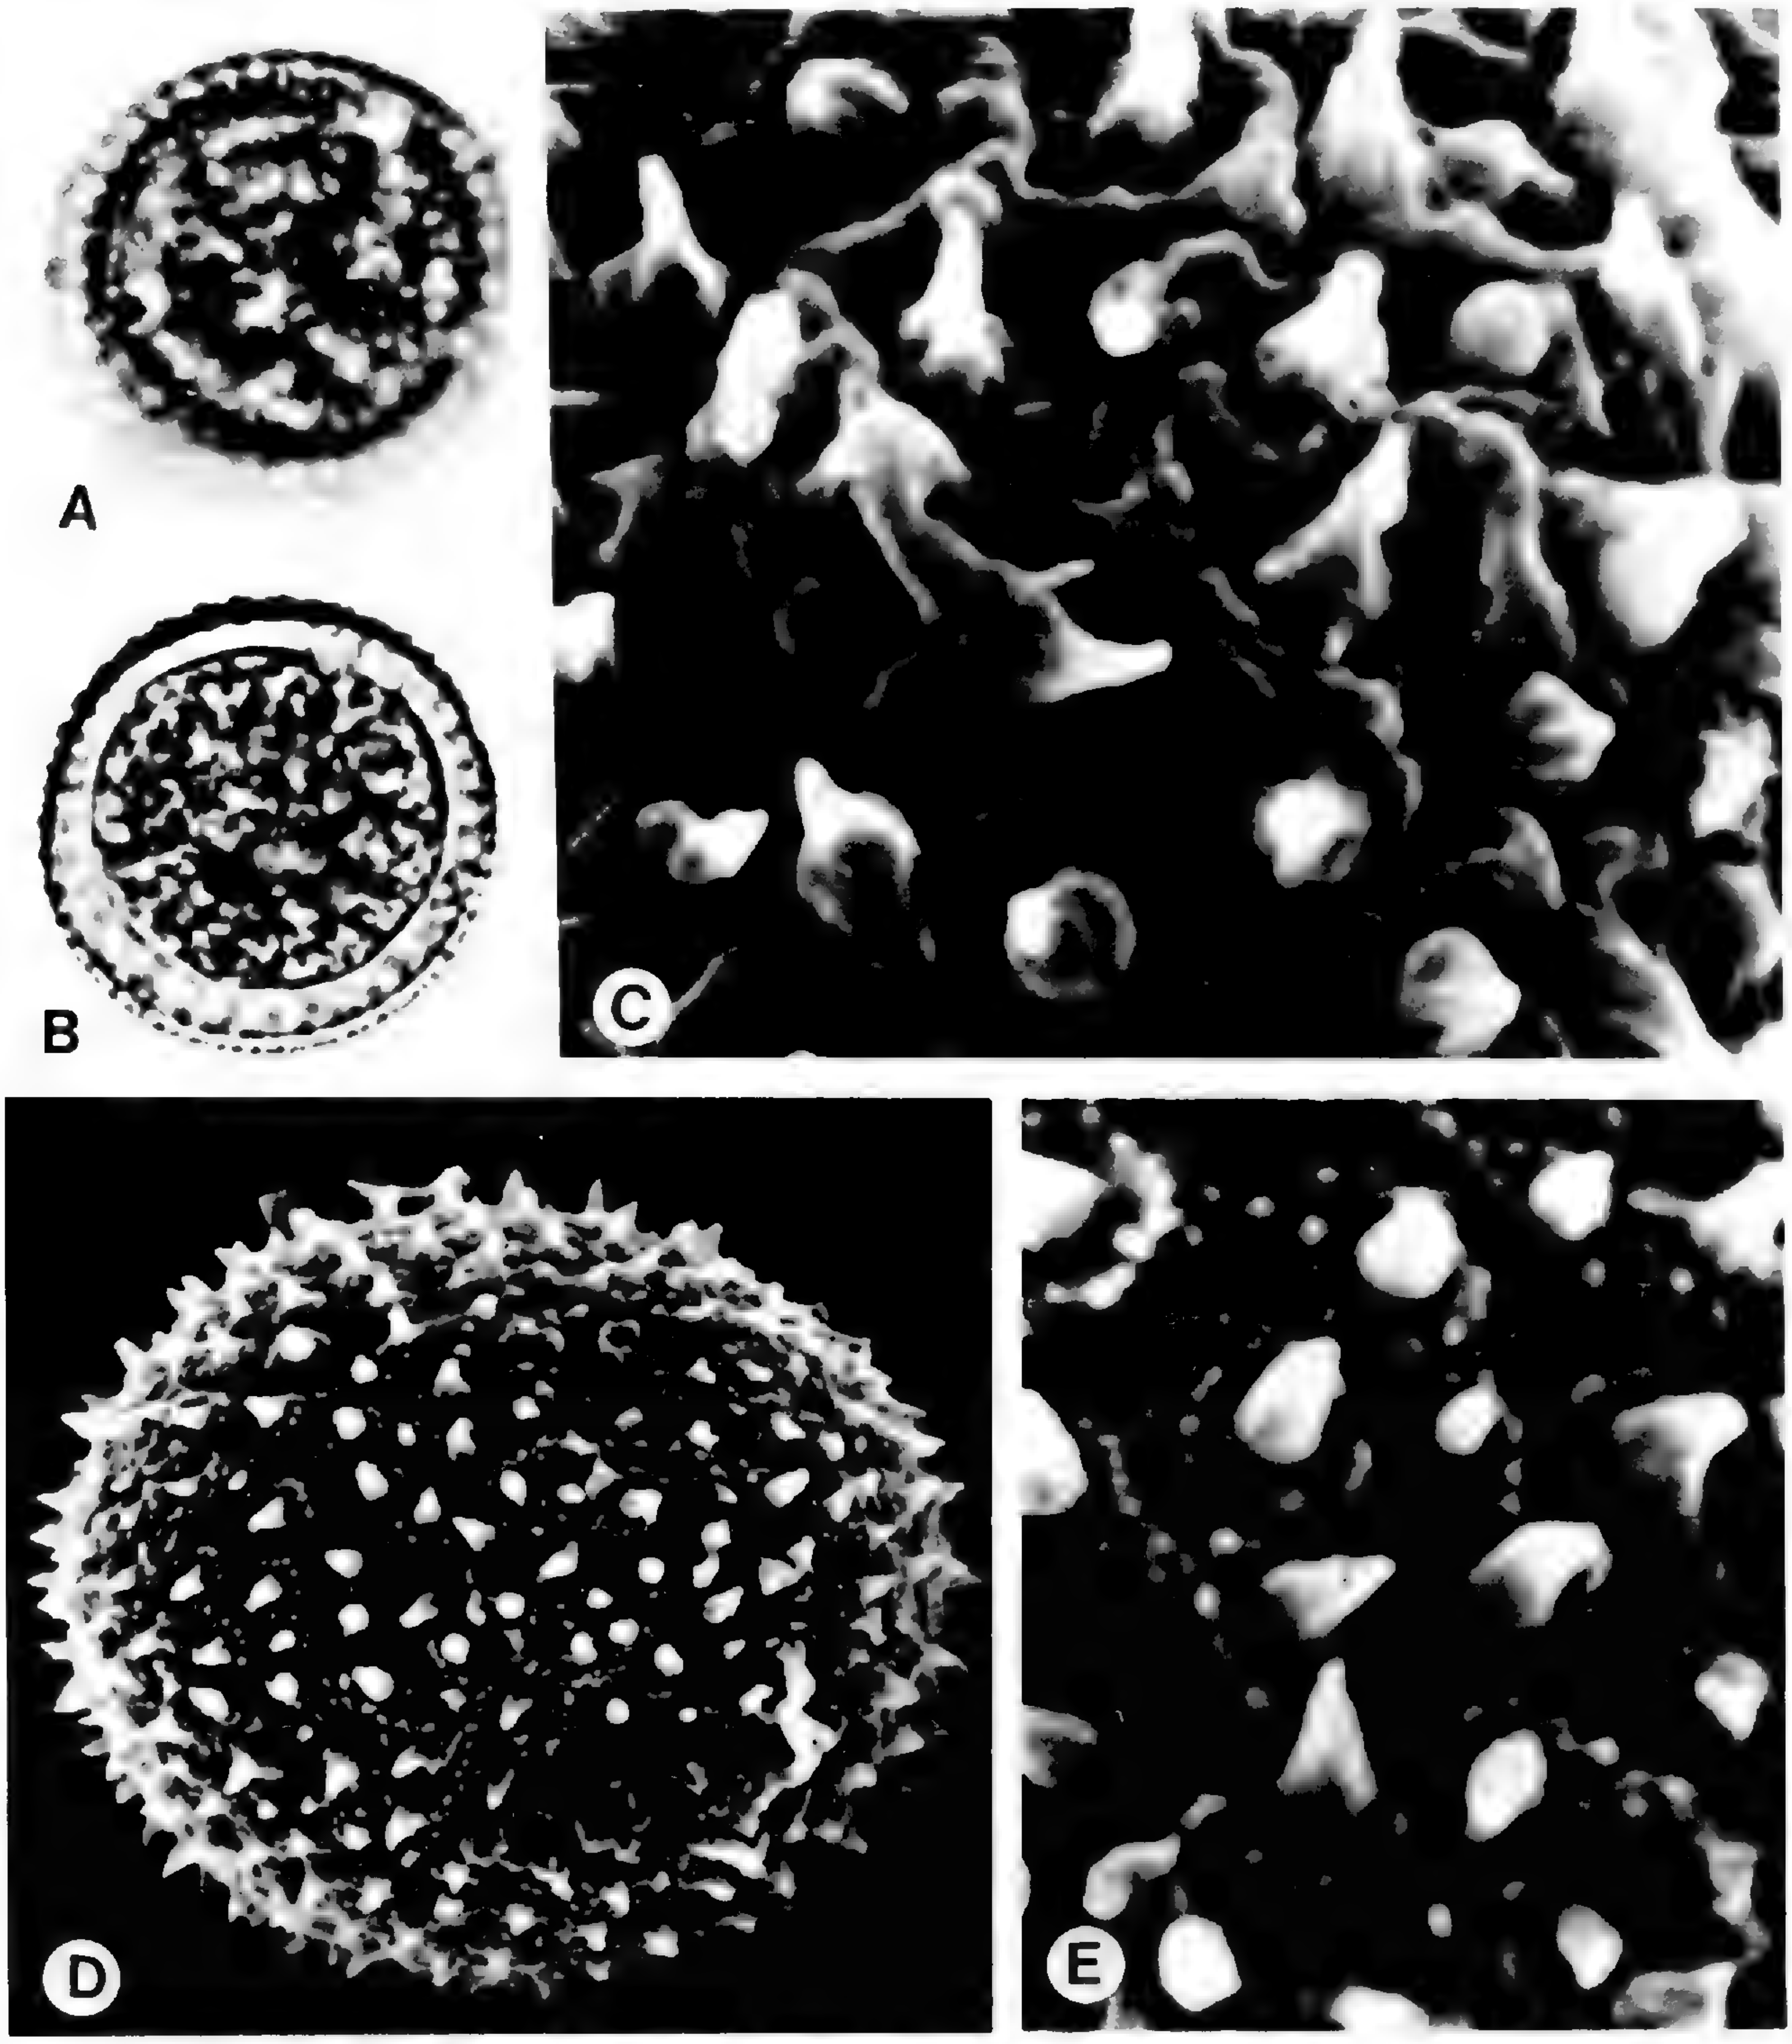

FIGURE 4. *A–C.* Beilschmiedia pendula.—*A. Entire pollen grain showing spinules as white dots.—B. The same in optical cross section. LM ×1,000.—C. Part of exine beset with spinules, their basal cushionlike form devoid of granular processes. SEM ×11,000. D, E.* Mezilaurus navalium.—*D. Entire pollen grain showing spinules, their basal cushions beset with minute processes. SEM ×3,300.—E. Part of the same at a higher magnification. SEM ×11,000.*

ular in shape, its surface devoid of processes. The general surface of exine sparsely covered with minute processes. Intine 2 μm thick, appearing homogeneous.

Beilschmiedia. Figure 4A–C.

Diameter of pollen grains 23–38 μm. Exine 1–2 μm thick, scattered with spinules 2–3 μm apart of easily discernible twisted strands. Spinules 1–1.5 μm long, pointed, with a basal cushionlike form of irregular shape; its surface and the general surface of exine devoid of processes. Intine 2.5–5 μm thick, appearing homogeneous.

Mezilaurus. Figure 4D, E.

Diameter of pollen grains 22–26 μm. Exine > 1 μm thick, scattered with spinules 2 μm apart of easily discernible twisted strands. Spinules < 0.5 μm long, pointed, with an ill-defined basal cushionlike form; its surface and the general surface of exine beset with densely spaced processes. Intine 2 μm thick, appearing homogeneous.

Ocotea. Figure 5.

Diameter of pollen grains 17–39 μm. Exine 1–2.5 μm thick, scattered with spinules 1–4 μm apart of distinctly discernible twisted strands. Spinules < 0.5–2 μm long, pointed or blunt with well-defined, thick, basal, circular, cushionlike form, its surface uneven. The cushionlike forms densely spaced and each surrounded by a ring of partially fused elements of varying size and shape. The general surface of exine beset with small processes of varying size and shape.

In a few species, such as *O. cernua* and *O. ira*, transparent porelike or colpuslike areas devoid of spinules occur. In *O. cuprea* the pollen grains are dimorphic; one type of pollen grain has pointed spinules made up of twisted strands, with a prominent, circular, basal cushionlike form. These cushionlike forms are densely spaced and appear as small islands surrounded by partially fused, small, globular processes. In places five or six spinules are grouped on a single cushion. In the second type of pollen grain, the spinules are pointed and broad basally but without a basal cushionlike form. The intine is 2–5 μm thick and homogeneous to many layered.

Ocotea puberula. Figure 5C. TEM observation: pollen wall 4 μm thick, differentiated into an outer, very thin, electron-dense ornamented exinous layer composed of minute, closely packed globular elements and minute, pointed, solid spinules, 3 μm apart with a distinct, circular basal cushion slightly intruding into the intinous layer and surrounded by densely spaced globular elements. The spinules and general exinous surface covered with a "fuzzy coating." The underlying massive intinous layer clearly distinguished into an outer, relatively thick layer beset with narrow, radially oriented channels in contact with the surface, these partly filled with bead-shaped osmiophilic material, and into a relatively thin, electron-dense, rather homogeneous layer of varying electron density, its inner margin irregular.

Nectandra. Figure 6.

Diameter of pollen grains 18–33 μm. Exine 0.5-1.5 μm thick, scattered with spinules 1–4 μm apart of faintly discernible twisted strands. Spinules 0.5–1.5 μm long, pointed, with a distinct, basal, circular to irregular cushionlike form, its surface and the general surface of exine devoid of processes.

In *N. ambigens* the spinules are crowded in places to form a rosettelike pattern or are sometimes found in pairs on a common basal cushion. In *N. falcifolia* the spinules are frequently crowded in places or are dimorphic. In *N. grandis* they are blunt and vestigial. The intine 1–4 μm thick and homogeneous or apparently bizonal or lamellated.

Nectandra gentlei. Figure 6E. TEM observation: pollen wall 5 μm thick, its outer, very thin, electron-dense, ornamented exinous layer composed of closely packed granular to globular elements and minute, pointed, solid, spinules 1 μm apart with a distinct, circular, basal cushion intruding into the underlying layer. The underlying massive intinous layer made up of an upper, relatively thick layer beset with ill-defined narrow channels partly filled with osmiophilic material and of an inner, relatively thin, many-layered granular stratum of varying electron density, its inner margin very irregular.

Pleurothyrium. Figure 7.

Diameter of pollen grains 21–30 μm. Exine 0.5 μm thick, scattered with spinules 1–2 μm apart of easily discernible twisted strands. Spinules < 0.5 μm long, pointed, with a prominent, basal, circular cushionlike form, totally or partially surrounded by a ring of densely spaced, partially fused minute processes. The general surface of exine beset with sparsely

spaced, minute processes. Intine 1.5 μm thick, appearing homogeneous.

Pleurothyrium zulianense. Figure 7D. TEM observation: pollen wall 2 μm thick, its outer thin, electron-dense ornamented exinous layer made up of granular to globular elements and minute, pointed, solid spinules 1 μm apart with a distinct, circular, basal cushion intruding into the intinous layer. The underlying massive intinous layer distinguished into an outer thick, structurally loose, granular stratum bearing closely packed, narrow, radially oriented channels filled with osmiophilic material and into an inner, thin, granular layer, its margin irregular.

Umbellularia. Figure 8.

Diameter of pollen grains 31–36 μm. Exine 1 μm thick, scattered with spinules 3 μm apart of faintly discernible twisted strands. Spinules < 1 μm long, pointed, with a prominent, basal, circular cushionlike form, partially surrounded by a ring of densely spaced, partially fused minute processes. The general surface of exine studded with densely spaced, minute processes of varying size and shape. Intine 2.5 μm thick, appearing homogeneous.

Umbellularia californica. Figure 8D. TEM observation: pollen wall 6 μm thick and consisting of an outer, thin, electron-dense ornamented exinous layer composed of densely spaced clavate to globular elements of varying size and of minute, solid, spinules 3 μm apart with a distinct, circular basal cushion intruding deeply into the intinous layer, and surrounded by densely spaced globular elements of varying size. The spinules and general exinous surface covered with loose "fuzzy coating." The underlying massive intinous region clearly distinguished into an outer, relatively thick stratum with scattered, radially oriented, ill-defined channels partly filled with osmiophilic material and into an inner, relatively thin, granular layer of varying electron density, its inner margin smooth.

Aiouea. Figure 9.

Diameter of pollen grains 19–29 μm. Exine 0.5 μm thick, scattered with spinules 1–3 μm apart of very faintly discernible twisted strands. Spinules 0.5 μm long, pointed, with a basal, thin, circular to irregularly shaped cushionlike form, frequently surrounded by a ring of densely spaced, partially fused, minute processes. Cushionlike forms usually fused, their surface uneven, devoid of processes. General surface of exine beset with sparsely spaced, minute processes. Intine 1.5–3 μm thick and appearing homogeneous.

In *A. costaricensis* the pollen grains exhibit in places porelike transparent areas devoid of spinules.

Aiouea trinervis. Figure 9D. TEM observation: pollen wall about 4 μm thick, differentiated into an outer, very thin, electron-dense ornamented exinous layer made up of compact granular elements and spinules. The spinules minute, pointed, solid, 1–3 μm apart with a distinct, circular basal cushion intruding into the subtending layer, and surrounded by densely spaced globular elements of varying size. The underlying massive intinous stratum consisting of an outer, relatively thick, structurally loose fibrillar layer made up of vacuoles and channels filled with osmiophilic material and of a denser inner, 2–3-layered granular zone of varying electron density, its inner margin slightly irregular.

Aniba. Figure 10A–C.

Diameter of pollen grains 16–27 μm. Exine 0.5 μm thick, scattered with spinules 1 μm apart of faintly discernible strands. Spinules < 0.5 μm long, pointed, without dis-

intinous stratum made up of 4 distinct layers of varying composition. The outermost relatively thick, transversely organized, compact fibrillar layer with scattered, narrow channels and vacuoles partly filled with osmiophilic material. The second layer equally thick, less electron dense, structurally loose and fibrillar, sprinkled with osmiophilic material. The third layer is thinner, densely granular in composition, much more electron dense, and sprinkled in places with osmiophilic material. The layer next to the cytoplasmic boundary extremely irregular in outline, in places very thin or absent, and also much denser than the other layers, structurally compact and granular.

Kubitzkia (*Systemonodaphne*). Figure 12B–D.

Diameter of pollen grains 24–27 μm. Exine 1 μm thick, scattered with spinules 2 μm apart of easily discernible twisted strands. Spinules 0.5 μm long, pointed, with a prominent basal, circular cushionlike form surrounded by a ring of densely spaced, partially fused processes of varying size and shape. The general surface of exine beset with densely spaced minute processes. Intine 3 μm thick, appearing homogeneous.

Litsea. Figure 13.

Diameter of pollen grains 27–35 μm. Exine 1 μm thick, scattered with spinules 3 μm apart of not easily discernible strands. Spinules < 1 μm long, pointed with a basal cushionlike form, circular to irregular in shape and devoid of processes, partially surrounded by a ring of densely spaced, minute processes. Intine 4 μm thick and appearing homogeneous.

Litsea glaucescens. Figure 13D. TEM observation: pollen wall 5 μm thick, its outer, very thin, electron-dense, ornamented exinous layer composed of scattered or irregularly clustered granular to globular elements and of minute, pointed, solid spinules 3 μm apart with a distinct basal cushion intruding into the intinous layer. The underlying massive intinous layer distinctly distinguished into a thicker outer layer inlaid with channels and vacuoles filled with osmiophilic material and into a thinner, denser, homogeneous layer with a slightly uneven inner margin.

Cryptocarya. Figure 14.

Diameter of pollen grains 30–33 μm. Exine 0.5–1 μm thick, appears disrupted in optical cross section (in LM), its outer surface much wrinkled. Intine 2.5–4 μm thick, appearing stratified.

Cryptocarya aschersoniana. Figure 14D. TEM observation: pollen wall about 4.5 μm thick, its outer very thin, electron-dense stratum consisting of an uneven tectum supported by densely spaced clavatelike to globular elements and of a supratectal thin coating of compact material. The subtending massive intinous layer distinctly distinguished into an outer thick, less electron-dense, structurally loose, transversely organized fibrillar layer inlaid with scattered vacuoles, these partly filled with osmiophilic material, and into an inner electron-dense, structurally compact, transversely organized fibrillar layer interrupted by long, narrow channels filled with osmiophilic material. These channels traversing the entire thickness of the layer, conical in shape, and having an outlet into the layer above. The intinous layer next to the cytoplasmic boundary denser than the other layers and in places beset with narrow, short channels filled with osmiophilic material.

Cassytha. Figure 15.

Diameter of pollen grains 22–28 μm. Exine 0.5 μm thick, its surface scattered with minute, spinuloid excrescences. Intine 4 μm thick, appears homogeneous.

DISCUSSION

GENERAL POLLEN-MORPHOLOGICAL FEATURES

The pollen grains of Lauraceae are inaperturate and more or less spheroidal. Kasapligil (1951), however, found monocolpate pollen

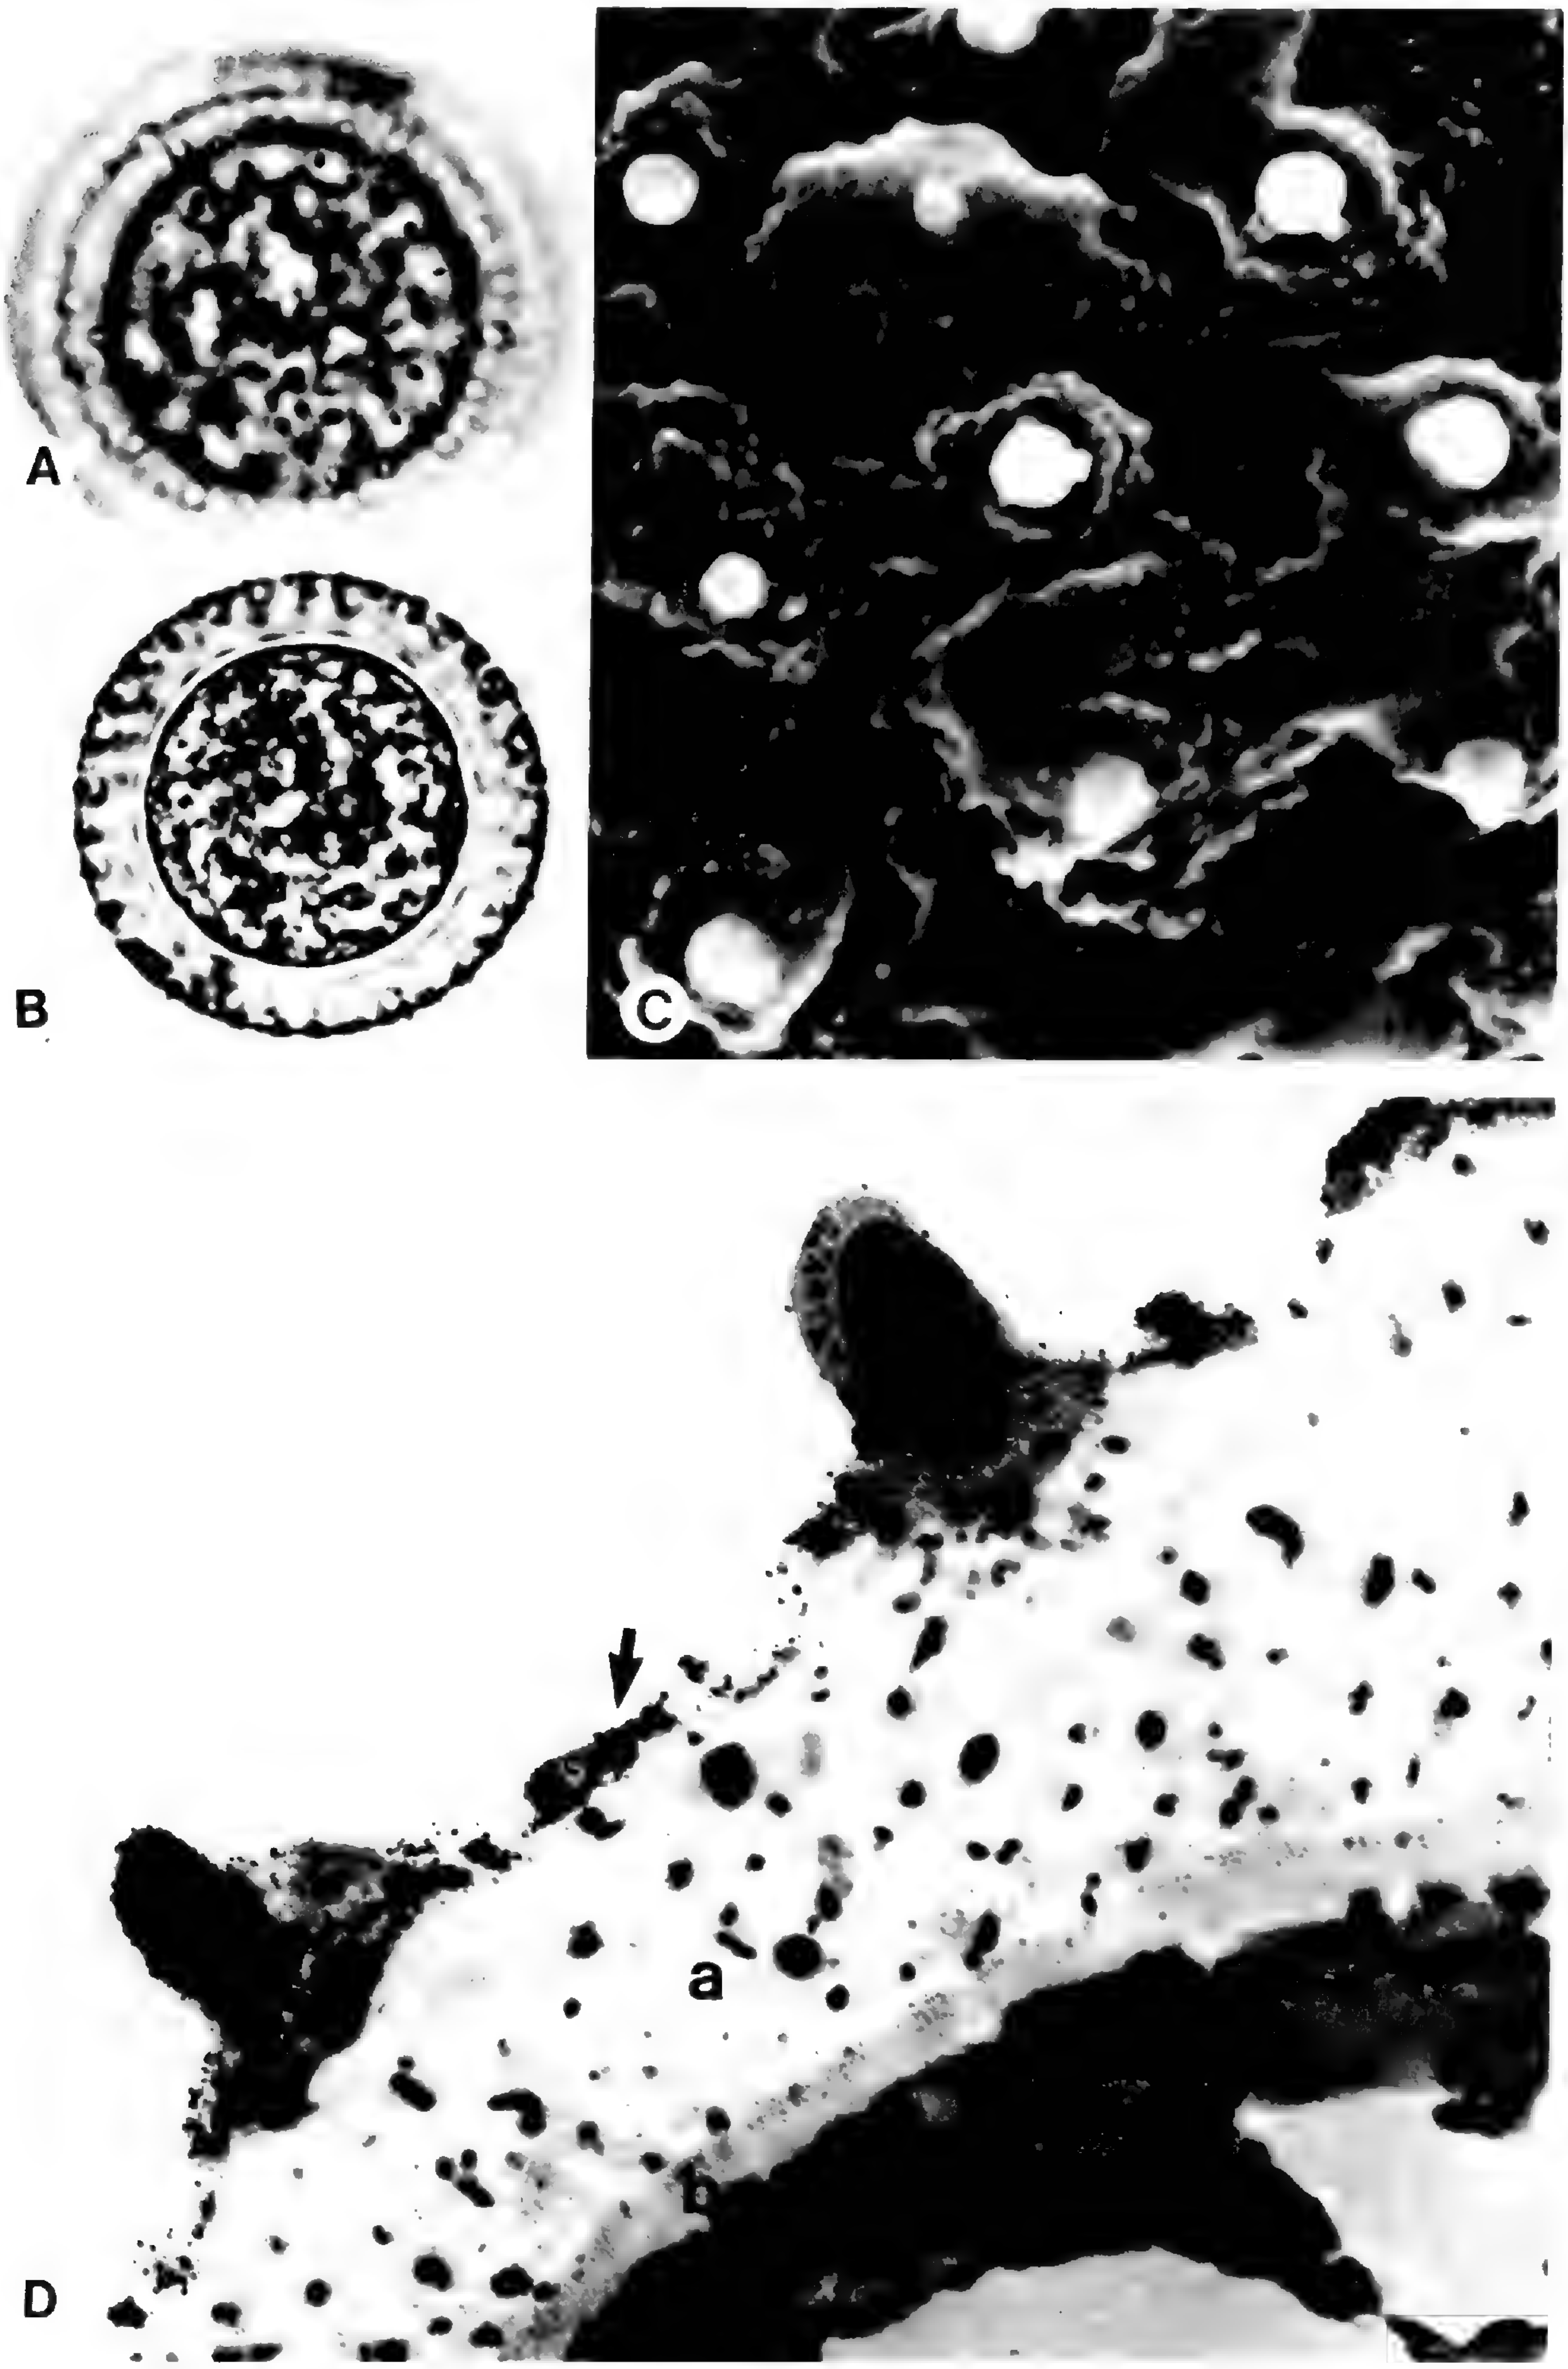

FIGURE 13. Litsea glaucescens.—*A. Entire pollen grain showing spinules as white and dark dots.—B. The same in optical cross section. LM ×1,000.—C. Part of exine showing spinules and their basal cushions. SEM ×11,000.—D. Part of pollen wall showing an outer very thin, electron-dense exinous layer composed of scattered or irregularly clustered granular to globular elements (arrow). Intine distinctly differentiated into an outer, thick stratum inlaid with channels and vacuoles filled with osmiophilic material (a) and an inner thin, denser, homogeneous layer (b). TEM ×20,000.*

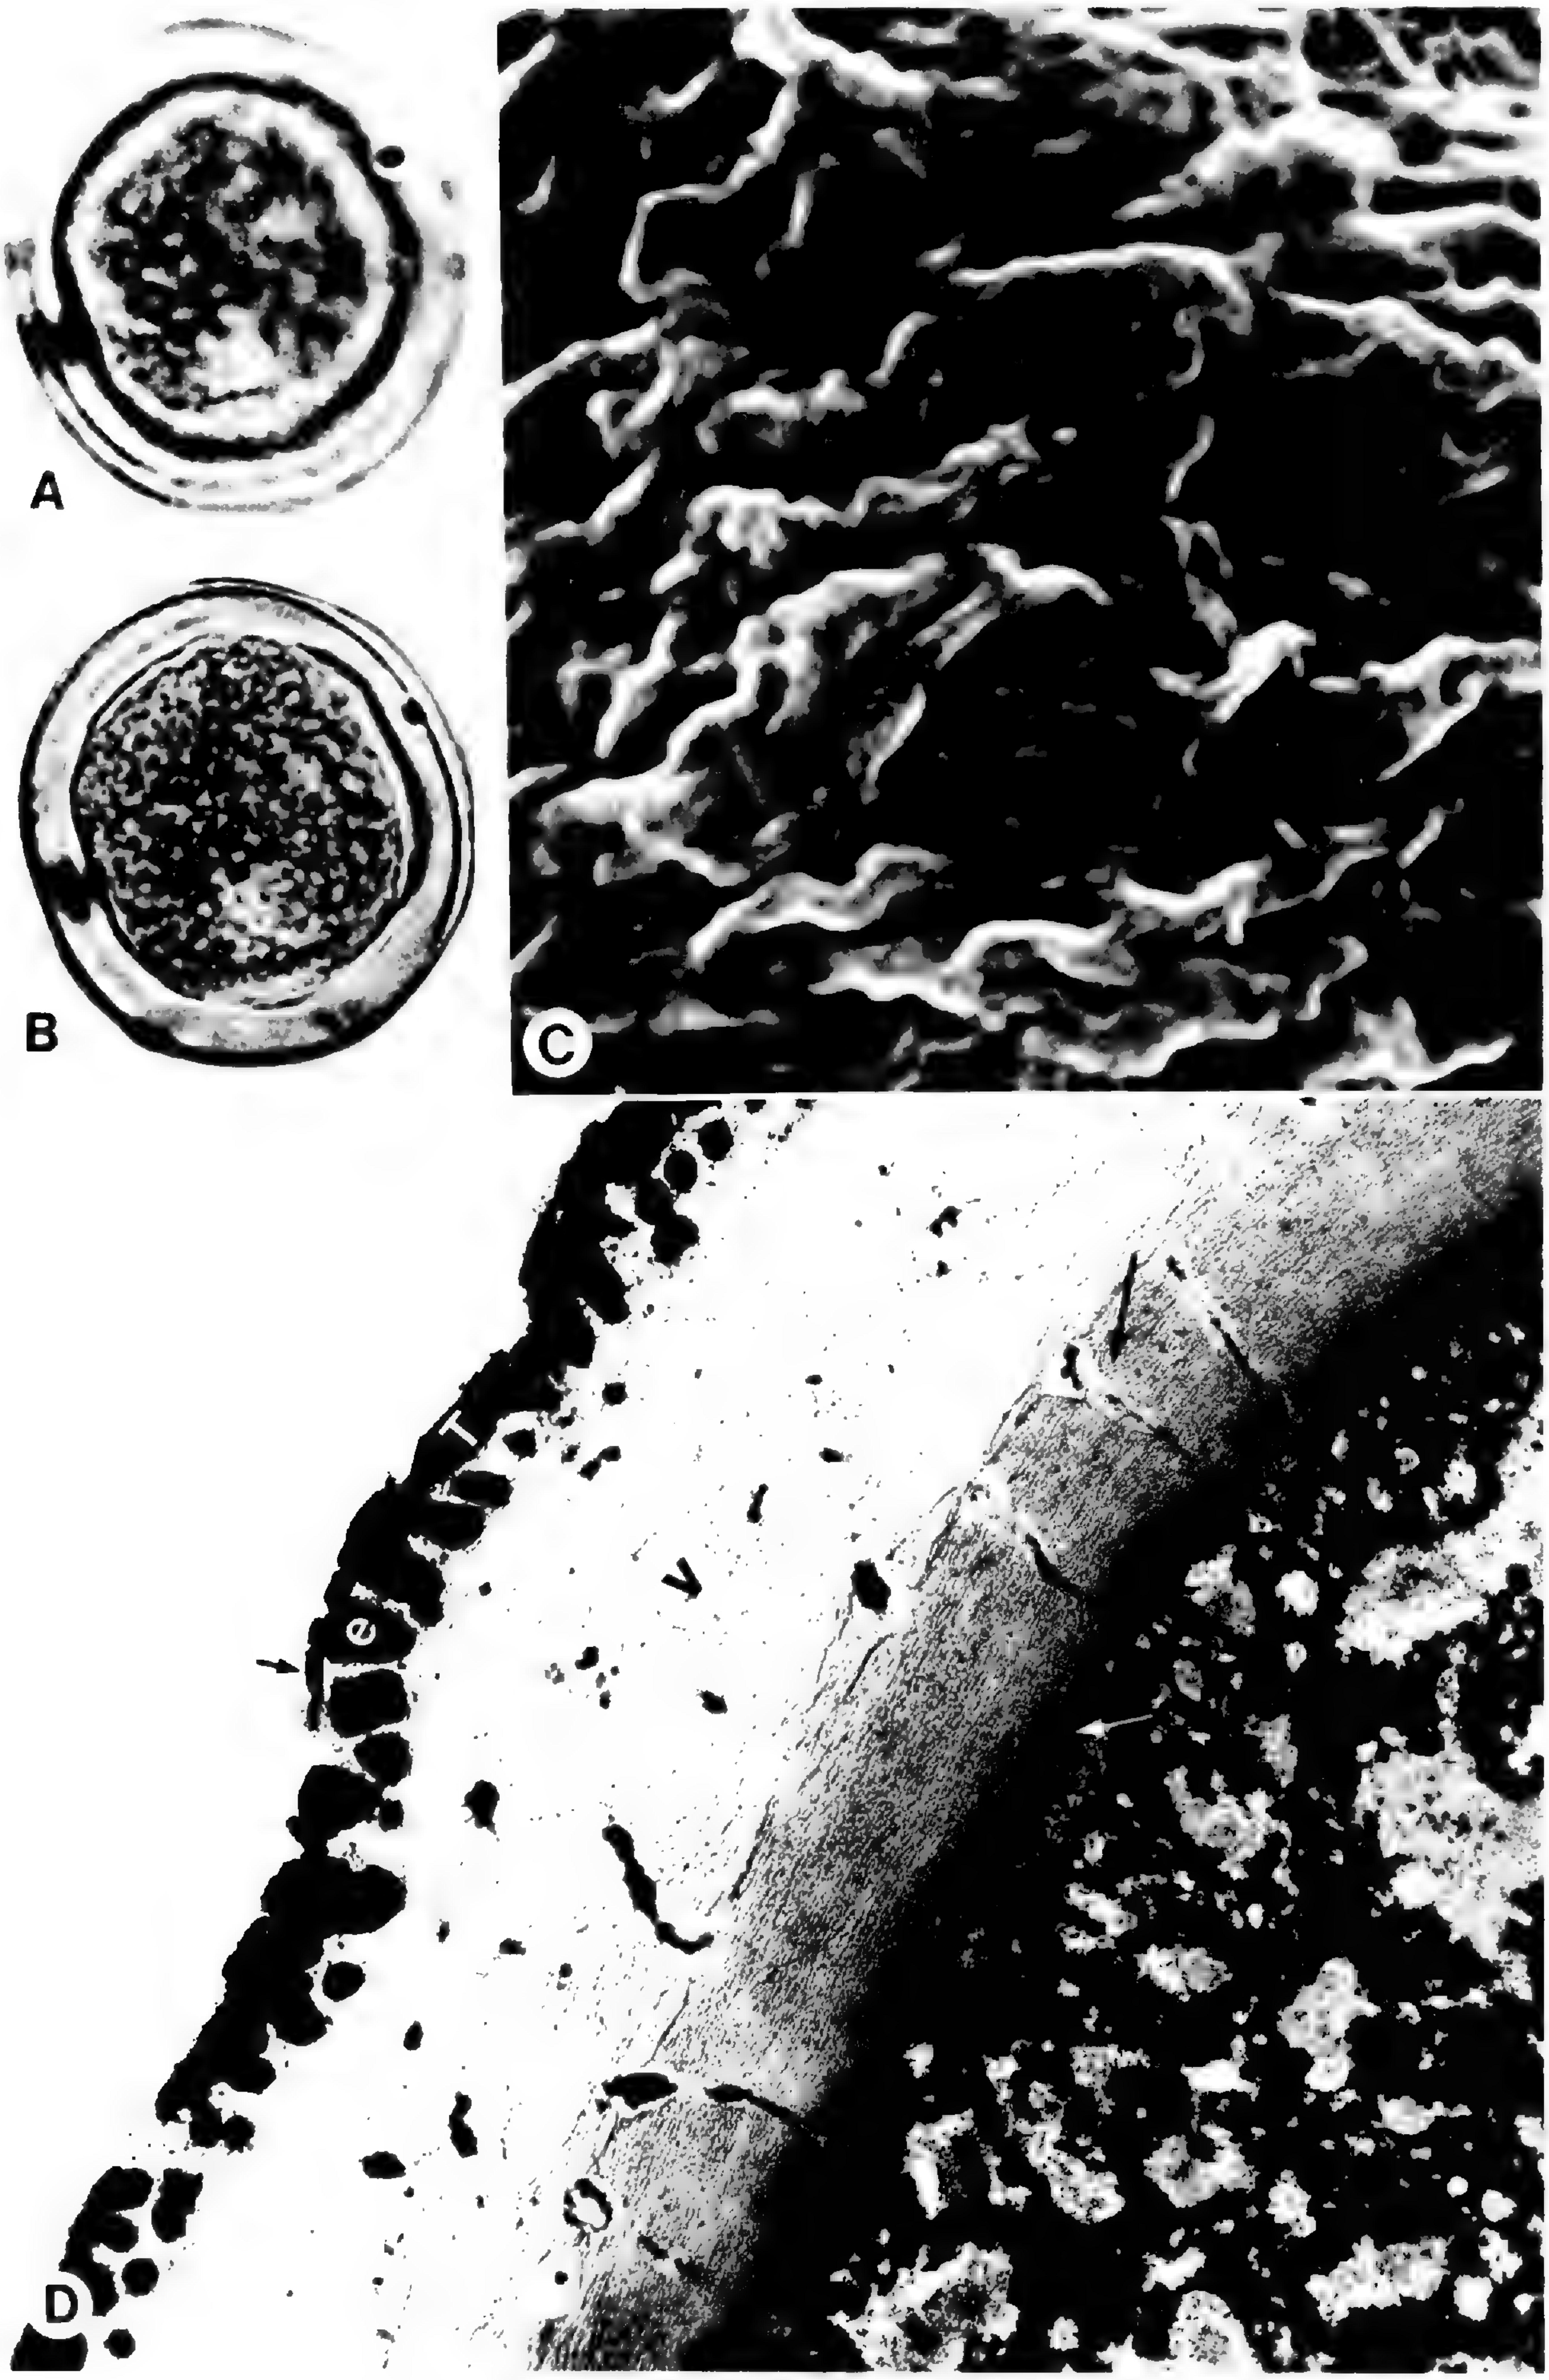

FIGURE 14. Cryptocarya aschersoniana.—*A. Entire pollen grain showing the smooth exinous surface.—B. The same in optical cross section. LM ×1,000.—C. Part of exine showing the smooth and wrinkled surface. SEM ×11,000.—D. Part of pollen wall showing a thin, electron-dense layer consisting of tectum (T), supported by clavatelike to globular elements (e), and covered by a thin coating of compact material (arrow). The subtending intinous layer distinguished into an outer thick, fibrillar layer inlaid with vacuoles (v), followed by*

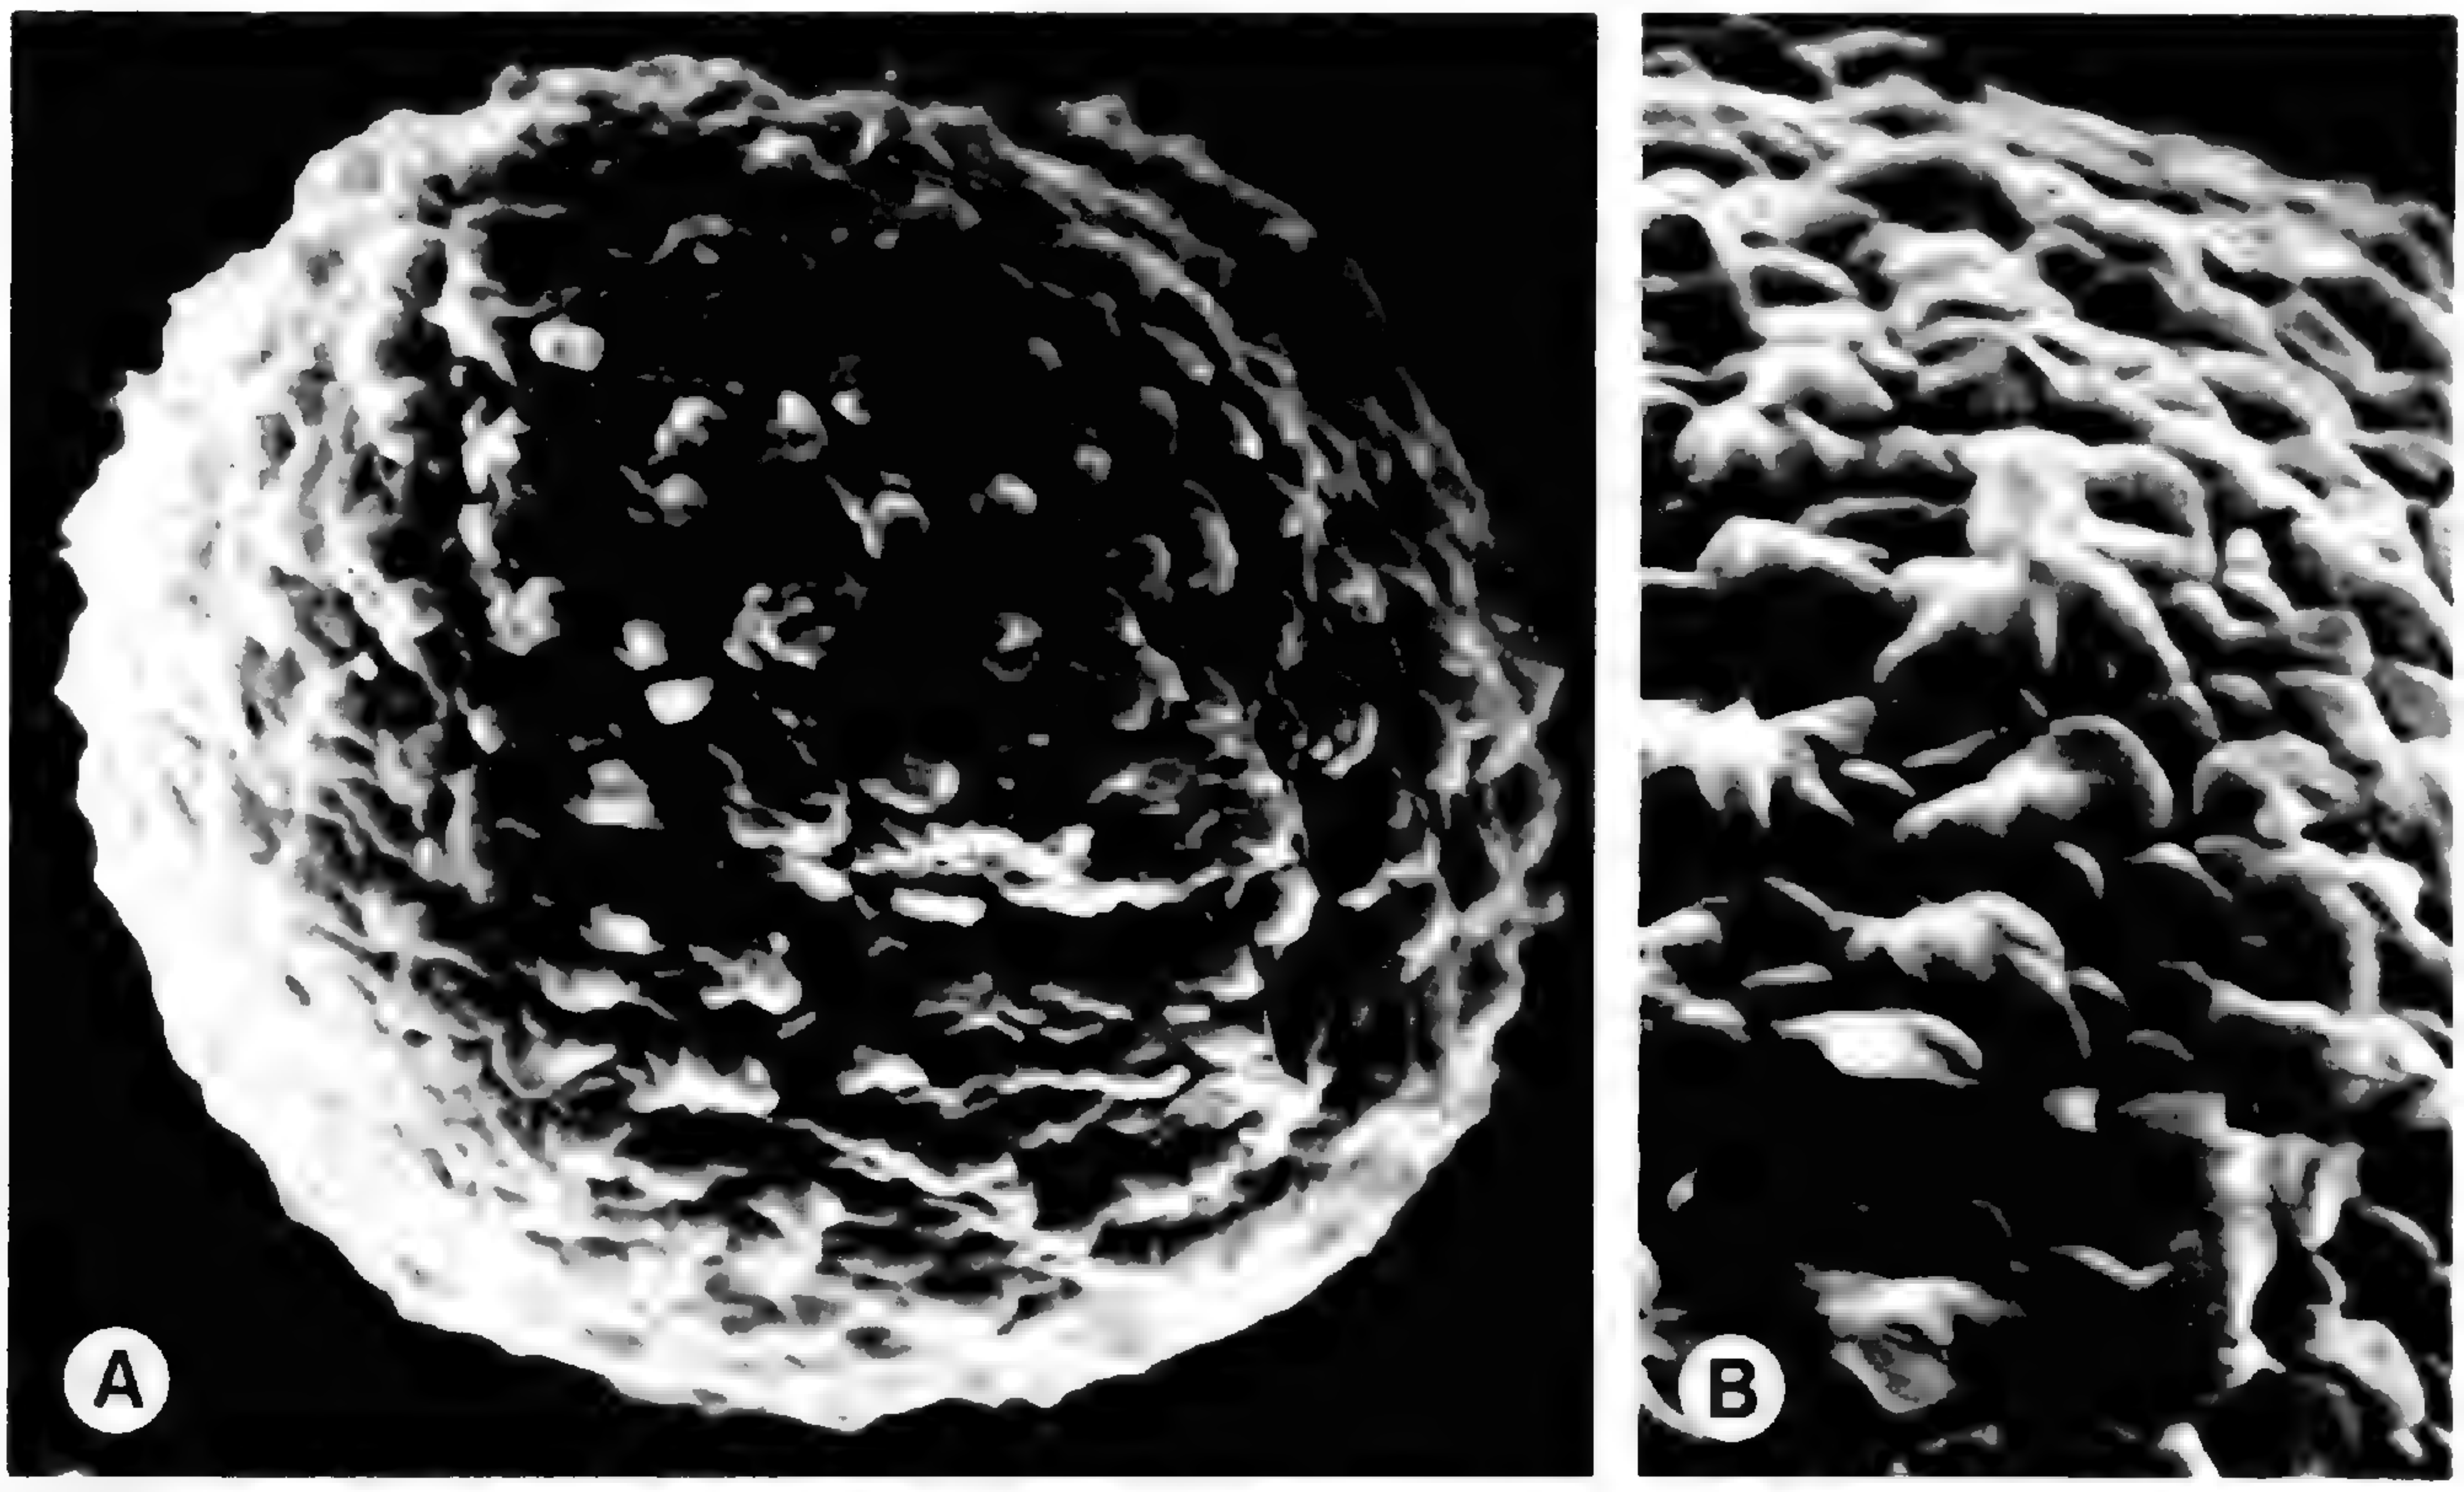

FIGURE 15. Cassytha filiformis.—*A. Entire pollen grain showing uneven exinous surface beset with spinuloid processes. SEM ×5,200.—B. Part of the same at a higher magnification. SEM ×10,000.*

grains in *Umbellularia californica* (not confirmed by the present investigation) and acolpate grains in *Laurus nobilis* (not included in the present study). Also Markgraf & D'Antoni (1978) described the pollen grains of *Nectandra angustifolia* as tricolpate, prolate spheroidal (not included in the present study).

The pollen grains of this family are considered to be "delicate" since they disintegrate readily or come out in a more or less shriveled and wrinkled condition after acetolysis. They are tenui-exinous and, as TEM observation shows, entirely ectexinous. The exine is provided with spinules or spinuloid projections, or rarely the exine is smooth as in *Cryptocarya aschersoniana* (Heusser, 1971, described the exine of *Cryptocarya alba* as foveolate). The intine represents the dominant, massive layer of the pollen wall.

Out of the 80 taxa investigated, the largest pollen grains are those of *Beilschmiedia miersii, Cryptocarya aschersoniana, Ocotea calophylla, O. spixiana, Persea americana, P. caerulea, P. fulva,* and others (over 30 μm in diameter); while the smallest belong to *Aniba burchellii, Endlicheria glomerata, Nectandra purpurea, Ocotea cernua,* and *Persea veraguasensis* (under 20 μm in diameter). In the remaining taxa the diameters are 20–30 μm. The grains are usually monomorphic; however, dimorphic grains occur in *Persea caerulea* and *P. schiedeana.*

Some species of *Persea* have dimorphic spinules. Because *Persea* shows various stages of reduction of the number of fertile stamens and/or anther cells (from the normal pattern of nine four-celled stamens to six four-celled and three two-celled or six four-celled stamens and three staminodia or nine two-celled stamens; Kopp, 1966), it would be worthwhile to investigate whether in species with dimorphic pollen grains each stamen has only one kind of pollen grain and inner and outer stamens have different pollen grains or whether each stamen possesses both kinds of pollen grains.

←

an electron-dense, structurally compact, fibrillar stratum inlaid with narrow, conical channels (arrow); the innermost layer denser than the other layers and likewise inlaid with channels (white arrow). TEM ×20,000.

TABLE 4. *Pollen-morphological data for Lauraceae. Five main pollen characters are compared: (1) diameter of pollen grains; (2) exine thickness; (3) intine thickness; (4) length of spinules; and (5) maximum and minimum number of spinules.*

C. filiformis	22–28	1	4	0.5	—	—	exine surface beset with densely spaced, minute excrescences

The exine ornamentation in all the taxa (except *Cryptocarya*) consists of solid, apparently simple spinules or as in *Nectandra reticulata, Ocotea cuprea, Persea americana, Phoebe porphyria,* and others, "wick-like" i.e., made up of twisted strands. They are pointed or blunt, uniformly spread over the surface or rarely, in some portions of a grain, in groups; the spinules are sometimes crowded as in *Nectandra ambigens* to give a rosettelike appearance, or they occur in pairs. Similar wicklike spinules have been reported in many groups, e.g., Euphorbiaceae (Thanikaimoni et al., 1984), Linaceae (Punt & den Breejen, 1981), Monimiaceae (Walker & Doyle, 1975) and Plumbaginaceae (Nowicke & Skvarla, 1977).

The density and morphology of spinules differs in different species. Thus the highest number of spinules per grain is met with in *Persea* and *Licaria,* and the lowest in *Beilschmiedia, Caryodaphnopsis,* and *Litsea.* Further, the size of the pollen grains does not seem related to the number of spinules. Spinules are usually monomorphic; however, dimorphic spinules have been found in *Nectandra falcifolia, Persea caerulea,* and *P. fulva.* Spinules are usually broad at base. Their common characteristic feature is the presence of a conspicuous, circular, cushion-like base which invariably protrudes proximally; its surface is either smooth or studded with granular to globular elements. In *Ocotea cuprea* these cushionlike structures are relatively big and compactly arranged, thereby giving a more or less rounded insulaelike appearance to the exine.

The stratification of the sporoderm presents interesting features that at times are difficult to interpret. A strikingly similar type of statified sporoderm has been reported in the Zingiberales and in certain monimiaceous genera. The fascinating aspect of the pollen wall is the extreme thinness of the exine and the thick, structurally complex intine.

The fine structure of the lauraceous genera investigated shows an electron-dense, extremely thin, coherent exine made up of granular, globular, or irregularly shaped elements and of spinules. Only in *Persea fulva* (Fig. 1C), *Endlicheria serica* (Fig. 11A), and *Cryptocarya aschersoniana* (Fig. 14D) is there a clear indication of parts of well-defined tectum supported by a well-defined bacular layer. In *Umbellularia californica* the exine surface and spinules are covered by a distinct, superficial coating referred to as "fuzzy surface coating" by Rowley & Skvarla (1986); traces of this material are also discernible in *Aiouea trinervis, Ocotea puberula, Persea fulva,* and *Phoebe helicterifolia.*

The coherent nature of the thin exine, which is emphasized in the present study, has often been compared with exines of some members of the Zingiberales (Kress et al., 1978; Stone et al., 1979) and reported as incoherent or "exine-less." The incoherent nature of any exine, however thin, or the conception of an "exine-less" pollen wall, both from a morphological and functional point of view, has been convincingly argued and rejected by Hesse & Waha (1983).

The dominant stratified layer of the sporoderm is the intine. This thick layer is completely destroyed by acetolysis and, in keeping with common wisdom, has to be interpreted as intine. In this layer an outer channeled zone can be easily recognized and has been designated variably: "lacunes" after Le Thomas, 1980; "tubules" according to Sedgley, 1979; "onciform zone" by Rowley & Vasanthy, 1980; "Zwischenkörper" in Kress & Stone, 1982; or simply outer intine or intine 1. These channels, which are long and narrow and of varying length, are predominantly radially aligned and partly or completely filled with osmiophilic material. Thin partition walls as encountered in *Strelitzia reginae* (Musaceae) (Hesse & Waha, 1983) are absent. It is postulated that these channels may act as deposits for material involved in pollen germinating or incompatibility processes (Stone et al., 1979; Hesse & Kubitzki, 1983).

It is remarkable that the characteristic sporoderm stratification encountered in lauraceous genera, namely extremely thin exine and a thick, stratified, channeled intine, is apparently limited to inaperturate pollen grains belonging to such disparate genera as *Canna*, *Heliconia*, *Hernandia*, and *Palmeria*.

Further, the massive channeled intinous zone mentioned above has been found also to resemble to a lesser extent that of the conifers (viz., *Larix europea*, Cupressineae, and Taxodineae) that Wodehouse (1932) noted and remarked as "one of the most remarkable examples of convergence I have yet encountered among pollen-grain forms."

The functional significance of the thickened intinous layers or onci frequently observed beneath apertures appears to be to act as storage areas for gametophytic incompatibility proteins (Heslop-Harrison, 1976).

TAXONOMY

There is uniformity of opinion among taxonomists that the family Lauraceae is rather old and probably derived from primitive members of the Monimiaceae of the *Hortonia*-type.

In Kostermans's (1957) classification, only a sequence of floral characters are adopted; not a chronological family tree, nor a paleontological succession, nor a phylogenetic trend has been envisaged, but similar genera are grouped.

Palynologically most of the relationships are justified, e.g., the genera *Persea* and *Phoebe* of the tribe Perseeae are satisfactorily included in the subtribe Perseineae, and thus separated from *Beilschmiedia* and *Mezilaurus* of the subtribe Beilschmiediineae. The pollen grains of *Persea* and *Phoebe* have the highest number of spinules per pollen grain, and their anthers are four-celled compared with *Beilschmiedia* and *Mezilaurus*, which have the lowest number of spinules and have two-celled anthers. The former two genera are easily separated from each other because the pollen grains of *Persea* are either dimorphic or if monomorphic, the spinules are dimorphic, whereas the pollen grains of *Phoebe* are wholly monomorphic. Among the Central American species of *Phoebe*, *P. mexicana* stands clearly apart due to its high number of spinules. This pollen feature supports the recognition of *P. costaricana* as distinct from *P. mexicana*.

The genera *Beilschmiedia* and *Mezilaurus* can be separated by the difference in size of spinules and in the surface of the basal cushions and exine. Pollen-morphologically, *Mezilaurus* does not seem to be close to *Licaria*.

Caryodaphnopsis, although similar to *Persea* in floral and fruit characters, has pollen grains quite unlike those of *Persea* and *Phoebe*. On the other hand, the pollen grains are comparable to those of *Beilschmiedia*, and recognition of *Caryodaphnopsis* is supported by pollen morphology. Its position in Richter's (1981) classification seems to be more appropriate than in those of Kostermans (1957) and Hutchinson (1964).

Kostermans (1957) divided *Ocotea*, of the tribe Cinnamomeae, subtribe Cinnamomineae, into three subgenera: *Ocotea*, *Nectandra* and *Pleurothyrium*. His contention that macromorphological differences, such as in the position of the anther cells, size and shape of the staminal glands, and cupule shape, are not big enough to maintain them as distinct genera does not improve the classification. Pollen-morphologically there are enough differences to recognize them as distinct genera. Pollen grains of *Ocotea* and *Pleurothyrium* are apparently very similar, including the organization of spinules, which suggest close relationship. However, the characters that distinguish them are pollen size and ultrastructural details of sporoderm. Pollen grains of *Nectandra* are quite distinct with respect to exine surface and to sporoderm details. There seems enough micro- and macromorphological characters to maintain these as three distinct genera. The transfer of the two species *Nectandra grandis* (Fig. 6D) and and *N. kunthiana* to the new genus *Rhodostemonodaphne* (Rohwer, 1986) seems justified, as the pollen grains are quite different from those of the other species investigated. The spinules in both species appear vestigial without the usual twisted strands easily discernible in other species.

The monotypic genus *Umbellularia* is considered to be related to *Litsea*. Pollen-morphologically such a relationship seems to exist as the pollen grains of the two genera are more or less of the same size, the number of spinules per pollen grain is more or less the same, and the ultrastructural details of the pollen wall are very similar.

Subtribe Anibineae of tribe Cinnamomeae is represented by seven genera, of which the pollen grains of five, *Aiouea*, *Aniba*, *Endlicheria*, *Licaria* and *Kubitzkia* (*Systemonodaphne* sensu Mez), have been investigated. These five genera are rather closely related, and taxonomic problems still remain unsolved in this group. *Aiouea*, recently revised by Renner (1982), appears to include species independently derived from four-celled ancestors. Some Central American *Aiouea* species are morphologically very similar to sympatric *Ocotea* species (van der Werff, 1987) and are much less similar to the Guyanan–Brazilian species group which includes the type species. The observation that *Ocotea ira* and *Aiouea costaricensis* both possess porelike, transparent areas devoid of spinules on the pollen wall (otherwise a very rare character in Lauraceae) strengthens the theory that *Aiouea costaricensis* is more closely related to sympatric *Ocotea* species of the *O. insularis* group (as defined by Rohwer, 1986) than to the S. American *Aiouea* species, and that *Aiouea* is a polyphyletic genus. Kubitzki (1982) considered *Aniba* and *Licaria* closely related but had no hesitation in maintaining them as separate genera, a point of view we share. MacBride's (1938) suggestion to treat *Licaria*, *Kubitzkia*, and *Endlicheria* (the only dioecious genus in this group) as subgenera of *Aniba* has never gained acceptance. *Kubitzkia* is probably closely related to *Licaria*, but is easily separated by the number of fertile stamens.

Pollen morphology also supports the interrelationship of the above genera, and at the same time distinguishes them from one another. All genera have pollen grains of more or less the same size and exhibit the highest number of spinules (excluding *Kubitzkia*) per pollen grain. The highest number of spinules is found in *Licaria*. There is a gradual decrease from *Endlicheria* to *Aniba* to *Aiouea*. *Kubitzkia*, with a much lower number of spinules per pollen grain (661/521), seems to be a misfit in this subtribe, and pollen morphology fails to support its taxonomic relationship with *Licaria*. Better placement would be in the vicinity of *Beilschmiedia* as classified by Hutchinson (1964).

In *Aiouea* the basal cushion of spinules is more or less smooth or in places surrounded by a ring of partially fused processes. In *Aniba* the basal cushions are not very pronounced, and the general surface of the exine is studded with granular processes. In *Endlicheria* densely spaced processes surround and hide the basal cushion of spinules. In *Licaria* the basal cushions are smooth and surrounded by a ring of densely spaced, partially fused processes of varying size and shape, and the general surface of exine is studded with densely spaced granular processes. In *Kubitzkia* the basal cushion of spinules is prominent and surrounded by a ring of densely spaced, partially fused processes of varying size and shape; the general surface of exine is studded with densely spaced, minute processes. Another group of pollen morphological features that distinguish these genera (except *Kubitzkia*, not investigated by TEM) are the ultrastructural details of the sporoderm.

In the classification proposed by Kostermans (1957), *Litsea* is included in subtribe Litseineae of tribe Litseeae. It is closely related to *Umbellularia*, and pollen morphology justifies this relationship. Pollen morphology would thus support the transfer of *Umbellularia* to subtribe Litseineae, corresponding with the classification of Hutchinson (1964) and Richter (1981).

Cryptocarya of tribe Cryptocaryeae, subtribe Cryptocaryineae, is considered isolated among the neotropical genera. Its isolated position is very well reflected in its pollen grains. Its pollen grains are quite different from those of the other genera investigated. The exine surface is devoid of spinules and spinuloid excrescences, instead it appears smooth and wrinkled. The inclusion of this genus by Richter (1981) is his Group I, along with *Beilschmiedia* and *Caryodaphnopsis*, is not supported pollen-morphologically.

Cassytha, of subfamily Cassythoideae, is a parasitic or partially autotrophic twiner. Because of its aberrant habit and ecology, it has often been treated as a separate family, Cassythaceae, but in floral characters it resembles Lauraceae and approaches *Cryptocarya*. The pollen grains of *Cassytha* are characteristic and unlike those of the other genera except *Cryptocarya*, which it resembles in the wrinkled exine surface but from which it differs by the presence of minute, scattered, irregular projections or low warts.

From the above account, pollen characters have been found useful in elucidating relationships of many genera but inadequate to clarify the positions of others. However, in the absence of any clear characters, it is important to assess critically each line of evidence and this we have attempted to do for the palynological data.

The treatment of Laurales in both classical and modern systems of classification is as a considerably old order. Hutchinson (1964) placed Laurales in his Lignoseae, this consisting of woody families. Engler (1936), however, did not consider the order as so primitive—in his view the amentiferous plants were the most ancient dicotyledons. Cronquist (1968) regarded the members of Laurales as rather primitive and placed them in the most primitive order Magnoliales. Takhtajan (1969), while formulating his system, took into account the importance of pollen morphology and considered the Magnoliales as the most primitive order; he accepted Laurales as near Magnoliales but slightly more advanced.

The inaperturate type of pollen grains of Lauraceae are also encountered in some families of Laurales, such as Amborellaceae, Gomortegaceae, Gyrocarpaceae, and Hernandiaceae and in *Sarcandra* (Chloranthaceae), *Hortonia*, *Levieria*, *Peumus*, and *Tambourissa* (Monimiaceae). The rest of lauralean families exhibit apertures that are monosulcate or disulculate or diporate. It is believed that the inaperturate condition is palynologically more advanced than a monosulcate condition from which the former has been derived; Doyle (1969) postulated such derivation on the basis of the Cretaceous pollen record.

Kostermans (1957) postulated a development within the Lauraceae from genera with a very shallow floral tube, where the fruit is not subtended by a cupule (tribe Perseeae), through genera with a deeper floral tube, where the fruit at maturity is subtended by a cupule up to one-third the size of the fruit (tribe Cinnamomeae) and genera with a deep floral tube that fully encloses the fruit (tribe Cryptocaryeae). If the pollen-morphological data are interpreted in relation to this view, *Persea* could be regarded as the most primitive genus because of the large number of spinules; and if the reduction of the number of spinules is interpreted as an advanced trait, *Cryptocarya*, because of the total absence of spinules, would stand out as advanced. Thus these two genera would represent the two extremes, and the remaining genera, because of the intergrading characteristics (size of pollen grains and number of spinules), would fall in between but not necessarily in a phylogenetic sequence. *Cassytha* is the only herbaceous genus that is distinct from the rest of the genera because of its habit. The pollen grains exhibit spinules reduced into minute excrescences, and this suggests a major evolutionary trend. Pollen morphology might provide additional evidence to support separating *Cassytha* into a subfamily of its own.

THE TAXONOMIC SIGNIFICANCE OF POLLEN MORPHOLOGY IN THE *COLUMNEA* ALLIANCE (GESNERIACEAE: GESNERIOIDEAE)[1]

Karen J. Fritze[2] *and Norris H. Williams*[3,4]

ABSTRACT

Pollen of 67 species of the five genera of the Columnea *alliance (Gesneriaceae: Gesnerioideae) was examined to assess its value in generic classifications. Several distinct groups of pollen can be recognized by pollen shape, pattern of exine sculpturing, and shape and size of the colpus.* Columnea *sensu stricto has a peculiar pollen type supporting its treatment as distinct from the other four genera of the alliance.* Bucinellina *is also distinct from the other genera, and its status as a genus is likewise supported. Pollen structure does not confirm the distinctiveness of* Trichantha, Pentadenia, *and* Dalbergaria *and may be used better at the sectional rather than the generic level.*

The mainly tropical family Gesneriaceae contains over 2,800 species. A large influx of collections of newly discovered species from the American tropics has cast doubts on some traditional generic limits in the exclusively neotropical subfamily Gesnerioideae. Parallel adaptations to certain classes of pollinators have become apparent and complicate the efforts of taxonomists. Taking this into consideration, Wiehler (1983) proposed new generic and tribal limits for the Gesnerioideae and a new subfamily (Coronantheroideae). His work parallels Burtt's (1963) for subfamily Cyrtandroideae, and it is in the context of Wiehler's classification that this study was done.

The *Columnea* alliance (tribe Episcieae) is a natural group of closely related genera that share ornithophily as the pollinator syndrome. The alliance comprises over 240 species in five genera: *Pentadenia* Hanst. (ca. 30 species), *Dalbergaria* Tussac (ca. 90 species), *Trichantha* Hook. (ca. 70 species), *Bucinellina* Wiehler (2 species), and *Columnea* L. (ca. 75 species, Wiehler, 1983). One of the main taxonomic problems in the Episcieae is the disposition of these taxa. Should species distributed variously in several groups formerly regarded as sections of *Columnea* in the broad sense be given generic status, or should they be treated as subgeneric groups of *Columnea*? Morley (1976), who based his conclusions mainly on cytological and hybridization results of Sherk & Lee (1967) and Moore & Lee (1967), disputed treating them as distinct genera. Morton, who worked with *Trichantha* and *Columnea* for a number of years, first lent support to the concept of the

genus *Trichantha* (Morton, 1963) but later reversed his opinion (Morton, 1971). He found that the appendages in the sinuses between corolla lobes that distinguished his concept of *Trichantha* from other taxa were rudimentary throughout the complex. However, Wiehler (1983) maintained that on the basis of several important characters, *Trichantha* and the other four genera are as distinct from one another as from any other genera in the tribe and therefore should be given generic status.

Among the characters Wiehler (1973) considered most important in arriving at generic limits within the *Columnea* alliance and in other Episcieae are fruit type, number of nectary glands present and their degree of dorsal connation, plant habit, and corolla shape. The importance of corolla shape is a source of debate in the classification of the *Columnea* alliance. Within this group, generic limits based on corolla morphology are vague. Although he used it as a convenient means for separating certain genera, Wiehler de-emphasized corolla shape in his overall classification of the subfamily, since it appears to be an adaptation to a pollinator class and is not necessarily indicative of close relationships among taxa. In other words, it is of taxonomic use in separating species but contributes little to an evaluation of systematic relationships. Morley (1973, 1974, 1976), however, believed that degree of corolla zygomorphy is correlated with degree of crossability and is therefore important to classification in the *Columnea* alliance.

Five separate nectary glands distinguish *Pentadenia* from the rest of the Episcieae. All other genera in the Episcieae possess glands which vary in degree of reduction and dorsal connation even within species (Wilson, 1974). In the *Columnea* alliance (except *Pentadenia*) the nectary consists solely of a large double dorsal gland.

The "fern-frond" habit (or extreme anisophylly) makes *Dalbergaria* distinct in the alliance (Wiehler, 1971). Plant habit varies within other genera of the *Columnea* alliance.

Fruit type in the Episcieae is a valuable suprageneric character. It separates the *Drymonia* complex from the *Episcia* complex, the two having different types of capsules, and separates both from the *Columnea* alliance, which has a berry. Within the *Columnea* alliance genera differ with respect to fruit shape and color. Subtle differences in shape create some skepticism regarding its reliability (Morley, 1976).

Published studies of gesneriaceous pollen are mainly morphological and make little mention of the taxonomic implications. Woods (1964) studied 180 species in over 50 genera and made a distinction between Burtt's subfamilies based on pollen-wall sculpturing and grain size. Uniform or homobrochate exines are more prevalent in the Cyrtandroideae; heterobrochate exines are more prevalent in the Gesnerioideae. Grains tend to be larger in the Gesnerioideae than in the Cyrtandroideae.

Erdtman (1966) surveyed 20 species from 17 genera of the Gesneriaceae with the light microscope and supplied a diagram of *Columnea microphylla* pollen. Melhem & Mauro (1973) obtained data on eight local species from three genera in São Paulo, Brazil. Based on their observations and those of Erdtman, they concluded that there was great variation of pollen types in the family. They remarked only on morphological distinctions among pollen of these species and included no taxonomic interpretations.

Skog (1976), in his taxonomic treatment of the tribe Gesnerieae, presented a brief discussion of his observations on the grains of 27 examples. He made use of the scanning electron microscope, but little information could be obtained from his micrographs other than sculpturing patterns, since the pollen grains were collapsed.

The absence of pollen data from Wiehler's (1973) study prompted a preliminary SEM survey by Williams (1978) of 30 species representing 19 genera to ascertain whether or not pollen might be of use in further clarifying systematic relationships in the Gesnerioideae. Williams (1978) found a wide variety of forms in the Gesneriaceae, particularly in tribe Epi-

scieae. Fritze (1979) found the diversity of pollen to be of potential taxonomic use in the *Columnea* alliance, and Williams (1978) introduced a successful technique for preparing gesneriaceous pollen that shows expanded, clean grains and allows full observation of all external features.

MATERIALS AND METHODS

Pollen was collected from mature anthers of living plants grown in the greenhouses at the Marie Selby Botanical Gardens, Sarasota, Florida (Table 1). The pollen was acetolyzed following a modified method of Erdtman (1966) and was stored in 70% ethyl alcohol (EtOH). Slides for vouchers were made from which sizes and shapes of pollen grains could be determined. Measurements of the lengths of the polar and equatorial axes of 50 grains per species of representative species were made at 400× using an ocular micrometer. Pollen for the scanning electron microscope (SEM) was dehydrated through an alcohol series followed by an amyl acetate/EtOH series (1 : 3, 1 : 1, 3 : 1, 100% amyl acetate). A drop of suspended pollen was then placed on a round glass coverslip and attached to an SEM stub with double-sided tape. The pollen was air dried under a cover to prevent contamination. Dried pollen was coated with 5 nm of gold palladium and scanned with a Cambridge Stereoscan model S4-10 instrument at 5, 10, or 20 kV. Fractured pollen was also viewed with the SEM. Pollen was transferred from the original SEM stub to a second stub fitted with a piece of double-sided tape covering the entire surface. Transfer was accomplished by touching the two stubs together until the pollen adhered to the tape. The process was repeated using a third stub with double-sided tape on it, which was pressed against the second stub. The adhesion of the pollen grains to both stubs pulled the grains apart. This procedure requires no elaborate microtomy and yields replicates with no loss of material. The fractured grains were recoated and scanned. Photographs were taken using Type 665 Positive/Negative Land film with a Polaroid camera mounted on the microscope, and negatives were later contact printed.

NOTE ON TERMINOLOGY

Terminology used for the apertures, shape, and areas of the surface of the pollen grain follows Erdtman (1966). Since Erdtman's terms do not extend to the detail of exine sculpturing revealed by the SEM, it is necessary to make a precise distinction between the punctate and reticulate patterns found in the *Columnea* alliance. An exine is punctate if the tectum is perforate and the majority of the perforations are much smaller in diameter than the width of the muri (remnants of the tectum). The exine is reticulate if the punctae are enlarged (lumina) and at least as wide as the muri. A long aperture extends beyond half the distance from the equatorial margin of the grain to the polar axis when seen in polar view (Fig. 2E). An aperture of intermediate length reaches about one-half this distance (Fig. 8C), and a short aperture extends less than half this distance (Fig. 12G, H). Terms describing exine structure follow Walker (1974a)

RESULTS AND OBSERVATIONS

Several pollen types appeared with some overlap among genera. Types are distinguished mainly by shape, exine pattern, and aperture length and shape. All grains are monads, isopolar, and tricolp(or)ate, and either punctate or reticulate. Their sizes, based on the length of the longest axis, range from approximately 28 to 51 μm. The features are summarized for each species in Table 2.

By far the greatest homogeneity turned up in *Columnea*, in which 26 species were examined (Figs. 1, 2, 3, 4, 5A–C). With the exception of three species, all have subprolate to spheroidal grains (see P/E, Table 2) with uniformly punctate exine, long, elliptic apertures, and circular ambs. There are slight differences in size and shape of punctae and apertures between species. *Columnea repens* and *C. rutilans* (Fig. 5B, C) stand apart by having suboblate or oblate grains, exine reticulate grading to punctate adjacent to the colpi and at the polar regions, tapered apertures, and triangular ambs. *Columnea kucyniakii* has suboblate grains, exine reticulate grading to punctate adjacent to the colpi and poles, long, sharply tapered apertures, and triangular ambs.

The majority of the 15 *Dalbergaria* species examined (Figs. 5D–H, 6, 7, 8) have grains distinct from those of *Columnea*. Those of the former are suboblate and have the exine reticulate grading to punctate adjacent to the colpi and at the poles, long, sharply tapered apertures, and angularaperturate, circular or triangular ambs. *Dalbergaria aureonitens*, *D. sanguinea*, and *D. florida* (Fig. 8) do not fit the general pattern; they have pollen suboblate to spheroidal, reticulate (as above, but

the reticulation not reduced to punctae at the poles), and with the colpi more elliptic, these of intermediate length. *Dalbergaria eburnea* (Fig. 7E, F) and *D. asteroloma* (Fig. 5G) grains are suboblate to spheroidal with the tectum nearly punctate, tectal perforations near the colpi and at the poles reduced in size or absent, and the apertures narrow.

Three distinct types of pollen are found within *Trichantha* (15 species examined). One type (Figs. 9A–G, 10E) is suboblate with a reticulate exine becoming punctate adjacent to the colpi and at the poles and has long apertures widest at the equator and a triangular amb. These grains resemble pollen of *Dalbergaria* and *Pentadenia orientandina. Tricantha ambigua*, a tetraploid, has pollen of this type but with four apertures (Fig. 10C). A second type of pollen with short colpi (Fig. 10A, B, G, H) is oblate to spheroidal, reticulate, and punctate around the colpi with intermediate elliptic apertures; this type has a somewhat triangular amb. The third type (Fig. 11A–D) is suboblate and punctate, and has very short oval apertures (almost like pores); its amb is circular to slightly triangular.

Most species of *Pentadenia* (9 species examined) possess suboblate to oblate grains that are reticulate, becoming punctate adjacent to the colpi but remain reticulate at the poles; they have either short or intermediate apertures and somewhat triangular ambs (Figs. 12A–H, 13C, D). *Pentadenia ecuadorana* (Fig. 12C, D), *P. microsepala* (Fig. 12E, F), and *P. angustata* (Fig. 13C) grains have narrow apertures of intermediate length, but the apertures are widest at the equator. Grains of *Pentadenia spathulata* (Fig. 12G) and *P. zapotalana* (Fig. 12H) have short elliptic apertures. *Pentadenia orientandina* pollen (Fig. 13A, B) is suboblate and reticulate, grading to punctate at the poles and adjacent to the colpi; it has long luminal baculae, long apertures tapered at the poles, and circular ambs. It stands apart from other pentadenias and resembles some *Trichantha* pollen types (e.g., Fig. 9). *Pentadenia strigosa* (Fig. 13E, F) pollen shows a combination of features found nowhere else in the *Columnea* alliance. The pollen is suboblate and reticulate with long luminal baculae, and the reticulum is neither reduced at the poles nor around the colpi. It has long, elliptic, slightly tapered apertures and a circular amb.

13G, H), has pollen that is readily recognizable by its extreme oblate shape, short oval apertures, and triangular ambs. The two species, however, show a sharp difference in exine patterns: *Bucinellina nariniana* has reticulate sculpturing (Fig. 13G) with wide muri, and *B. paramicola* (Fig. 13H) is nearly tectate-imperforate.

One fracture was made of each type of grain in the *Columnea* alliance. Although they do not reveal layers visible with TEM, fractures provide useful data. One can see a diversity of exines, each with a different nexine-to-sexine ratio and nexine-to-tectum and columellae ratios. The exine of *Columnea dressleri* pollen (Fig. 3H) is very uniform with closely packed columellae and a nexine-to-sexine ratio of approximately 1 : 6. The tectum and nexine are of equal thickness. *Dalbergaria ericae* pollen (Fig. 5H) by contrast, has a nexine-to-tectum ratio of about 1 : 3. The nexine-to-sexine ratio approximates 1 : 8. The nexine becomes thick next to the colpus, and the columellae are evenly spaced but

absent in the lumina. *Dalbergaria aureonitens* (Fig. 8H) has a similar exine, but the columellae are much more irregularly spaced, since they do not occur in the lumina where there is no tectum.

Trichantha calotricha pollen (Fig. 9H) has a tectum over three times thicker than the nexine. The columellae are short and vary in girth. *Trichantha pulchra* pollen (Fig. 11B) is at variance with all others examined in that its nexine is about five times thicker than the tectum and increases in thickness at the colpus. The columellae are unequally spaced and relatively short.

The nexine and tectum of *Pentadenia spathulata* (Fig. 13D) are of equal thickness, and the columellae are well spaced but absent where there is no tectum. *Pentadenia strigosa* (Fig. 13F) shows a thick tectum relative to the nexine, and baculae fill the lumina.

Discussion

Pollen characters are constant, at least within certain genera and subgeneric groups, and appear to be of taxonomic use. The characters found to be most useful are overall shape, sculpturing, and aperture length. Size did not appear significant, although pollen of *Tricantha* tends to be slightly larger compared with other genera.

Some pollen forms are associated with corolla form and sometimes with general morphology of the parent plant. The more variation there is in corolla form in a genus, the more variation there is in pollen form. The cohesiveness of macromorphological characters in *Columnea* is supported by remarkable pollen uniformity; the uniformly punctate exine is characteristic of the genus. All species with this pollen type possess the characteristic galea of the flower. However, species outside the genus *Columnea* that exhibit a similar "columneoid" corolla do not have the pollen characteristics of *Columnea* (*Dalbergaria picta*, *D. ericae*, *D. kalbreyeriana*).

Pollen of *Columnea repens* and *C. rutilans*, the only two columneas examined that occur outside the mainland of Central and South America, is different from that of mainland species (Figs. 5B, C). These two species are endemic to Jamaica, and different selection pressures there could be a factor in their divergence from the general pattern. *Columnea kucyniakii* does not fit very well with the remainder of the genus *Columnea*. Its pollen is more similar to the pollen of *Dalbergaria* or *Trichantha*, but the species does not easily fit into the concept of either of the genera in terms of floral features and general habit (Wiehler, pers. comm.).

The two species of *Bucinellina* share the same grain shape and aperture size, but they have different exine patterns and a slight difference in grain size. They are from the same general locality, and their flowers and habit are fairly similar; the reason for the pollen difference is not evident.

Trichantha purpureovittata, *T. tenensis*, and *T. brenneri* are closely related and have similar corollas as well as similar general plant habit (Wiehler, 1975). The similarity of their pollen correlates well with these characters. *Trichantha pulchra*, *T. herthae*, and *T. parviflora* make up another group of morphologically similar species (Wiehler, 1977, pers. comm.). They have small yellow corollas with tough, incurved lobes and similar pollen. *Trichantha calotricha* has a corolla similar to those of the rest of this group, but its pollen is very different. *Trichantha citrina* and *T. mira* are also closely related to each other (Wiehler, 1978), and their pollen reflects this relationship.

Dalbergaria species have similar pollen and a moderate degree of uniformity in their

corollas. Most pollen grains show slight variations on a theme, e.g., long apertures and a tectum punctate around the colpi and at the poles. Pollen of *Dalbergaria sanguinea*, a tetraploid, is no larger than that of the rest of the genus but is distinct by showing no reduction of the reticulum at the poles and by having apertures of intermediate length. *Dalbergaria aureonitens* is closely related to *D. sanguinea* (Wiehler, 1973), which is reflected by pollen similarities between them. *Dalbergaria florida* is somewhat atypical in the genus although its pollen exhibits features that closely resemble *Dalbergaria sanguinea* and *D. aureonitens*.

In *Pentadenia* there is a relatively high degree of uniformity in corolla forms (Wiehler, pers. comm.) and in the pollen. Most corollas are tubular, small, and generally nondescript. *Pentadenia strigosa*, however, is strikingly different from the rest of the species in the alliance in its much larger corolla and peculiar pollen characteristics, probable adaptations to pollination by bats.

The Gesneriaceae are placed in the relatively advanced order Scrophulariales, and the reticulate, tricolpate pollen of Gesneriaceae is advanced among dicotyledons (Walker & Doyle, 1975). This family has a specialized shape in that it departs from the spherical. The exine pattern is specialized as it differs from the primitive tectate grain. A reduction in aperture size can be seen, particularly in the Episcieae.

Some similarities to pollen of other families in the order Scrophulariales can be seen in pollen of the Gesneriaceae. In the Scrophulariaceae and Myoporaceae one finds tricolpate pollen (Niezgoda & Tomb, 1975) and finely reticulate exines reminiscent of *Columnea*. The colpi are long, but the apertures are diorate, a rare type not found in the Gesneriaceae. Erdtman (1966) found tri-colp(or)ate, oblate-spheroidal, subprolate, or prolate-spheroidal pollen in the Scrophulariaceae. These attributes are within the range of pollen features of the Gesneriaceae.

Boj (1961) made an extensive survey of

the Acanthaceae and found few features that can be compared to the Gesneriaceae other than the reticulate exine. Erdtman (1966) examined 55 species in 35 genera of Acanthaceae and found it to have uniform pollen. One tricolporoid type is subprolate to prolate and has fine reticulation in which the brochi decrease in size toward the colpi. The grains are also within the size range found in the Gesneriaceae.

Buurman (1977) found a number of features in Bignoniaceae similar to those of gesneriaceous pollen. The number of apertures varies, but the tricolpate type exhibits a prolate shape and a uniformly punctate tectum, the lumina of which decrease (almost imperceptibly) in size adjacent to the colpi. These features are predominant in Gesneriaceae tribe Gloxineae (see Williams, 1978). Buurman (1977) outlined within the tricolpate group some evolutionary trends that may have some application to the Gesneriaceae (see below). Erdtman (1966) examined pollen of 25 species in 20 bignoniaceous genera and found a size range that exceeds that of the Gesneriaceae.

This study has answered several questions regarding pollen use in taxonomic considerations of the *Columnea* alliance. Pollen characters separate *Columnea* and *Bucinellina* from the rest of the alliance, but there is much variation within the other genera. Pollen appears to be useful, however, in several ways. Subgeneric groups that exhibit similar pollen could be classified as sections, since they are found to be closely related by other criteria. Differences between species in some pollen features are more apparent than differences between genera, so pollen characters seem to be good species indicators. Pollen does appear to be useful for separating the *Columnea* alliance from other alliances and other alliances from each other.

Evolutionary trends based on the pollen information gathered here can be related to Buurman's (1977) scheme. Tectal features in the *Columnea* alliance exhibit a trend from perforate to uniformly reticulate to punctate near colpi and at poles. Caution must be exercised when this scheme is applied to the *Columnea* alliance, however, since next to *Bucinellina*, *Columnea* is considered most advanced, but it has a uniformly punctate tectum. The shape and size of the grains in the *Columnea* alliance exhibit a trend from spherical and small to oblate or prolate and large. We postulate that the ancestral pollen was tricolpate, spherical, and uniformly reticulate with small lumina, much like pollen that occurs in the tribe Gloxineae (Williams, 1978).

OBSERVATIONS ON THE CHROMOSOME CYTOLOGY OF VELLOZIACEAE

Peter Goldblatt[1] *and Muriel E. Poston*[2]

ABSTRACT

Chromosome numbers of 15 species in four of the six genera of Velloziaceae were counted from root tip squashes. The family was previously known cytologically from a single count, although our preliminary findings have been reported elsewhere. The American Barbacenia *has* n = *17, while* Vellozia *has species with* n = *8 and 7. The African* Xerophyta *has* n = *24 in two species examined, and the monotypic* Talbotiopsis *has* n = *24, a count substantiating an earlier record of* n = *24–26. A base number of* x = *9 is proposed for Velloziaceae.* Barbacenia *appears to be a paleotetraploid genus,* Vellozia *a hypodiploid, and* Xerophyta *and* Talbotiopsis *are possibly paleohexaploids on the derived base of* n = *8.*

Velloziaceae are a small family of petaloid monocots comprising six genera, *Barbacenia* (102), *Barbaceniopsis* (3), *Nanuza* (1), and *Vellozia* (122) in South America, and *Xerophyta* (50) and *Talbotiopsis* (1) in sub-Saharan Africa, south Arabia, and Madagascar. Until recently, Velloziaceae were barely known cytologically, the only chromosome record being $n = 24$–26 for *Talbotiopsis elegans* (Stenar, 1925, as *Vellozia*). Attention was first drawn to the lack of cytological information for Velloziaceae by Ayensu (1973) in his extensive study of the family. In a review of cytological evolution in the angiosperms, Raven (1975) again focused attention on the scant cytological data for the family, stimulating this investigation. Preliminary findings, unfortunately inexact, were included in Raven's review. These and additional counts are presented here with corrections where necessary.

MATERIALS AND METHODS

Plants for study were obtained from a live collection maintained at the Smithsonian Institution by Drs. L. B. Smith and E. S. Ayensu for their anatomical and taxonomic studies of the family. The material of *Xerophyta retinervis* was gathered in the wild by Goldblatt specifically for cytological study. Species examined are listed in Table 1 with collection data and chromosome numbers.

All counts were made from root tip mitoses. Roots were harvested from actively growing plants and pretreated in 0.003 M hydroxyquinoline for six hours at refrigerator temperatures. They were then fixed in 3 : 1 ethanol–acetic acid, hydrolyzed in 10% HCl for six minutes, and then squashed in lacto-propionic orcein.

OBSERVATIONS

Barbacenia

A diploid number of $2n = 34$ was found in each of four species of *Barbacenia* examined (Table 1). A preliminary count for this genus, $n = 16$ (Goldblatt in Raven, 1975), is incorrect. Chromosomes are all of similar size, 1–2.5 μm long, and are metacentric to submetacentric.

Vellozia

The preliminary count (Goldblatt in Raven, 1975) for the genus, $n = 9$, was not confirmed by further examination. Species of *Vellozia* sect. *Radia* have $2n = 14$, while $2n = 16$ and 14 were found in species of sect. *Vellozia*. A third section, *Xerophytoides*, is so far uncounted. The chromosomes are comparable in size and appearance to those of *Barbacenia*. In some preparations two diffuse, lightly staining areas stand out. The significance of these shadowy chromatic bodies is unclear, but they do not seem to be chromosomes.

Xerophyta

A diploid number of $2n = 48$ was found in the two species of this Afro-Madagascan genus counted, *Xerophyta humilis* and *X. retinervis*. Chromosomes are generally similar in size and appearance to those of *Barbacenia*, and 1–2 μm long.

Talbotiopsis

One collection of this monotypic genus, renamed *Talbotiopsis* (= *Talbotia*) by Smith (1985), was examined. Our count, $2n = 48$, substantiates Stenar's (1925) report of $n = 24–26$ for *T. elegans* (published under the synonym *Vellozia elegans*). Chromosomes of *Talbotiopsis* are similar to those of *Xerophyta.*

DISCUSSION

The chromosome data presented can only be regarded as preliminary for Velloziaceae, given that we now have counts for just 15 species in four genera out of a total of 250 species in six genera. Nevertheless, the available counts are fairly consistent within genera and so suggest that they comprise a representative sample of the chromosome variation in Velloziaceae.

The counts suggest the following hypothesis of cytological evolution. First, base number may be $x = 9$ for Velloziaceae. It follows that the number $n = 17$ in *Barbacenia* would represent aneuploid reduction from a paleotetraploid base of $n = 18$. The numbers $n = 8$ and 7 in *Vellozia* are then interpreted as aneuploid on the family base of $n = 9$. *Xerophyta* and *Talbotiopis* appear to be paleohexaploids derived from the secondary base of $x = 8$. The shared number in *Xerophyta* and *Talbotiopsis* supports the current belief (Ayensu, 1973) that these two African genera are more closely allied to one another than to the other genera of the family, all South American. Other scenarios can be constructed, but the one outlined seems to us the most parsimonious, and thus recommended at least in the light of current knowledge of Velloziaceae and the patterns of numerical chromosome change that occur in plants (Raven, 1975; Goldblatt, 1980). A base number of $x = 8$ for Velloziaceae appears at first to be a more parsimonious interpretation, with polyploid doubling (to $n = 16$) and subsequent aneuploid increase to achieve $n = 17$ in *Barbacenia.* However, given that ascending aneuploidy is at least four times less common in the flowering plants than descending aneuploidy, we think the latter possibility is less likely, although not implausible.

The chromosome numbers in Velloziaceae tell us little about possible relationships of the family. The most critical current phylogenetic opinion (Dahlgren et al., 1985) treats Velloziaceae as the sole family of Velloziales, one of six single family orders comprising Bromeliiflorae. The reasons for removing Velloziaceae from Liliiflorae and Liliales, to which the family is traditionally assigned, include the *Strelitzia*-like epicuticular waxes, copious starchy endosperm, and stomata with subsidiary cells (Dahlgren et al., 1985). All of these apparently fundamental features correspond with other families of Bromeliiflorae and conflict with Liliiflorae.

Base number in the Bromeliaceae, the family and order possibly closest to Velloziaceae, is $x = 25$ (Raven, 1975), which contrasts sharply with the suggested $x = 9$ in Velloziaceae. Cytology thus appears to contribute little to our understanding of relationships of the families of Bromeliiflorae. However, there seems reason to suppose that if Bromeliiflorae sensu Dahlgren et al. do constitute a natural alliance, then $x = 9$ or 8 are important base numbers. Other orders of Bromeliiflorae include Philydrales (Philydraceae, $x = 9$ or 8), Haemodorales (Haemodoraceae, possibly $x = 8$), and Pontederiales (Pontederiaceae, $x = 8$) (base numbers from Goldblatt, 1980). The last order included in Bromeliiflorae by Dahlgren et al., Typhales, with $x = 15$, is very different and may even be misplaced here.

CHROMOSOME COUNTS AND KARYOMORPHOLOGY OF SOME WEST TROPICAL AFRICAN SCILLEAE (LILIACEAE)

S. O. Oyewole[1]

ABSTRACT

Karyomorphological analyses of Urginea ensifolia, U. pauciflora, Drimiopsis barteri, Dipcadi tacazzeanum, *and* D. longifolium *are presented. All the materials investigated were obtained from the wild in Nigeria. The karyotypes and chromosome counts are new records for the five species. Both* Urginea *species are* 2n = *20,* Drimiopsis barteri *is* 2n = *24,* Dipcadi tacazzeanum and D. longifolium *are* 2n = *12 and* 2n = *24, respectively. Other members of* Urginea *and all the known species of* Albuca, *which have previously been investigated and reported, are summarized.*

The tribe Scilleae Bak. (Liliaceae) consists of six genera in West Tropical Africa (*Albuca* L., *Dipcadi* Medic., *Drimia* Jacq., *Drimiopsis* Lindl., *Scilla* L., and *Urginea* Stein). The latest treatment of the Liliaceae in West Tropical Africa (Hepper, 1968) shows that these genera are represented by three (five, Gledhill & Oyewole, 1972), two, one, one, one, and four (six, Oyewole, 1975a) species, respectively. Most of the representatives of each genus show striking morphological similarities as well as population variations within each species, which make their taxonomic treatment difficult. There is evidence that many natural populations of the representatives of the tribe are not yet in herbarium collections, so it is likely that there are more taxa in the tribe than are now known.

In this paper, new reports on chromosome number and morphology are given for five representatives of the Scilleae.

MATERIALS AND METHODS

Populations of each species were sampled during several field trips to different parts of Nigeria (Table 1). The species were identified using specimens at the Herbarium of the Federal Institute of Forest Research, Ibadan (FHI). Plants of each species were cultivated at the University of Ilorin, Nigeria. Voucher specimens are deposited at FHI, Ahmadu Bello University Herbarium (ABUH), and the Herbarium of the University of Ilorin (IUH).

Each plant was investigated separately, but plants of the same species were treated together. Cytological studies were carried out on squash preparations of young root tips following conventional methods as earlier reported (Oyewole, 1972). Chromosome index, *r* (ratio of long chromosome arm to the short arm), was determined according to Levan et al. (1964) as modified by Oyewole (1972), and the values were employed in analyzing the karyomorphology of each taxon.

RESULTS AND DISCUSSION

Table 2 summarizes earlier work on the tribe Scilleae while Table 3 summarizes karyotype data on the new reports.

URGINEA

The basic chromosome numbers of this genus are $x = 5$ and $x = 7$ (Darlington & Wylie, 1955; De Wet, 1957; Jones & Smith, 1967). The four species listed in the *Flora of West Tropical Africa* (Hepper, 1968) are

U. altissima Baker, *U. indica* (R. & B.) Kunth, *U. ensifolia* (Thonn.) Hepper, and *U. pauciflora* Baker. More recent work, however, has shown that *U. altissima* is a complex of three distinct species (Oyewole, 1975a), all of which have been investigated karyotypically (see Table 2). *Urginea indica* has been treated separately on account of its variable nature (Oyewole, 1987b, c) and is included in Table 2.

Urginea ensifolia has a somatic complement of 20 chromosomes. The karyotype is represented by twelve long and eight short chromosomes (Figs. 1A, 2A). Chromosome lengths vary between 1.0 μm and 7.0 μm. The six long pairs have terminal to subterminal centromeres. The first two short pairs have submedian to median centromeres, while the last two pairs are dotlike and without observable second arms: they are telocentric. The third long pair has an inconspicuous second arm and a secondary constriction on the long arm.

Urginea pauciflora also has a somatic complement of 20 chromosomes. The karyotype is represented by three long and seven short pairs. The chromosome lengths vary from 2.5 μm to 9.13 μm. All the long chromosomes have subterminal to terminal centromeres. Three short pairs have subterminal to terminal centromeres; three others have submedian to median centromeres, while the seventh pair has a very inconspicuous second arm (Figs. 1B, 2B).

All *Urginea* species so far investigated have $2n = 20$ except *U. volubilis*, a Madagascan species ($2n = 14$, Jones & Smith, 1967). With a basic number of $x = 5$ or $x = 7$, the West African species of *Urginea* are polyploids. However, from karyotype studies, these species have somatic complements that are resolvable into homologous pairs. *Urginea altissima* sensu stricto, with $2n = 20 + 2\text{ff}$, has been shown to have normal meiosis with ten bivalents (Oyewole, 1987a). The basic number of $x = 5$ therefore applies to the West African *Urginea* species which are thus tetraploids.

DIPCADI

Two basic numbers, $x = 4$ and $x = 9$, are already reported for this genus (Darlington & Wylie, 1955); Hepper (1968) recognized two species, *D. longifolium* Lindl. and *D. tacazzeanum* (Hochst. ex A. Chev.) Baker, into which he merged Morton's (1961) *D. filamentosa* Medic. as a morphological variant. Several natural populations of individuals identifiable as *D. filamentosa* have recently been encountered during field trips in Nigeria, and the cytogenetic relationship of this group with the other species of the genus is still being investigated at Ilorin, Nigeria.

Dipcadi tacazzeanum (excluding all materials identifiable as *D. filamentosa*) has a somatic chromosome complement of $2n = 12$. Chromosome lengths range between 2.2 μm and 7.3 μm, and the karyotype consists of three long and three short pairs. The fifth pair has a submedian centromere, while all the others have terminal to subterminal centromeres (Figs. 1C, 2C). The third pair has a secondary constriction in the long arm.

Dipcadi longifolium has a somatic complement of $2n = 24$. The complement consists of 16 long and eight short chromosomes, with chromosome lengths ranging from 2.2 μm to 8.9 μm. One pair of short chromosomes is telocentric, another has submedian centromere, while the remaining two short and all the eight long pairs have terminal to subterminal centromeres (Figs. 1D, 2D). One of the short pairs with the centromere in the terminal region varies morphologically in different individuals—one or both members have an extended centromeric region. Four pairs (1st, 3rd, 4th, and 6th) have a secondary constriction each in the long arm. With a somatic complement of 24 chromosomes, this species is a polyploid.

Jones & Smith (1967) reported a somatic chromosome number of $2n = 12$ for a diploid species suspected to be *D. gracillium*. The records of $2n = 8$, 18, and 34 for three different species, by which the basic numbers of $x = 4$, 9 were determined, were from southern African materials (see Darlington &

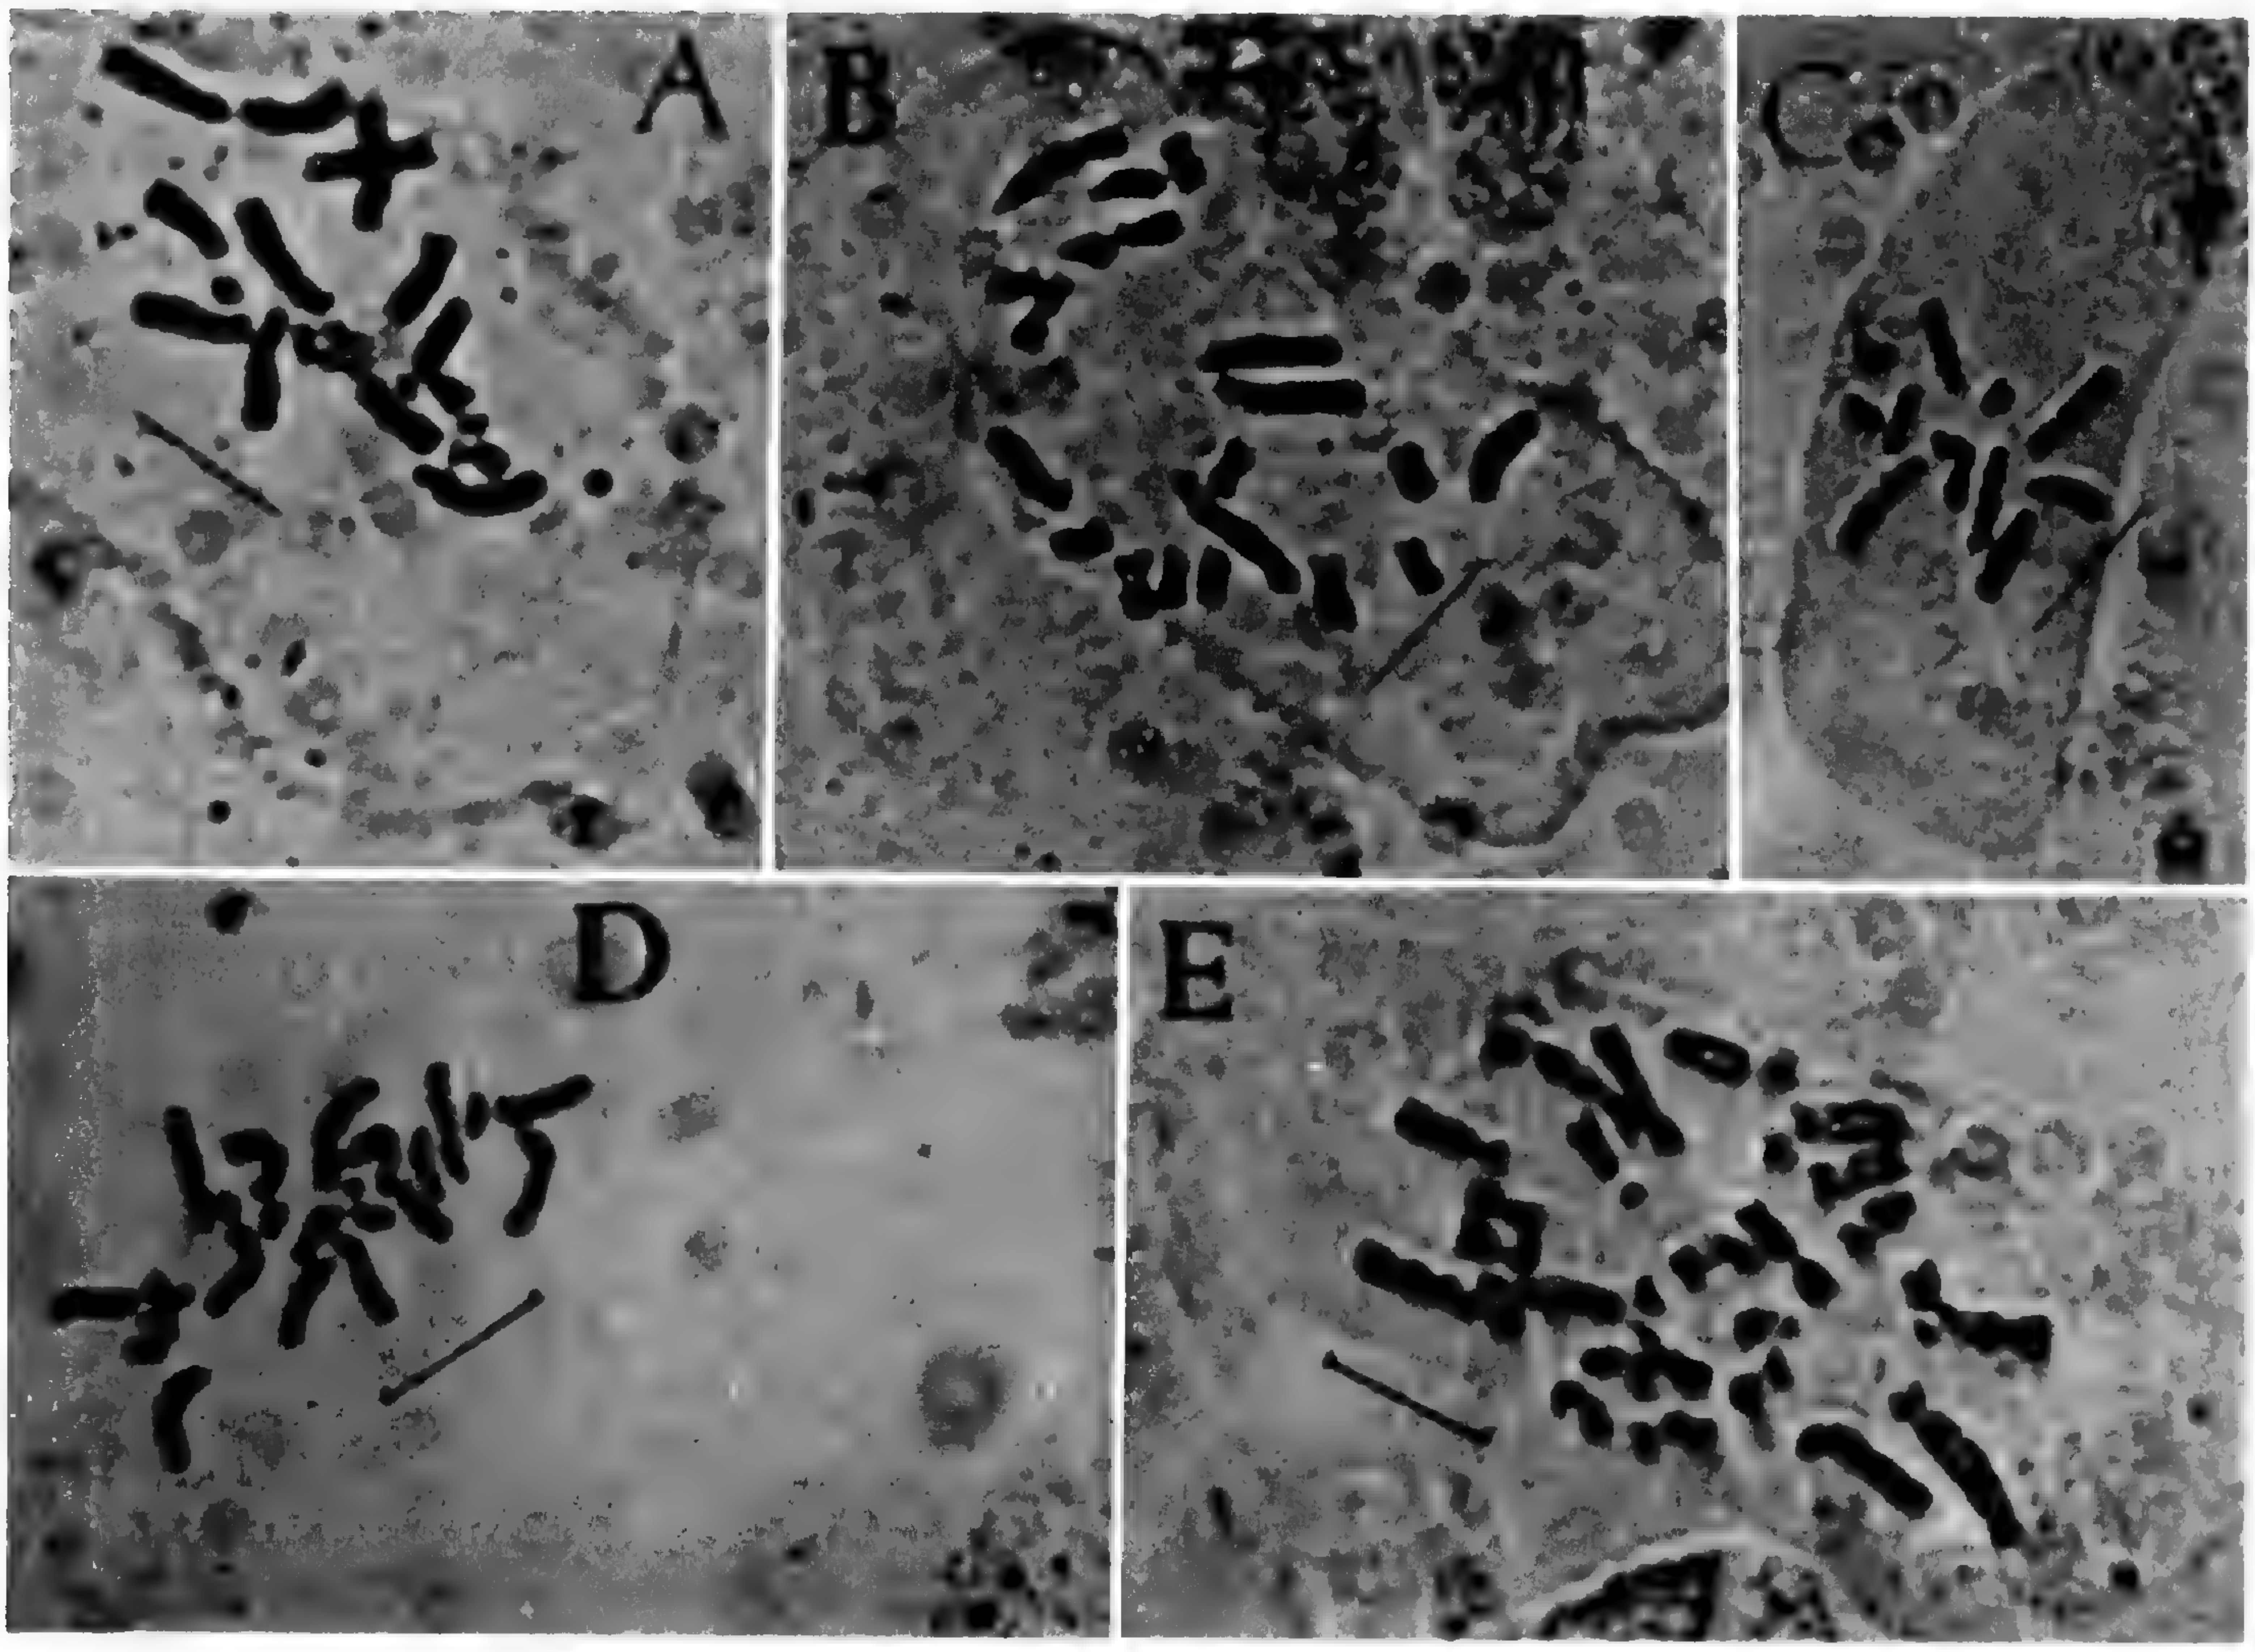

FIGURE 1. *Somatic metaphase complements.* —*A*. Urginea ensifolia.—*B*. Urginea pauciflora.—*C*. Dipcadi tacazzeanum.—*D*. Dipcadi longifolium.—*E*. Drimiopsis barteri.

Wylie, 1955). The two somatic numbers reported here show two ploidy levels and favor a new basic number of $x = 6$, which is supported by chromosome morphology. Thus, one of the two species is a diploid, $2n = 12$ (*D. tacazzeanum*) and the other a tetraploid, $2n = 24$ (*D. longifolium*).

DRIMIOPSIS

This genus is represented by *D. barteri* Baker, as Hepper (1968) recorded. This species has a somatic number of $2n = 24$. The chromosomes fall into twelve morphological pairs, with members of the pairs generally unequal. Chromosome lengths vary between 3.0 μm and 10.0 μm. The complement does not show bimodal categorization into long and short chromosomes. However, seven pairs are longer than 5.0 μm while the other five are shorter than 5.0 μm. Four pairs (1st, 2nd, 3rd, and 10th) have terminal to subterminal centromeres, while the others have submedian to median centromeres (Figs. 1E, 2E). Plants of this species are known to be sexually sterile; meiotic behavior and cause of sexual sterility have been reported (Oyewole, 1984a, b).

Darlington & Wylie (1955) reported a basic chromosome number of $x = 8$ for the genus from South African materials. A somatic chromosome count of $2n = 24$ indicates triploidy. However, Oyewole (1984a, b) showed that a basic number of $x = 6$ rather than $x = 8$ is more consistent with the somatic complement of the West African species of *Drimiopsis*. Two wild and morphologically distinct populations recently sampled in Nigeria have a somatic complement of $2n = 24$ each, as in *D. barteri*, and are sexually reproductive. Their cytogenetic relationship with *D. barteri* and with each other, as well as their taxonomic positions, are being investigated at Ilorin, Nigeria.

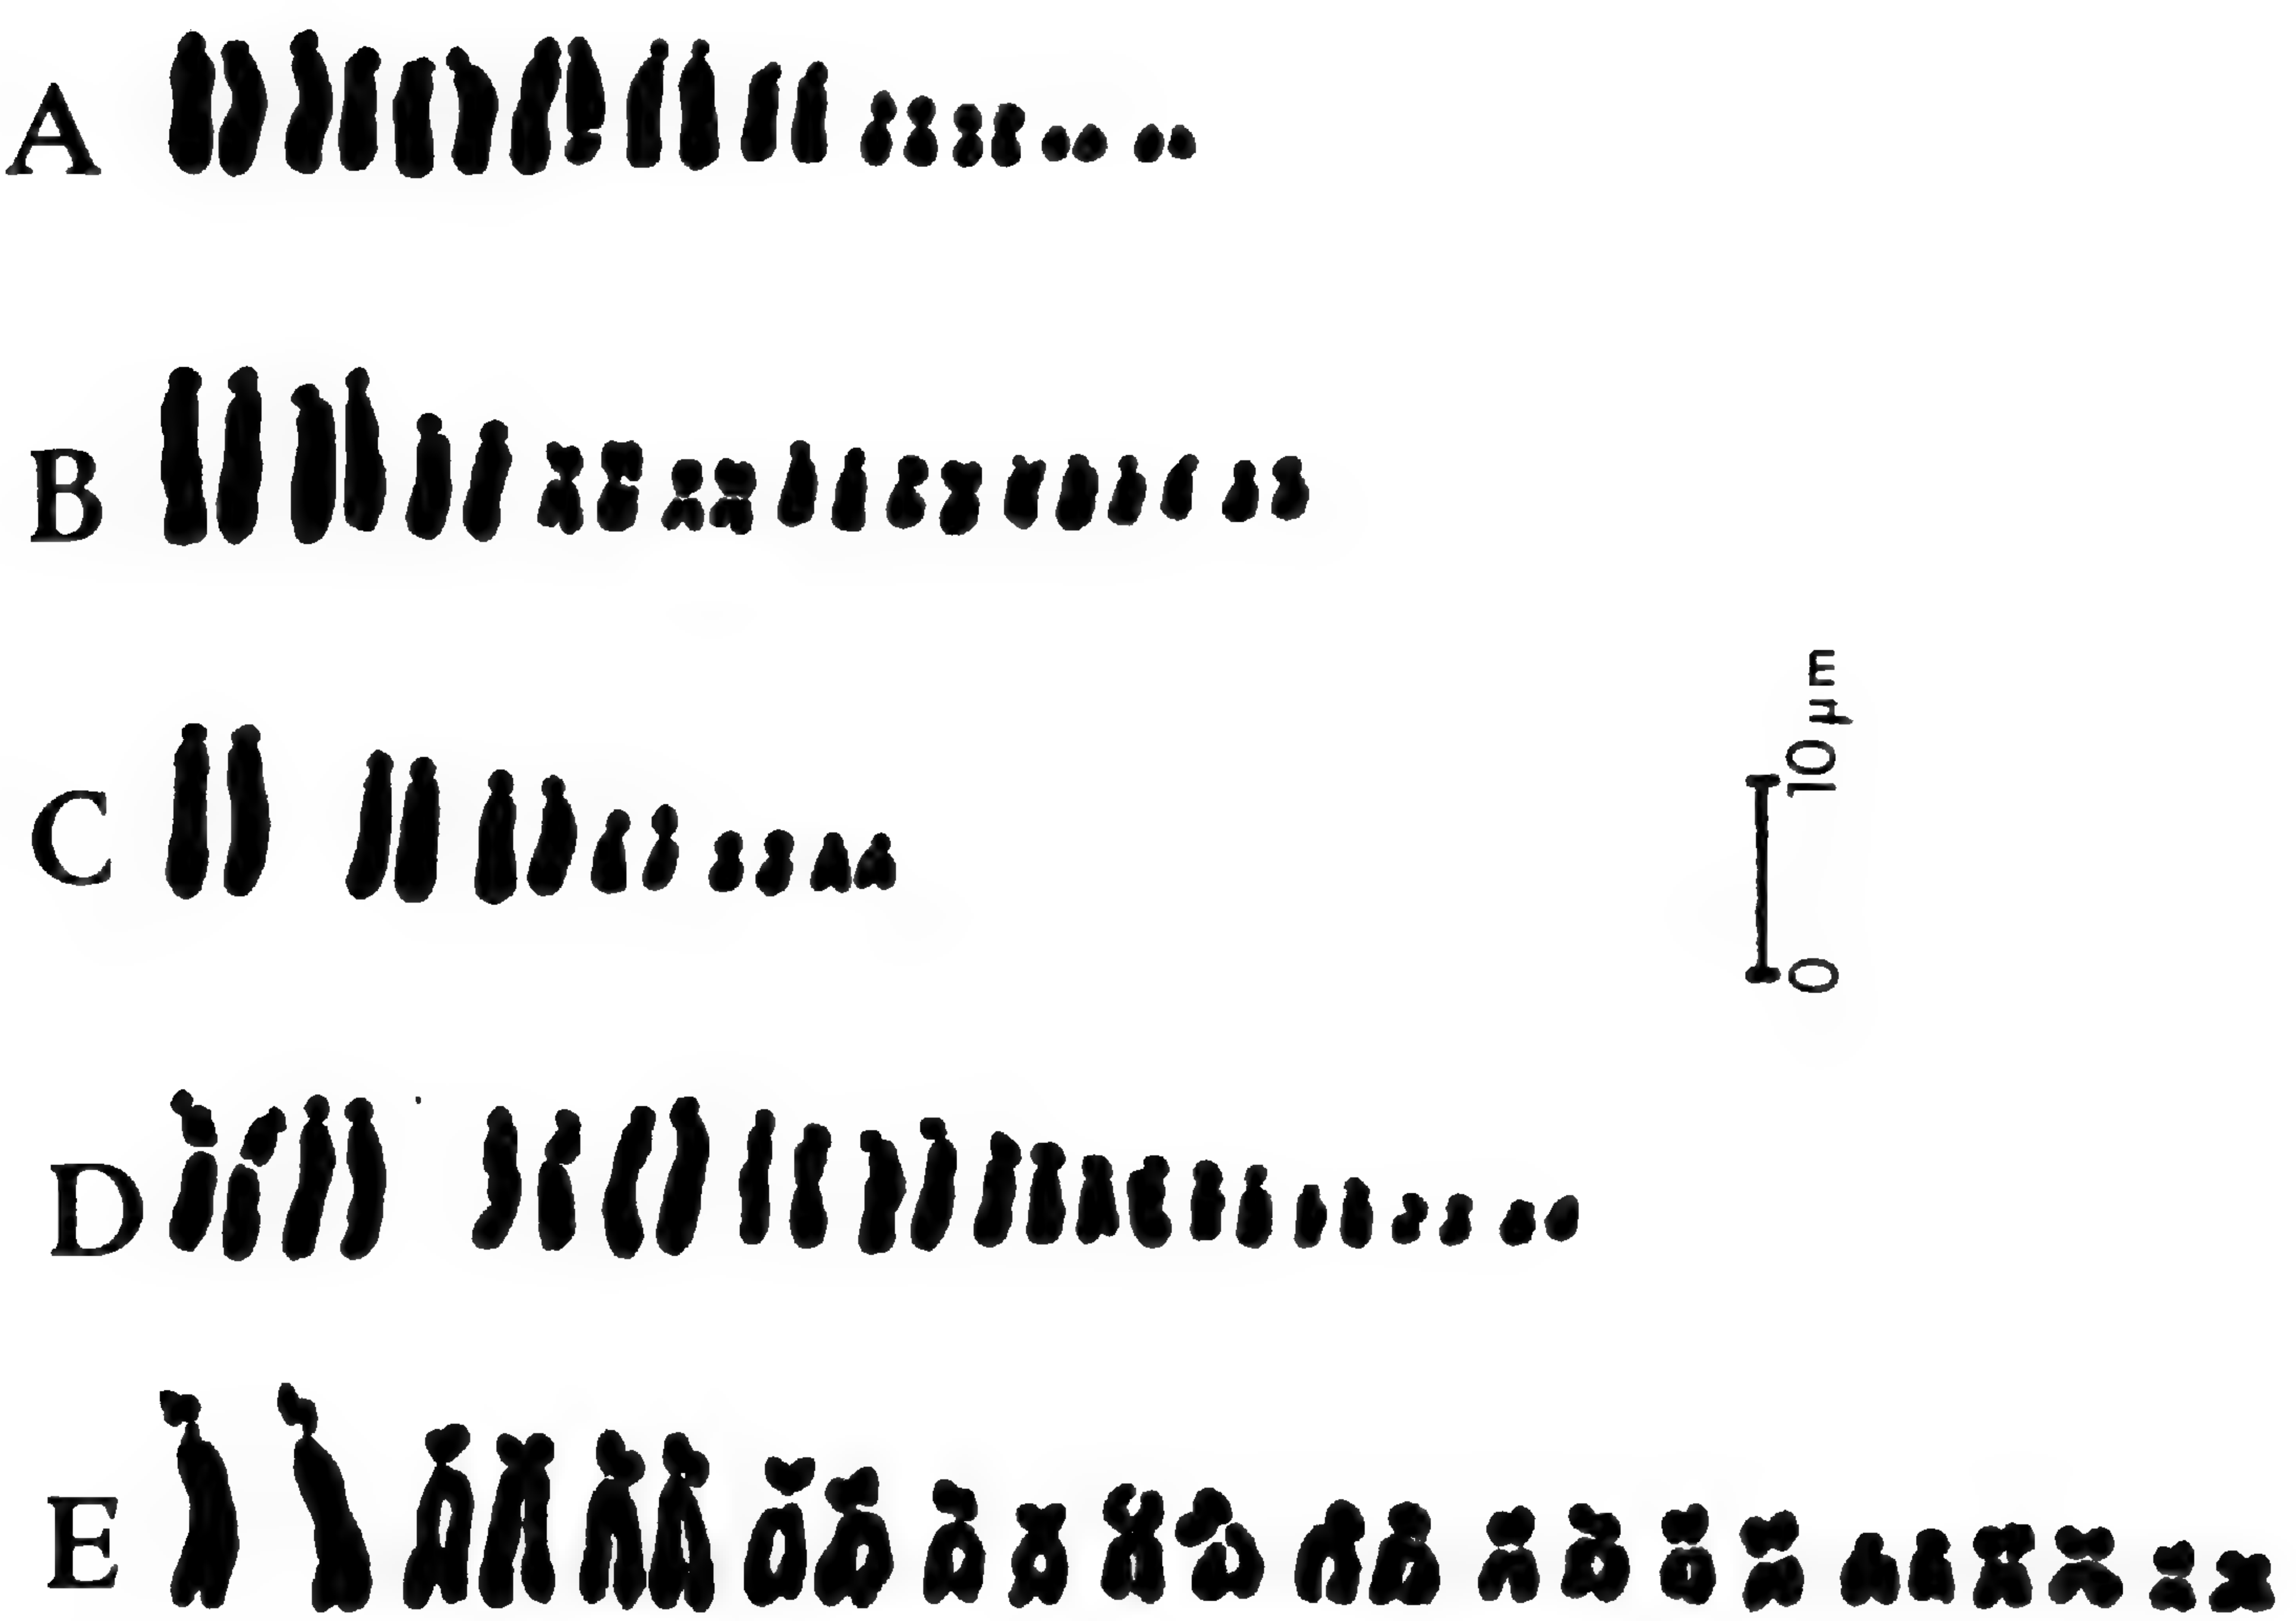

FIGURE 2. *Drawings of the somatic karyotypes.—A.* Urginea ensifolia.—*B.* Urginea pauciflora.—*C.* Dipcadi tacazzeanum.—*D.* Dipcadi longifolium.—*E.* Drimiopsis barteri.

Chromosome length bimodality in certain members of the tribe Scilleae has been reported (Jones & Smith, 1967; Oyewole, 1972, 1975b). This has held true in the present work for the two species of *Urginea* and the diploid *D. tacazzeanum* but not with *D. longifolium* and *D. barteri.* Also, while the West African members of *Albuca, Urginea,* and *Dipcadi* can be said to have a preponderance of chromosomes with terminal to subterminal centromeres, *Drimiopsis* contains a higher number of submetacentrics. It is not possible, therefore, to formulate a common pattern of karyotype evolution in the tribe from mere chromosome morphology.

The morphological similarity among the different genera in this tribe is not correlated with similarity in karyotype morphology. If the morphological similarity is a result of common ancestry for the members of the tribe Scilleae, then karyotypes have evolved along various lines.

Alternatively, morphological similarity in the tribe may be a result of convergent evolution, in which case the tribe would be polyphyletic.

PRESTOEA (PALMAE) IN CENTRAL AMERICA[1]

Andrew Henderson[2] *and Greg de Nevers*[3]

ABSTRACT

Differences among the morphologically similar Prestoea, Euterpe, *and* Neonicholsonia *are discussed. All species of* Prestoea *occurring in Central America are treated.* Prestoea semispicata *and* P. integrifolia *are described as new species.* Prestoea allenii, P. darienensis, P. decurrens, P. roseospadix, P. sejuncta, *and* P. longipetiolata *are characterized.* E. brachyspatha, E. williamsii, *and* E. simiarum *are placed in synonymy under* P. longipetiolata. Euterpe simplicifrons *is transferred to* Prestoea. *A key and illustrations are provided.*

The neotropical *Prestoea* Hook f. has remained problematic. Moore (1963) argued in favor of keeping *Prestoea* separate from the morphologically similar *Euterpe*. Wessels Boer (1965) argued for uniting the two. Doubts about the characters used by Moore have been expressed by Galeano-Garcés (1986) and Henderson (1986). A third genus, *Neonicholsonia*, is also similar to *Prestoea* but had formerly been distinguished by its spicate inflorescence. Our discovery of a *Prestoea* having usually spicate inflorescences has raised doubts about the distinctness of *Neonicholsonia* from *Prestoea*. Differences between the three genera as understood by us are given in Table 1, which shows that three groups exist. However, any change in ranking should await a study of all species throughout their neotropical ranges.

The Central American species of *Prestoea* are poorly known; too many names are in use; and the regional floras (Standley, 1937, for Costa Rica and Bailey, 1943, for Panama) are outdated. Here we treat all Central American species, based on extensive fieldwork and study of herbarium specimens, including all relevant types. Eight species are recognized. Although *Prestoea carderi* (W. Bull) Hook f. was reported by Hooker (1890) to have come from Guatemala, the description clearly states that the type material came from Colombia.

Although the species are relatively easy to distinguish in the field, this is not so in the herbarium, where the most useful character is the hairs, or their absence, on the rachillae. Sections of rachilla are illustrated for each species, as is the habit. The flowers and fruits of Central American *Prestoea* provide few distinguishing characters. There is substantial variation within species.

KEY TO THE SPECIES OF *PRESTOEA* IN CENTRAL AMERICA

1a. Leaves entire .... (4) *P. integrifolia*
1b. Leaves regularly pinnate 2
    2a. Sheaths closed, forming a green, maroon, or purple-black crownshaft; rachillae at anthesis with sessile, crustose, mostly unbranched hairs (occasionally brown tomentose) .... (1) *P. allenii*
    2b. Sheaths open, not forming a crownshaft; rachillae at anthesis free of crustose hairs (except *P. darienensis*) 3

TABLE 1. *Comparison of* Neonicholsonia, Prestoea, *and* Euterpe.

	Neonicholsonia	*Prestoea*	*Euterpe*
Leaf sheaths	open and not forming a crownshaft	either semiopen and forming an asymmetric crownshaft or open*	always closed and forming a symmetric tubular crownshaft*
Pinnae	always spreading	spreading to vertical	pendulous, occasionally spreading
Inflorescences	always spicate	usually branched, rarely spicate	always branched
Prophylls	much shorter than the peduncular bract	much shorter than the peduncular bract	more or less equal to the peduncular bract
Rachillae	essentially glabrous, but with groups of hairs, rachillae surface visible	occasionally glabrous, but often with various hairs, rachillae surface visible	never glabrous, densely white- to brown-appressed tomentose or velutinous, rachillae surface not visible
Sepals of staminate flowers	united into a cupule with 3 long-acuminate lobes	free and imbricate or briefly connate at base	free and broadly imbricate
Filaments of staminate flowers	inflexed at apex	inflexed at apex	not inflexed at apex
Staminodes	absent	6, dentate	absent
Pistillate flowers	superficial on rachillae; bracteoles not prominent	superficial on rachillae; bracteoles obscure, rarely prominent	sunken in rachillae; bracteoles prominent
Stigmatic residue positions	subapical	lateral	lateral
Raphe branches	few, large, deeply sunken	numerous, anastomosing to form a network	numerous, anastomosing to form a network

* *Prestoea* inflorescences are more or less terete in bud, and in species with a crownshaft the bud expands before the subtending leaf falls, thereby giving a swollen and open crownshaft. *Euterpe* inflorescences are dorsiventrally compressed and mostly expand after the subtending leaf falls, thus the crownshaft is generally tubular and closed.

3a. Inflorescence spicate or with 2–4 rachillae; pinnae elliptic and abruptly tapered at apex; inflorescence horizontal; endosperm homogenous to slightly ruminate .... (8) *P. semispicata*

3b. Inflorescence usually with many branches; pinnae linear and gradually tapered; inflorescence erect or horizontal; endosperm ruminate 4

  4a. Rachillae at anthesis with short, stiff, simple to branched, white hairs; staminate petals pilose; stem smooth, shiny, with leaf sheaths cleanly abscising and nodes prominent .... (3) *P. decurrens*

  4b. Rachillae at anthesis glabrous, or with sessile, crustose, branching hairs, or densely reddish brown tomentose, or with patches of long, loosely intertwined hairs; staminate petals glabrous; stem mostly rough with persistent leaf sheaths and obscure nodes (occasionally with clean stems and deciduous sheaths in *P. sejuncta* and *P. longipetiolata*) 5

5a. Rachillae at anthesis with sessile, crustose, branching hairs; inflorescence erect, 2–2.5 m long .... (2) *P. darienensis*

5b. Rachillae at anthesis glabrous, or with patches of long, loosely intertwined hairs, or densely reddish brown tomentose; inflorescence erect or horizontal, less than 1.6 m long 6

  6a. Rachillae at anthesis glabrous; stem usually less than 2 m tall; inflorescence erect .... (6) *P. roseospadix*

  6b. Rachillae at anthesis with patches of long, loosely intertwined hairs, or densely reddish brown tomentose; stem usually greater than 2 m tall; inflorescence arching to horizontal 7

7a. Rachillae at anthesis densely reddish brown tomentose; stem thin, often procumbent, less than 2.5 m tall; inflorescence arching; rachis 1–8 cm long with 2–15 rachillae .... (5) *P. longipetiolata*

7b. Rachillae at anthesis with patches of long, loosely intertwined hairs; stem stout, erect, greater than 2 m tall; inflorescence arching to horizontal; rachis 33–50 cm long with (18–)42–48 rachillae .... (7) *P. sejuncta*

1. **Prestoea allenii** H. Moore, Principes 9: 72. 1965. TYPE: Panama. Chiriquí: vicinity of Cerro Punta, 2,000 m, 24

May 1946, *P. Allen 3531* (holotype, BH; isotype, MO). Figures 1, 2.

Stems solitary or cespitose, erect, to 12 m tall, 9–18 cm diam. Leaves 6–8; sheaths deciduous, forming a distinct green, maroon, or purple-black crownshaft 68–75 cm long; petiole 20–60 cm long; rachis 1.8–2.5 m long; pinnae 33–51 per side; middle pinnae 118 cm long, 6 cm wide; apical pinna not wider than others. Inflorescence infrafoliar, horizontal; peduncle ca. 20 cm long, 1.8–2.3 cm diam.; prophyll 40–51 cm long, 10.5 cm wide; peduncular bract ca. 1.1 cm long, 4–6 cm wide, inserted 5–6 cm above base of peduncle; rachis 41–85 cm long; rachillae 23–100, to 73 cm long, at anthesis with sessile, crustose, mostly branched hairs (occasionally brown tomentose); flowers glabrous; fruit 10–11 mm diam.; seeds with ruminate endosperm.

Common name. "Maquenque" (Panama).

Distribution. Eastern Nicaragua to western Panama, in cloud forest 1,000–3,000 m.

Additional specimens examined. NICARAGUA. RIVAS: Isla de Ometepe, NW slopes of Volcán Maderas, 11°26–27'N, 85°30–31'W, 1,000–1,350 m, 24 Feb. 1978, *Stevens 6510* (MO). COSTA RICA. Prestoea allenii varies considerably with altitude. At lower elevations mature plants are sometimes solitary and have green crownshafts, and immature plants can lack crownshafts. At higher elevations the stems are usually cespitose, and the crownshafts maroon or purple-black. In Nicaragua and Costa Rica, lower-elevation populations with green crownshafts may represent a distinct taxon (e.g., *de Nevers et al. 7779*). However, the rachilla hairs are similar to those of *P. allenii*, and such collections are tentatively referred to that species. Robert Read (pers. comm.) reports that color variability in crownshafts of the same species is not uncommon in certain palms.

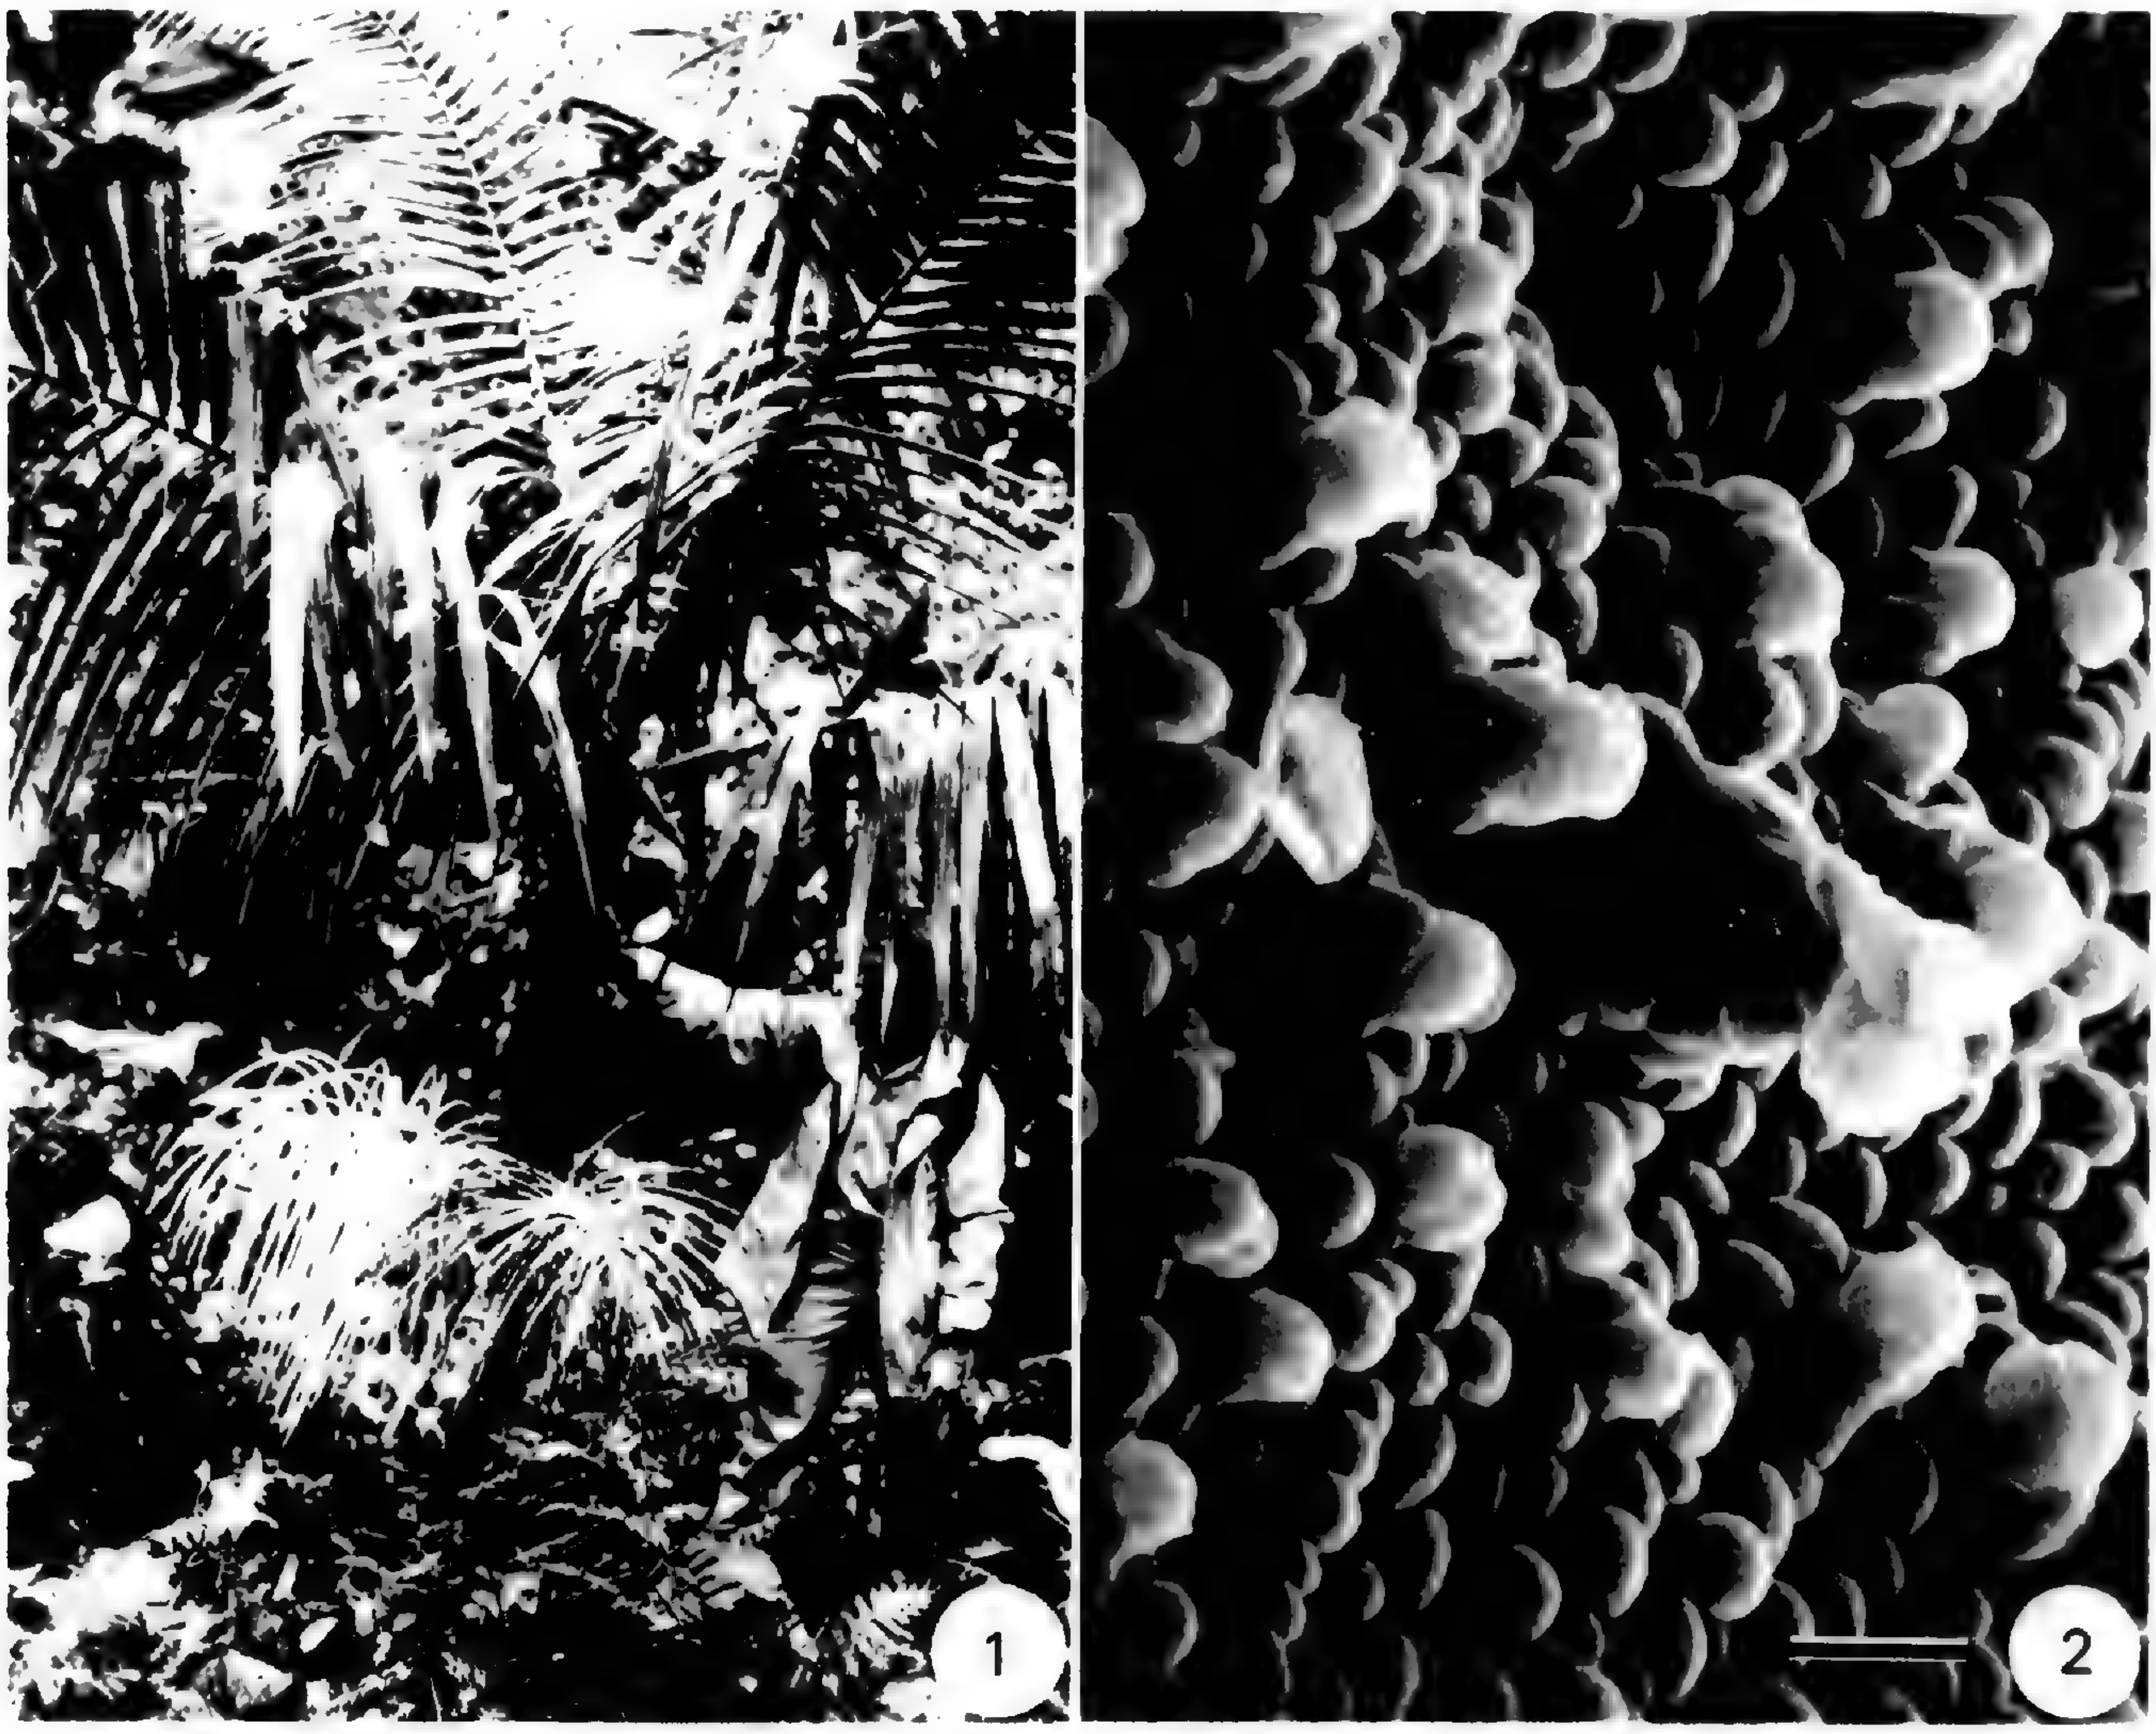
Prestoea allenii is the largest species of the genus in Central America and occurs at the highest altitude. This is not an uncommon correlation in neotropical palms, occurring, for example, in *Geonoma* and *Chamaedorea.*

2. **Prestoea darienensis** A. J. Henderson, Brittonia 38: 266. 1986. TYPE: Panama. Darién: Serranía de Pirre, on the ridge, 1,130 m, 18 Jan. 1985, *A. Henderson & J. Contraires 97* (holotype, NY; isotype, PMA). Figures 3, 4.

Stem solitary, erect, 2.5 m tall, 10 cm diam. Leaves 6; sheaths persistent, not forming a crownshaft; petiole 80 cm; rachis 165 cm; pinnae 29 per side; middle pinnae 75 cm long, 5 cm wide; apical pinna not wider than others. Inflorescence inter- or infrafoliar, erect; peduncle 75 cm long, ca. 1.5 cm diam.; prophyll 60 cm long, 4 cm wide; peduncular bract 2.23 m long, 2.5 cm wide, inserted 23 cm above base of peduncle; rachis 80–135 cm long; rachillae ca. 60, 45–72 cm long, at anthesis scabrid with crustose, branching hairs; flowers glabrous; fruit 8 mm diam.; seeds with ruminate endosperm.

Distribution. Known only from the type locality.

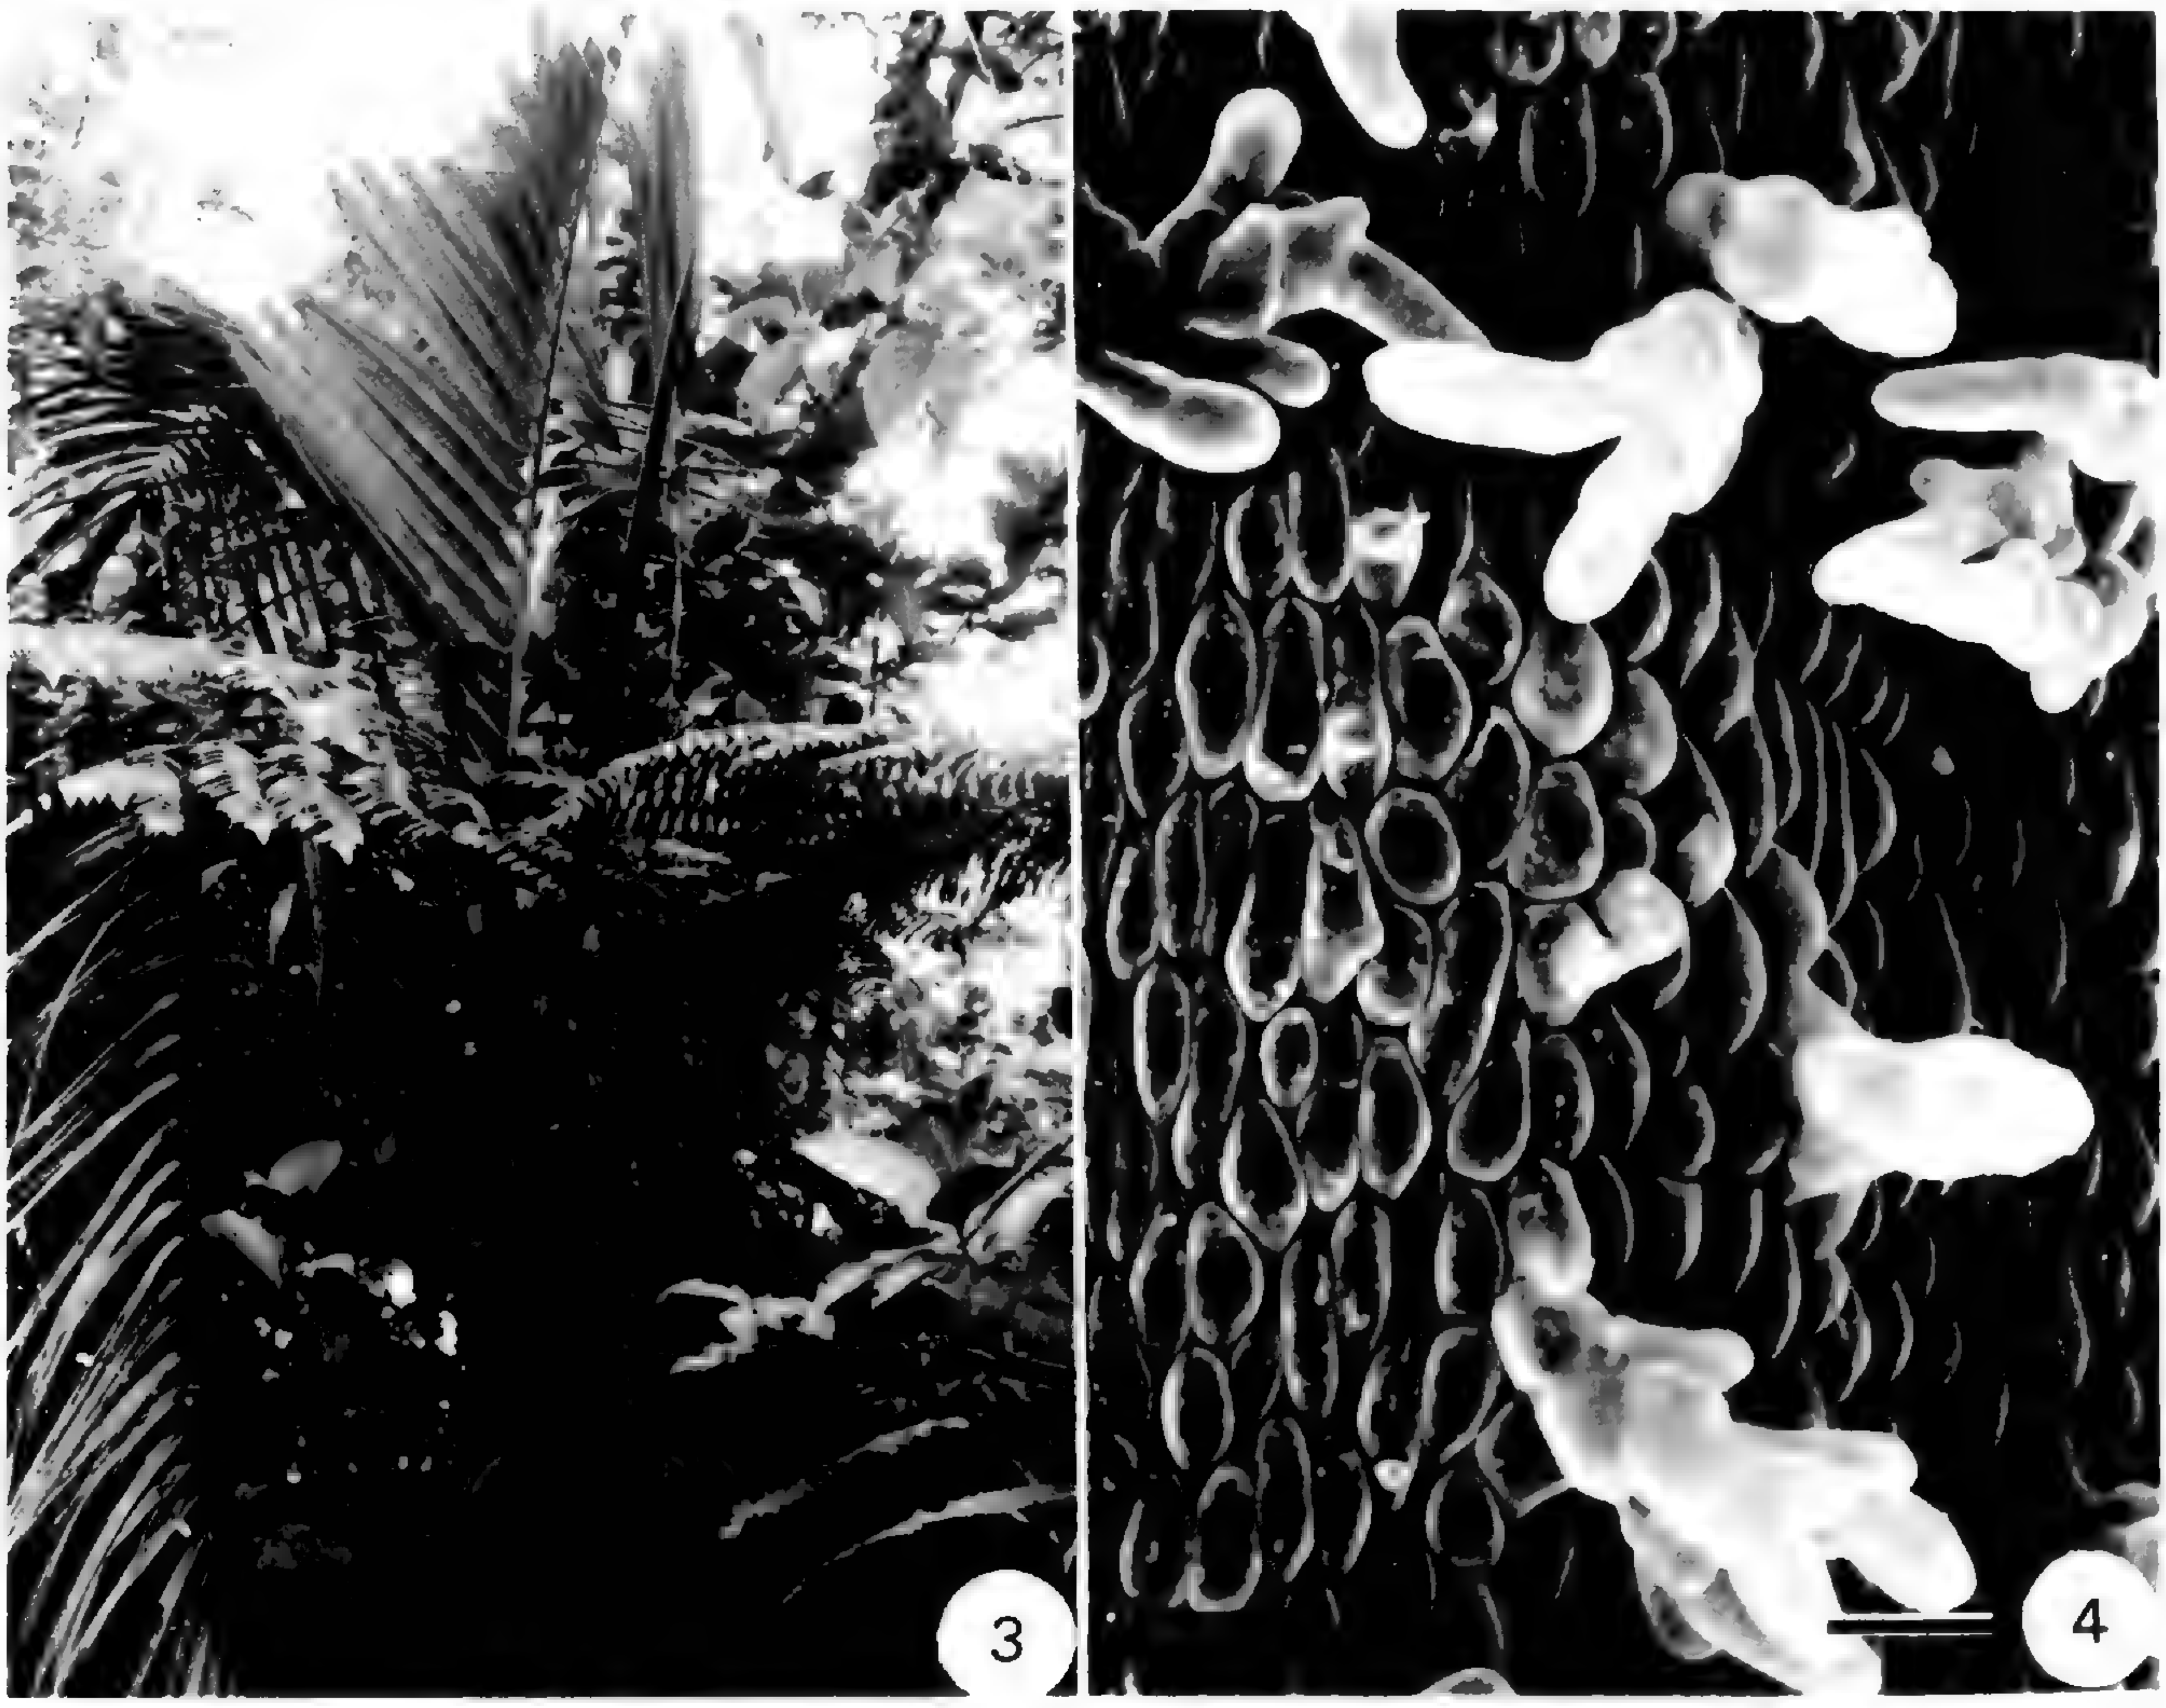


FIGURES 1, 2. Prestoea allenii.—*1. Habit, showing crownshaft and infrafoliar inflorescence (*de Nevers & McPherson 6800*).—2. Part of rachilla, showing sessile, crustose, mostly unbranched hairs (*Allen 3531*). Scale bar = 250 µm.*

Prestoea dariensis can be distinguished from the similar *P. sejuncta* by the rachillae with short, crustose, branching hairs. The inflorescence bud of the type is 2.5 m long, the longest of any *Prestoea* seen, and only approached by some specimens of *P. sejuncta,* which occasionally reach 2.1 m.

3. **Prestoea decurrens** (H. A. Wendl. ex Burret) H. Moore, Gentes Herb. 9: 286. 1963. *Euterpe decurrens* H. A. Wendl. ex Burret, Bot. Jahrb. Syst. 63: 63. 1929. TYPE: Costa Rica. Alajuela: San Carlos, 24 Mar. 1901, *Koschny s.n.* (B, destroyed). Neotype (here designated): Costa Rica. Heredia: Finca La Selva on Río Puerto Viejo just E of its junction with Río Sarapiquí, 12 Dec. 1984, *A. Henderson 50* (NY). Figures 5, 6.

Stems usually cespitose, (1–)2–7, erect, 3–7(–10) m tall, 3.2–10 cm diam., smooth and shiny, green or yellow. Leaves 7–9; sheaths 26–34 cm long, semipersistent, not forming a crownshaft; petiole 50–95 cm long; rachis 1.6–2.3 m long; pinnae 36–50 per side; middle pinnae 52–66 cm long, 3–4 cm wide; apical pinna not wider than the others. Inflorescence infrafoliar, white at anthesis, erect or diagonal; peduncle 15–25(–42) cm long, (0.7–)1–3 cm diam.; prophyll 17.5–19.5 cm long, 3 cm wide; peduncular bract 42–81 cm long, 2.5 cm wide, inserted 2.5–6.5 cm above base of peduncle; rachis 8–27 cm long; rachillae 7–50, 20–56 cm long, at anthesis with short, stiff, simple to branched, white, persistent hairs; staminate petals pilose near apex; fruit 6.5–8 mm diam.; seeds with ruminate endosperm; seedling leaves pinnate.



FIGURES 3, 4. Prestoea darienensis.—*3. Habit, showing long, erect, interfoliar inflorescence bud (*Henderson *97).—4. Part of rachilla, showing sessile, crustose branching hairs (*Henderson 97*). Scale bar = 250 μm.*

Common name. "Palmitillo" (Costa Rica).

Distribution. Throughout Nicaragua, Costa Rica, and Panama, usually between sea level and 1,500 m. This species is also known from northern Colombia (Galeano-Garcés, 1986).

Additional specimens examined. NICARAGUA. MATAGALPA: Comarca Wanawás, beside Río Bilampi, 12°3'N, 85°13'W, 180–200 m, 14 May 1980, *Moreno & Araquistain 2389* (MO, US). RÍO SAN JUAN: near Caño Chontaleño, 20 km NE of El Castillo (Río Indio watershed), 200 m, 7–9 Mar. 1978, *Neill 3320* (MO); 18 Apr. 1978, *Neill & Vincelli 3495* (MO, US). ZELAYA: "Kurinwacito," 13°8'N, 84°57'W, 80 m, 24 Mar. 1984, *Moreno 23880* (US); Mun. Siuna, Caño El Léon, road to Hormiguero, 2 Feb. 1983, *Ortiz 730* (MO); Mina Nueva America, ca. 11.3 km N of main road leading W from 14.3 km N of El Empalme to Rosita, 22 Apr. 1979, *Pipoly 5322* (US); Caño between Cerro La Pimienta and El Hormiguero, ca. 13°45'N, 85°59'W, 800–1,000 m, 15 Mar. 1980, *Pipoly 6018* (MO, US); ca. 6.3 km S of bridge at Colonía Yolonia and ca. 0.8 km S of ridge of Serranías de Yolonia on road to Colonía Manantiales (Colonía Somoza), 11°36'N, 84°22'W, 200–300 m, 29–31 Oct. 1977, *Stevens 4823* (BH, MO, US); 13–14 Feb. 1978, *Stevens 6387* (MO); Caño Costa Riquita, ca. 1.8 km SW of Colonía Naciones Unidas, above road between Colonía Nueva León and Colonía Naciones Unidas, ca. 11°43'N, 84°18'W, 150–180 m, 6–7 Nov. 1977, *Stevens 5034* (BH, MO, US); S slope of Cerro El Inocente down to near Caño Majagua, ca. 13°45'N, 85°0'W, 800–1,000 m, 9 Mar. 1978, *Stevens 6814* (BH, MO); trail from Cerro Saslaya to San José del Hormiguerro, between Caño Majagua and Caño Sucio, ca. 13°45'N, 84°59'W, 600–800 m, 10 Mar. 1978, *Stevens 6838* (BH, MO); 6.3 km S of bridge of Colonía Yolonia on road to Colonía Manantiales of Nueva Guinea, 200–300 m, 13 Feb. 1978, *Vincelli 250* (MO). COSTA RICA. ALAJUELA: E of San Rafael, S of hot springs, W of La Marina, 10°23'N, 84°23'W, 500 m, 19 May 1968, *Burger & Stolze 5021* (F, NY); plains of San Carlos, 100 m, 3 Apr. 1903, *Cook & Doyle 54* (BH, US); Reserva Biológica de San Ramón, road from Las Lagunas to Colonía Palmareña, 10°4'W, 84°32'N, 850–1,100 m, 30 May 1986, *de Nevers et al. 7780* (MO, NY); slopes of Miravalles, above Bijagua, lower montane rainforest, ca. 1,500 m, Nov. 1982, *Gómez et al. 19185* (CAS, CR, MO); vicinity of Guatuso de San Rafael on Río Frío, 10°43'N, 84°48'W, 80–100 m, 4 Aug. 1949, *Holm & Iltis 996* (BH, MO); Río Cuarto, Sarapiquí valley, 1945, *Langlois 12* (BH); beside Laguna María Aguilar, 780 m, 28 Mar. 1969, *Lent 1531* (NY); 2 km N of

Santa Rosa, 15 km N of Boca Arenal on Quesada–Muelle San Carlos–Los Chiles road, 100 m, 10°38′N, 84°31′W, 28 Apr. 1983, *Liesner et al. 15045* (MO, WIS); Río María Aguilar between Cariblanco and San Miguel, valley of Río Sarapiquí, ca. 700 m, 23 Mar. 1953, *Moore 6560* (BH); between Corazón de Jesús and La Virgen, Río Sarapiquí, 340 m, 24 Mar. 1953, *Moore 6576* (BH); 9.1 km before Venado on road from Arenal, 750 m, 1974, *Read & Daniels 74-26* (US). CARTAGO: between Río Pacuare and Grano de Oro, 7 km below Hacienda Moravia, ca. 900 m, 13 Apr. 1953, *Moore 6699* (BH). HEREDIA: Finca La Selva, on Río Puerto Viejo above junction with Río Sarapiquí, 20 Feb. 1981, *Folsom 9056* (DUKE); 27 June 1979, *Holdridge 5107* (BH); 17 Oct. 1980, *Hammel 10189* (DUKE); 5 May 1982, *Hammel 12036* (DUKE); 10 May 1982, *Hammel 12168* (DUKE); 13 June 1984, *Jacobs 2306* (DUKE); 15 July 1984, *Jacobs & Peralta 2883* (DUKE); 28 Jan. 1967, *Moore & Parthasarathy 9407* (BH); 18 Apr. 1972, *Opler 723* (F); 13 May 1984, *Wilbur & Jacobs 34374* (DUKE); 13 May 1984, *Wilbur & Jacobs 34393* (DUKE); 1 June 1985, *Wilbur 37722* (DUKE). LIMÓN: Hacienda Tapezco-Hda. La Suerte, 29 air km W of Tortuguero, 40 m, 10°30′N, 83°47′W, 7 Mar. 1978, *Davidson et al. 6737* (MO). PUNTARENAS: along short cut road to Golfito from Villa Briceño on Interamerican Highway, W side of Fila Gamba, ca. 6 km from Golfito airport, 8°41′N, 83°12′W, ca. 100 m, 6 Mar. 1985, *Croat & Grayum 59925* (CAS, MO); road to Rincón de Osa, 16.5 km W of Chacarita, 83°22′W, 8°45′N, 25 May 1986, *de Nevers et al. 7755* (MO, NY); along the Camino al Pacifico, W of Rincón de Osa, Osa Peninsula, 30 m, 7 Aug. 1967, *Raven 21593* (DS, F, NY). PANAMA. CHIRIQUÍ: above Chiriquí Grande on road to Fortuna Dam, 20 Jan. 1985, *Read et al. 85-20b* (US). COCLÉ: along river leading up mountain to Alto Calvario and trout stream from La Junta near Limón, 800–1,000 m, 12 Oct. 1977, *Folsom 5904* (BH, MO); forest at base of Cerro Pilón above El Valle, 9 Jan. 1972, *Gentry & Dwyer 3655* (BH, MO); 46 km N from Penonomé on road to Coclesito, 30 m, 22 Feb. 1978, *Hammel 1711* (BH, MO). COLÓN: Río Guanche, 3 km upstream of the road, 27 Oct. 1985, *de Nevers & Charnley 6107* (MO, NY); 18 Jan. 1980, *Moore et al. 10515* (BH); 14 Dec. 1974, *Mori & Kallunki 3716* (BH); 15 Mar. 1986, *Hammel & Trainer 14775* (MO); 6 Oct. 1983, *Nee 7253* (CAS, MO); ridge top leading N from Río Escandaloso toward Cerro Bruja, 450 m, 27 Apr. 1978, *Hammel 2707* (MO). COMARCA DE SAN BLAS: El Llano–Cartí road, km 27.6, Río Pingandi, downstream of road, 9°19′N, 78°55′W, 150 m, 9 Mar. 1985, *de Nevers et al. 5065* (CAS, MO); El Llano Cartí road, km 26.5, along Río Cartí Chico, 9°19′N, 78°55′W, 200 m, 12 Apr. 1985, *de Nevers et al. 5346* (MO, NY); 13 Mar. 1986, *de Nevers et al. 7379* (MO, NY); Yar Bired, continental divide between Cangandi and San José, 9°20′N, 79°08′W, 400–500 m, 5 Feb. 1986, *de Nevers et al. 6900* (MO, NY); Río Cangandi at confluence of Quebrada Titamibe, 9°24′N, 79°7′W, 60 m, 8 Feb. 1986, *de Nevers & Herrera 7017* (MO, NY); Río Taindi (Taimdi of maps), 2–3 km above confluence with Río Mandinga, 9°25′N, 79°11′W, 3 Apr. 1986, *de Nevers et al. 7626* (MO, NY); 3 Apr. 1986, *de Nevers & Herrera 7629* (MO); trail to Cerro Obu (Habu of maps) from Río Urgandi (Río Sidra), 9°23′W, 78°48′N, 100–300 m, 24 June 1986, *de Nevers & Herrera 7988* (MO); Cerro Mali, near Colombian border, 1,400 m, 23 Jan. 1975, *Gentry & Mori 13823* (BH, MO, NY). PANAMÁ: pipeline road near Gamboa, 9°10′N, 79°45′W, 100 m, 24 Feb. 1985, *de Nevers & Charnley 4942* (MO).

The type is no longer extant at Berlin. Burret cited a paratype (*Wendland 63*) consisting only of fruit. This is not at Göttingen among Wendland's other specimens, and is apparently lost. We therefore designate *Henderson 50*, from the same general area as the paratype, as neotype. Burret (1929) considered *P. decurrens* to be closely related to *Euterpe macrospadix* Oerst. and placed them in the same subsection (see Henderson, 1986), but they are unrelated. The confusion probably arose because the type of *E. macrospadix* at Copenhagen appears to be a mixture of *Prestoea* leaves (probably *P. longipetiolata*) and a *Euterpe* inflorescence.

Specimens from the Osa Peninsula in Costa Rica (*Raven 21593*, *Croat & Grayum 59925*) and Río Guanche in Panama have the typical tomentum of *P. decurrens*, but the inflorescence is less stout, the peduncle is longer and thinner, and there are 7–20 (vs. 50) rachillae. The strongly cespitose (vs. erect) stems are thinner and weaker than usual for the species.

4. **Prestoea integrifolia** de Nevers & A. J. Henderson, sp. nov. TYPE: Panama. Colón: Santa Rita Ridge, km 21.2, 9°20′N, 79°45′W, 350 m, 24 Feb. 1986, *G. de Nevers 7212* (holotype, MO; isotypes, CAS, COL, K, PMA, NY). Figures 7, 8.

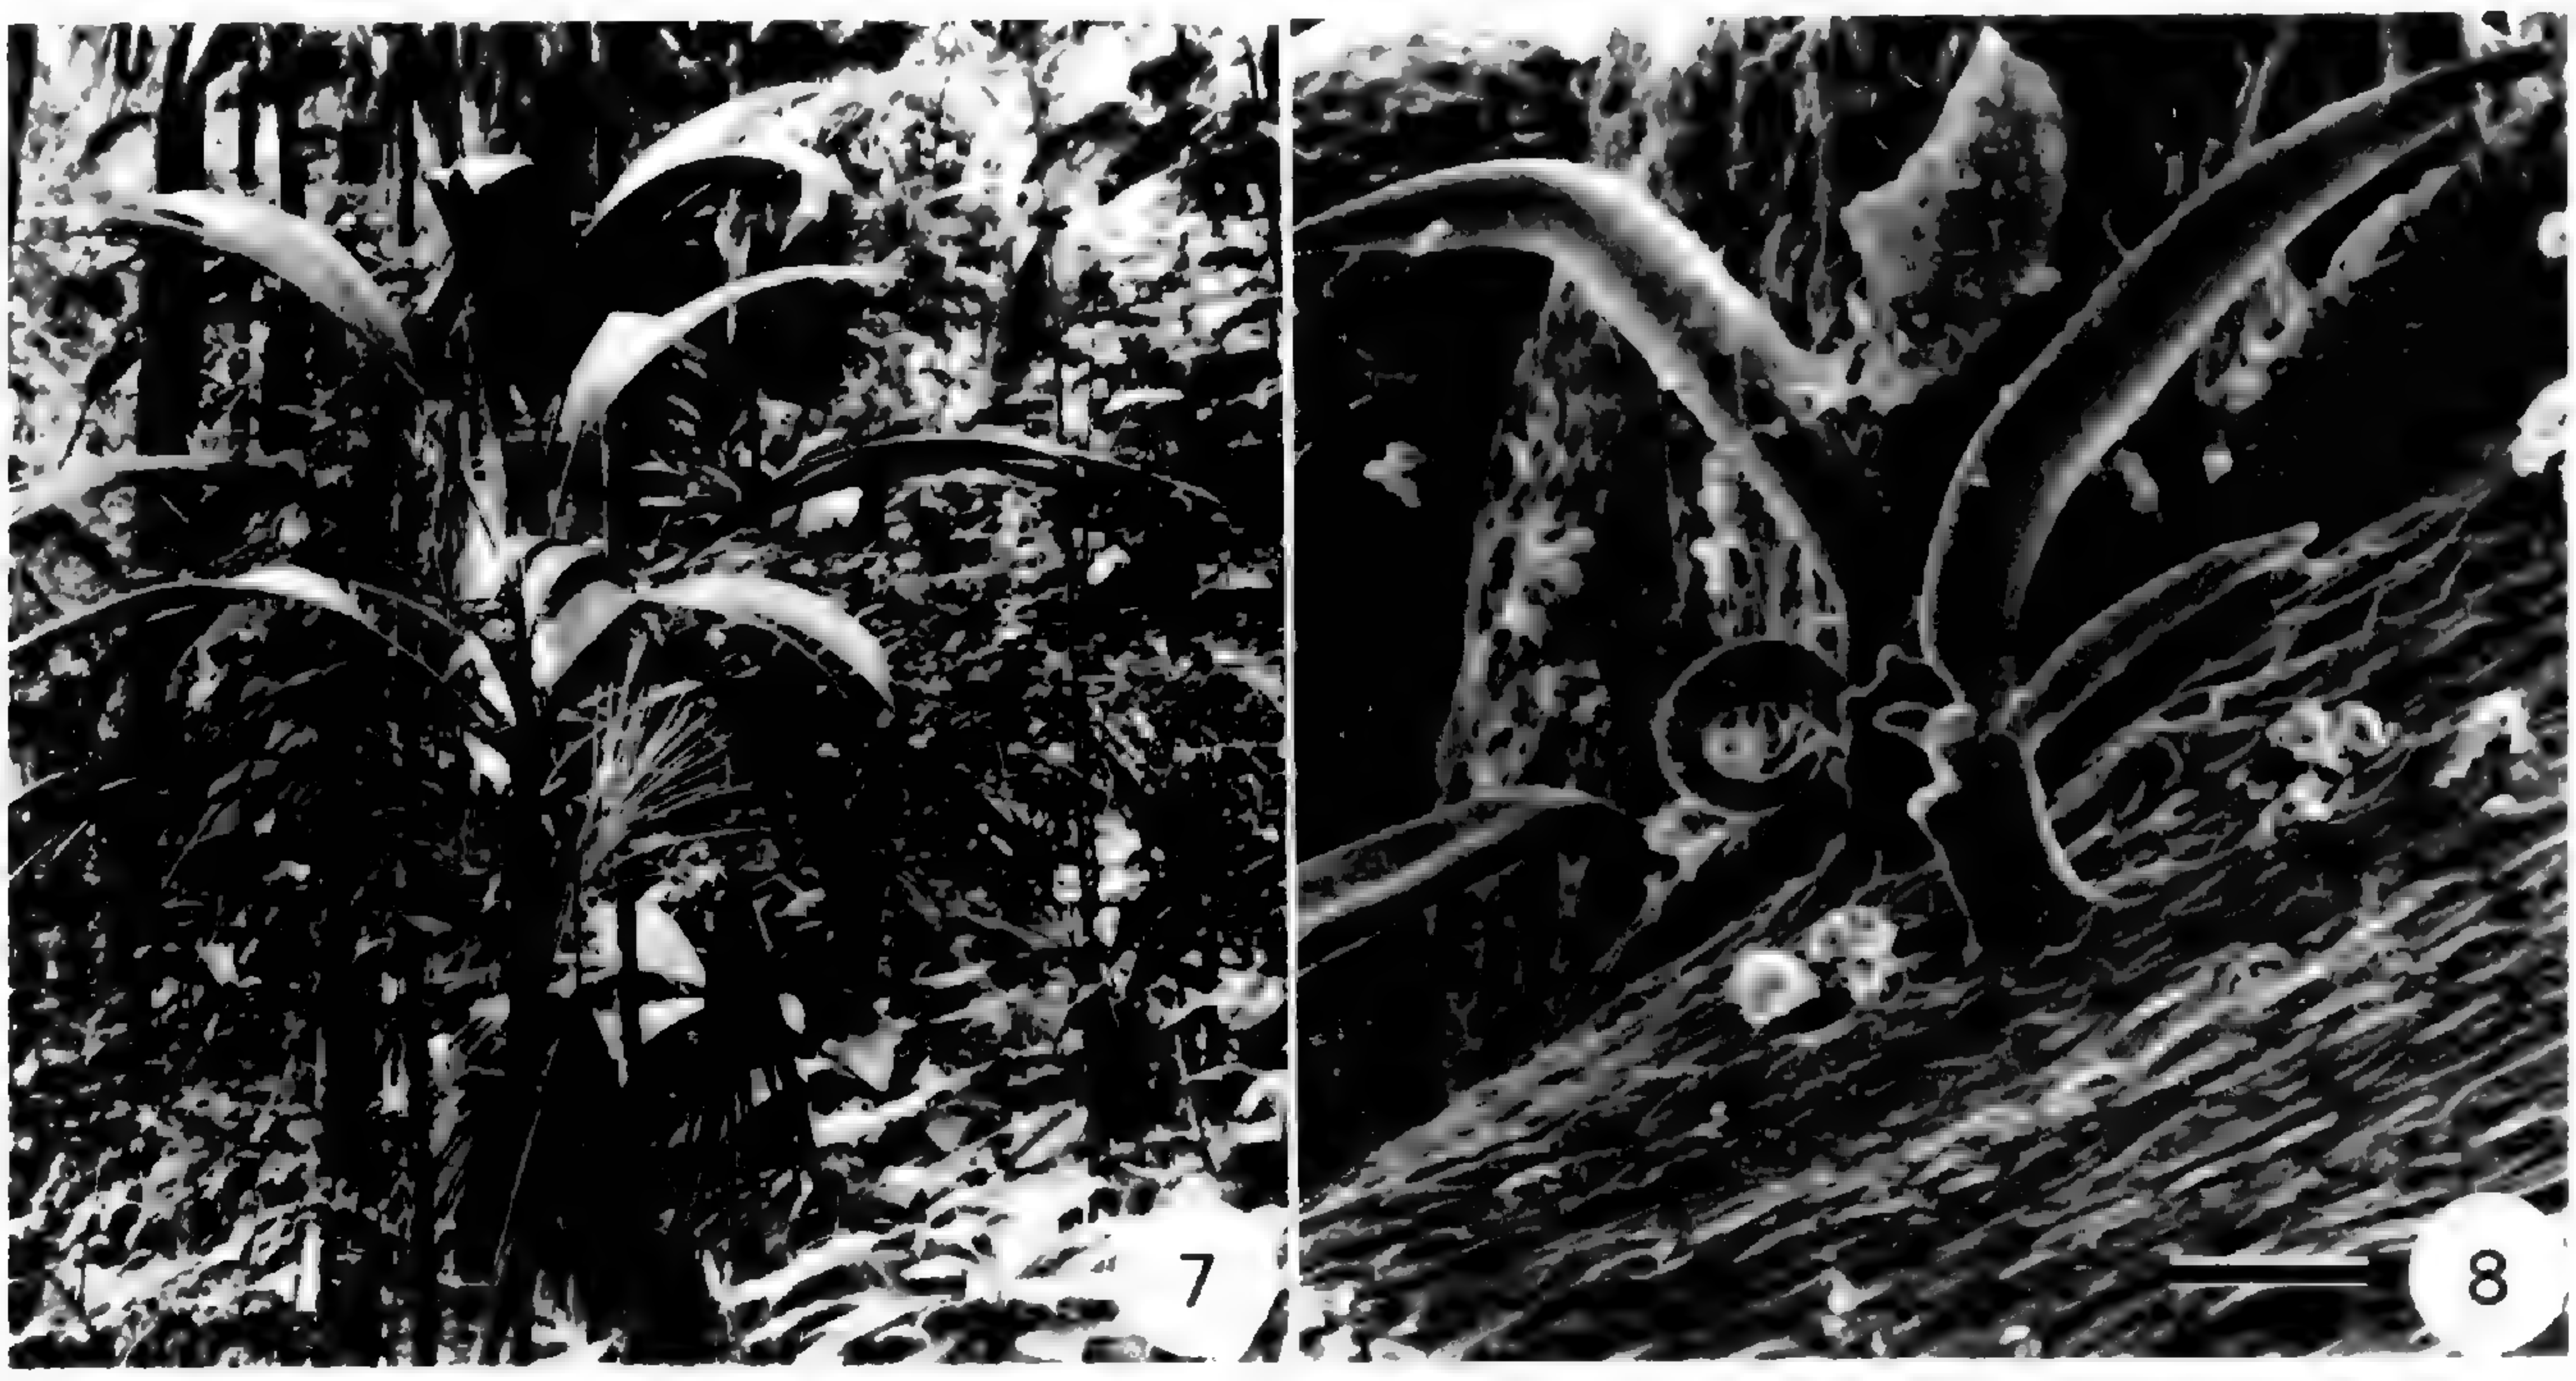
Ab aliis speciebus integrifolius inflorescentia erecta, rachillis tenuibus pilis simplicibus obsitis necnon seminum endospermate ruminato diversa.

Stems cespitose, one well-developed, erect, 2.8–5.8 m tall, 3–4 cm diam.; internodes 3–8 cm long; adventitious roots forming a prominent cone at base of stem, 18–30 cm long, 6–8 mm diam., red, covered with small round projections. Leaves 8–12, spreading; sheaths not forming a crownshaft, 30–38 cm long, closed basally for 15–18 cm, open apically, covered sparsely with closely appressed whit-

FIGURES 5, 6. Prestoea decurrens.—*5. Habit, showing smooth stem, persistent leaf sheaths not forming a crownshaft, erect, interfoliar inflorescence bud, and infrafoliar inflorescence (*Langlois 12*). Photograph courtesy of BH.—6. Part of rachilla, showing short, stiff, simple to branched hairs (*Henderson 50*). Scale bar = 500 µm.*

ish-brown scales; petiole channeled adaxially, rounded abaxially, 30–50 cm long, covered with closely appressed brown scales; rachis 40–65 cm long, ridged adaxially, rounded abaxially and with scales similar to those of petiole; blade entire, 103–113 cm long, 30–35 cm wide, deeply bifid at apex for 60–65 cm; veins prominent adaxially, 14–15 per side, with brown scales proximally. Inflorescence interfoliar, erect at anthesis; peduncle 40–75 cm long, sparsely covered with brown scales; prophyll 21–35 cm long, covered with scales similar to those of peduncle; peduncular bract inserted 5–10 cm above base of peduncle, 80–130 cm long, with scales similar to those of peduncle, at anthesis brown on outside, whitish on inside; rachis 18–32 cm long; rachillae 23–28, 35–54 cm long, 1 mm diam. at middle at anthesis; rachis and rachillae white at anthesis, becoming reddish in fruit, with sparse, hyaline, simple or branched hairs; triads subtended by a low bract; staminate flowers 4 mm long, sessile; sepals 3, free, imbricate, triangular, keeled, membranaceous, hyaline margined, apiculate, 1.5 mm long; petals 3, free, valvate, lanceolate, 4 mm high; stamens 6; filaments unequal, 0.9–1.5 mm long; anthers dorsifixed at center of thecae, introrse; thecae unequal, 0.8–1.2 cm long; pistillode 1 mm long, deeply trifid; pistillate flowers 2 mm long, surrounded by 2 low bracteoles; sepals 3, free, imbricate, glabrous, broadly ovate; petals similar to sepals but slightly smaller; gynoecium ovoid, pseudomonomerous, 1.5 mm long; stigmas sessile; staminodes minute, dentate; immature fruits with ruminate endosperm.

Distribution. Only known from the type locality.



FIGURES 7, 8. Prestoea integrifolia.—7. *Habit, showing entire leaves and interfoliar, erect inflorescence (*de Nevers 7212*).—8. Part of rachilla, showing hyaline, simple and branched hairs (*de Nevers 7212*). Scale bar = 500 µm.*

Additional specimens examined. PANAMA. COLÓN: same locality as type, 13 May 1986, *de Nevers et al. 7738* (MO, NY); km 22, 500 m, 17 Feb. 1986, *Hammel et al. 14473* (MO, NY).

Prestoea integrifolia differs from all other Central American members of the genus by its entire leaves. Three other extra-Central American species have entire leaves: *P. simplicifrons*,[4] *P. simplicifolia* Galeano, and *P. cuatrecasasii* H. Moore.

The holotype of *P. simplicifrons* is no longer extant at B, and no isotypes are known, but there is another collection from at or near the type locality (*Henderson & Bernal 156*). Thus represented, *P. simplicifrons* has relatively short rachillae with a moderate to dense covering of reddish brown hairs, whereas *P. integrifolia* has long rachillae sparsely covered with hyaline hairs.

Prestoea simplicifolia (represented at NY by an isotype and by *Henderson & Bernal 140*) has a stout, pendulous inflorescence with thick rachillae, in contrast with *P. integrifolia*, which has a thin, erect inflorescence with thin rachillae.

Prestoea cuatrecasasii (represented by the original description) has seeds with homogenous endosperm, as opposed to the ruminate endosperm of *P. integrifolia.*

Prestoea pubigera (Griseb. & H. A. Wendl.) Hook. f. is sometimes reported to have entire leaves (e.g., Galeano-Garcés, 1986), but all specimens examined, including the type at Göttingen, have the lower part of the leaf with separate but unequal pinnae, and these are joined in the upper part.

5. **Prestoea longipetiolata** (Oersted) H. Moore, Gentes Herb. 9: 286. 1963. *Euterpe longipetiolata* Oerst., Vidensk. Meddelel. Kjoebenh. 1858: 32. 1859. TYPE: Costa Rica. Cartago: Turrialba, May 1847, *A. S. Oersted 6562* (holotype, C). Figures 9, 10.

Euterpe brachyspatha Burret, Bot. Jahrb. Syst. 63: 57. 1929. TYPE: Costa Rica. Puntarenas: Cañas Gordas, 1,100 m, Feb. 1897, *H. Pittier 11124* (holotype, B destroyed; isotypes, M, US).

Euterpe williamsii Glassman, Fieldiana, Bot. 31: 5. 1964. TYPE: Nicaragua. Matagalpa: Cordillera Central de Nicaragua, along road to La Fundadora, cloud forest area, 1,300–1,400 m, 23 Feb. 1963, *L. O. Williams, A. Molina & T. P. Williams 24922* (holotype, F).

Malortiea simiarum Standley & L. O. Williams, Ceiba 3: 102. 1952. *Euterpe simiarum* (Standley & L.

---

[4] **Prestoea simplicifrons** (Burret) A. J. Henderson & de Nevers, comb. nov. *Euterpe simplicifrons* Burret, Engler Bot. Jahrb. 63: 53. 1929.

O. Williams) H. Moore, Principes 1: 145. 1957. TYPE: Nicaragua. Jinotega: vicinity of Finca San Roque, sierra E of Jinotega, 1,300–1,500 m, 5 July 1947, *P. Standley 10923* (holotype, F).

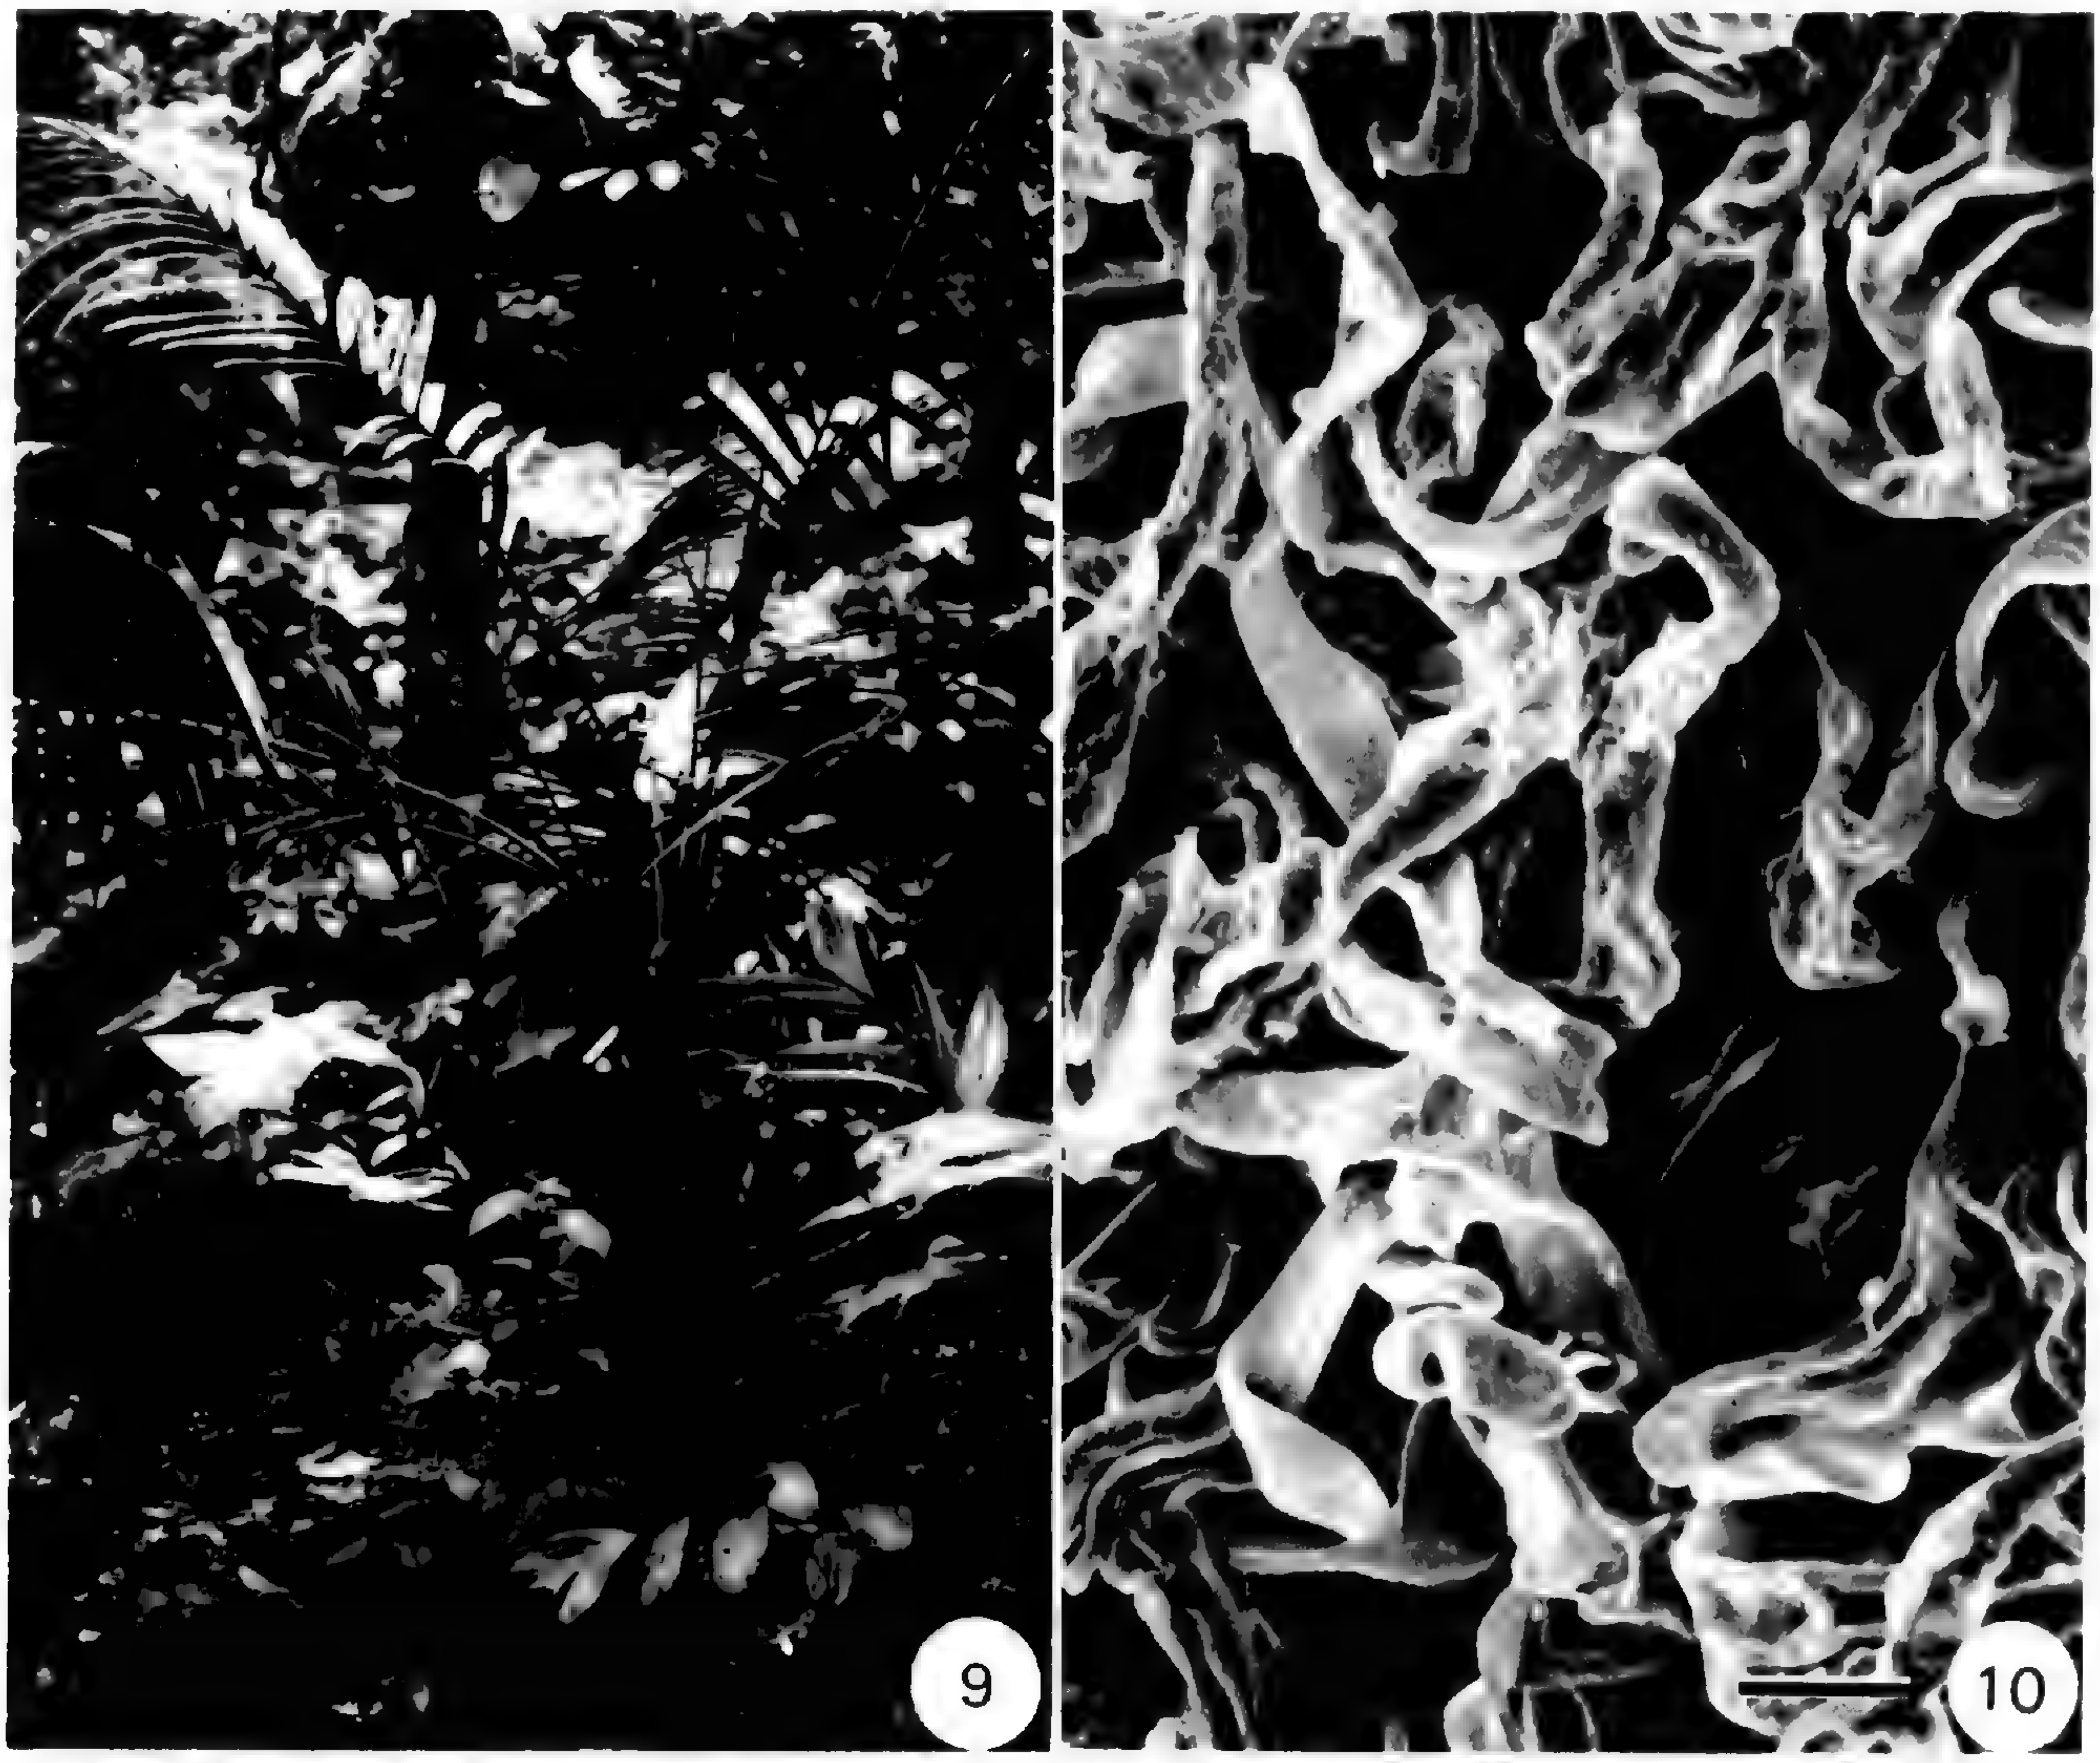
Stems solitary or cespitose, often procumbent, 0.5–3 m tall, ca. 5 cm diam. Leaves 4–8; sheaths persistent, not forming a crownshaft; petiole 80–240 cm long; rachis 116–209 cm long; pinnae 21–33 per side; middle pinnae 45–56 cm long, 1.5–3 cm wide; apical pinna often markedly wider than others. Inflorescence interfoliar or infrafoliar, arching; peduncle 12–100 cm long, 3–6(–11) mm diam.; prophyll (9.5–)15–30 cm long, 1.5–2 cm wide; peduncular bract (32–)56–114 cm long, 2–4 cm wide; rachis 2–9 cm long; rachillae (2–)3–8(–20), (8–)16–35 cm long, at anthesis densely reddish brown tomentose; flowers glabrous; fruit 6–11 mm diam.; seeds with ruminate endosperm.

Distribution. From Nicaragua to western Panama (Chiriquí), 1,000–1,800 m. Contrary to a report by Wessels Boer (1971), this species does not occur in Venezuela (Henderson & Steyermark, 1986).

Additional specimens examined. NICARAGUA. JINOTEGA: Ocotillo near Sta. Lastenia, Cordillera Centrál de Nicaragua, 1,550 m, 17 Jan. 1965, *Williams et al. 27806* (F, NY). MATAGALPA: Cerro Carlota, 12°58′N, 85°52′W, 1,250–1,300 m, 23 Oct. 1982, *Moreno 18129* (MO); Cerro El Picacho, N of Selva Negra, 13°0′N, 85°55′W, 1,500 m, 7 July 1983, *Moreno 21670* (MO, US); 7 July 1983, *Moreno 21671* (MO); Cerro Carlota, 12°58′N, 85°52′W, 1,250–1,300 m, *Moreno 18149* (MO); along Highway 3, ca. 1.9 km W of Aranjuez road entrance, ca. 13°2′N, 85°56′W, 1,460–1,480 m, 30 June 1983, *Stevens 9168* (MO, US); along Highway 3, ca. 1 km NW of La Fundadora entrance, unnamed peak ca. 500 m W of Highway, ca. 13°1′N, 85°56′W, 1,450–1,520 m, 24 May 1981, *Stevens & Henrich 20456* (MO); W slope of summit of Cerro El Picacho, ca. 13°0′N, 85°55′W, 1,350–1,590 m, 3 June 1983, *Stevens & Moreno 22168* (MO, US); Cordillera Central de Nicaragua, along road to La Fundadora, 1,300–1,400 m, 23 Feb. 1963, *Williams et al. 24918* (F); Cordillera Central de Nicaragua, Xelaju, 13°02′N, 85°55′W, 1,500 m, 12 Feb. 1965, *Williams et al. 29266* (F, NY). COSTA RICA. ALAJUELA: Buena Vista, road to San Carlos valley, 600 m, 11 Apr. 1903, *Cook & Doyle 38* (US); Juan Viñas, Reventazón valley, near Juan Viñas River, 1,000 m, 21 Apr. 1903, *Cook & Doyle 173* (US); along Camino Raíz de Hule, SE of Planatillo (Tsipiri), 1,200–1,400 m, 1 July 1976, *Croat 36792* (MO); Reserva Biológia de San Ramón, road from Las Lagunas to Colonía Palmareña, 10°4′N, 84°22′W, 850–1,100 m, 30 May 1986, *de Nevers et al. 7769* (MO, NY); near Río Naranjo, 2 km W of Orosi, 1,400 m, 16 Jan. 1977, *Lent 4066* (F); slopes of ridge separating Río Paz Grande and Río Paz Chiquita, about halfway between Vara Blanca and Cariblanco, valley of Río Sarapiquí, 1,340–1,500 m, *Moore 6639* (BH); Paraiso, area of Muñeco, 9–10 Mar. 1974, *Read & Daniels 74-80* (US); Guadalupe de Zarcero, 1,200 m, 1 Nov. 1973, *Smith A567* (F); La Peña de Zarcero, Cantón Alfar Ruiz, 1,375 m, 23 Jan. 1939, *Smith 1544* (NY); El Muñeco, S of Navarro, 1,400 m, 8 Feb. 1924, *Standley 33600* (F, US). CARTAGO: Cañón del Río Grande de Orosi y Aluvión, 23 Oct. 1983, *Chacon et al. 1489* (MO); Río Tambor, 3 km SE of Cachí, 1,420 m, 22 Aug. 1971, *Lent 2060* (F); about 5 km beyond Hacienda Moravia, 1,000–1,200 m, 13 Apr. 1953, *Moore 6686* (BH); fords of Las Vueltas, Tucurrique, 635 m, Dec. 1898, *Tonduz 12924* (F, US). SAN JOSÉ: El General, 1,490 m, Feb. 1939, *Skutch 4184* (US); between San Isidro and La Georgina, 17 Nov. 1973, *Moore & McAlpin 10150* (BH); 17 Nov. 1973, *Moore & McAlpin 10150A* (BH). PANAMA. BOCAS DEL TORO: La Fortuna Dam Area, N of dam along continental divide trail W of oleoducto road, 8°47′N, 82°15′W, 1,200–1,300 m, 11 Feb. 1986, *Hammel & McPherson 14458*; near continental divide in vicinity of Cerro Colorado, 9.4 road miles from Chami camp, ca. 8°35′N, 81°45′W, ca. 1,700 m, 15 Apr. 1986, *McPherson 8917* (MO, NY). CHIRIQUÍ: 9 mi. from Río Chiriquí Viejo bridge near Nueva California on road to Río Sereno, 7 Apr. 1979, *Hammel et al. 6829* (MO).

Malortiea simiarum was originally distinguished by its pinnate leaves and little-branched inflorescence when being compared with *Reinhardtia* (*Malortiea*). The size, degree of branching, and pubescence of the type fall within the range of variation observed in Costa Rican material of *P. longipetiolata*.

Euterpe brachyspatha, as judged from the original description, was named after a misinterpretation of the inflorescence. Burret (1929) described the spadix (inflorescence) as 98 cm long and the spathe (peduncular bract) as 17 cm long, which is impossible. The ho-



FIGURES 9, 10. Prestoea longipetiolata.—*9. Habit, showing procumbent stem and arching, interfoliar inflorescence (*Moore 9426*). Photograph courtesy of BH.—10. Part of rachilla, showing dense tomentum (*McPherson 8917*). Scale bar = 250 µm.*

lotype is lost, and the isotypes are incomplete. However, the specimens described by Burret represent *P. longipetiolata.* The Munich isotype has the broad apical pinna typical of most but not all specimens of *P. longipetiolata.* A topotype, *Croat 22232,* is typical *P. longipetiolata.*

Euterpe williamsii was originally contrasted with *E. brachyspatha,* presumably represented by the original description. In Burret's (1929) key, *E. brachyspatha* and *E. longipetiolata* are contrasted in the same couplet. In its protologue, Glassman did not contrast *E. williamsii* with *E. longipetiolata. Euterpe williamsii* agrees in the diagnostic characters of size, branching, and pubescence of the inflorescence with *E. longipetiolata.*

6. Prestoea roseospadix (L. Bailey) H. Moore, Principes 9: 73. 1965. *Euterpe roseospadix* L. Bailey, Gentes Herb. 6: 201. 1943. TYPE: Panama. Chiriquí: vicinity of Bajo Chorro, 1,900 m, 20–22 July 1940, *R. E. Woodson & R. W. Schery 623* (holotype, MO; isotype, BH). Figure 11.

Stems solitary, erect, 0.3–3 m tall, 8–10 cm diam. Leaves 4–6; sheaths persistent, not forming a crownshaft; petiole 61–76 cm long; rachis 120–125 cm long; pinnae 21–27 per side; middle pinnae 38–50 cm long, 2–2.5 cm wide; apical pinna not wider than others. Inflorescence infrafoliar, erect; peduncle 16–38 cm long, 0.5 cm wide; prophyll 20–23 cm long, 2 cm wide; peduncular bract 70–80 cm long, 2 cm wide, inserted ca. 14 cm above base of peduncle; rachis 16–40 cm long; rachillae 9–16, 20–40 cm long, glabrous; flowers glabrous; fruit 9–10 mm diam.; seeds with ruminate endosperm.

Distribution. Western Panama (Chiriquí and Veraguas) at altitudes around 1,500 m.

Additional specimens examined PANAMA. CHIRIQUÍ: Cerro Horqueta, 2,100 m, 24 July 1966, *Blum & Dwyer 2665* (MO); 24 July 1966, *Blum & Dwyer 2671* (MO); 8 Aug. 1967, *Kirkbride 162* (MO); Bajo Chorro, Boquete, ca. 2,000 m, 11 Jan. 1938, *Davidson 100* (F); lower slopes of Cerro Pate Macho, 8°49'N, 82°24'W, 1,600 m, 31 Dec. 1985, *de Nevers & Charnley 6697* (MO, NY); 17 Jan. 1986, *de Nevers & McPherson 6829* (MO, NY); La Fortuna hydroelectric dam project, behind camp, 1,300–1,400 m, 23 Mar. 1978, *Hammel 2255* (BH, MO). VERAGUAS: valley of Río Dos Bocas on road between Alto Piedra (above Santa Fé) and Calovébora, 350–400 m, 29 Aug. 1974, *Croat 27440* (MO).

7. **Prestoea sejuncta** L. Bailey, Gentes Herb. 6: 201. 1943. TYPE: Panama. Canal Area: Madden Lake area, upper Río Pequení, 100 m, 29 July 1941, *A. G. B. Fairchild & D. Jobbins 2635* (holotype, BH; isotype, MO). Figures 12–14.

Stem solitary or cespitose, erect, 5–9 m tall, (4.5–)9–13 cm diam. Leaves 5–8; leaf sheaths persistent or deciduous, not forming a crownshaft; middle pinnae 61–86 cm long, 3–4.5(–6) cm wide; apical pinna not wider than others. Inflorescence interfoliar, erect, or arching, or horizontal, straight or curved; prophyll 13–45(–75) cm long, (1.2–)3–5 cm wide; peduncular bract 69–156(–215) cm long, (2.5–)3.6–5.5 cm wide, inserted (2–)4.5–13 cm above prophyll; peduncle 23–71 cm long, 0.6–1.4 cm wide, narrow, cylindric, not flaring at base; rachis (15–)33–50 cm long; rachillae (18–)42–48, 30–70 cm long, essentially glabrous but with patches of long, loosely intertwined hairs; flowers glabrous; fruits 7–10 mm diam.; seeds with ruminate endosperm.

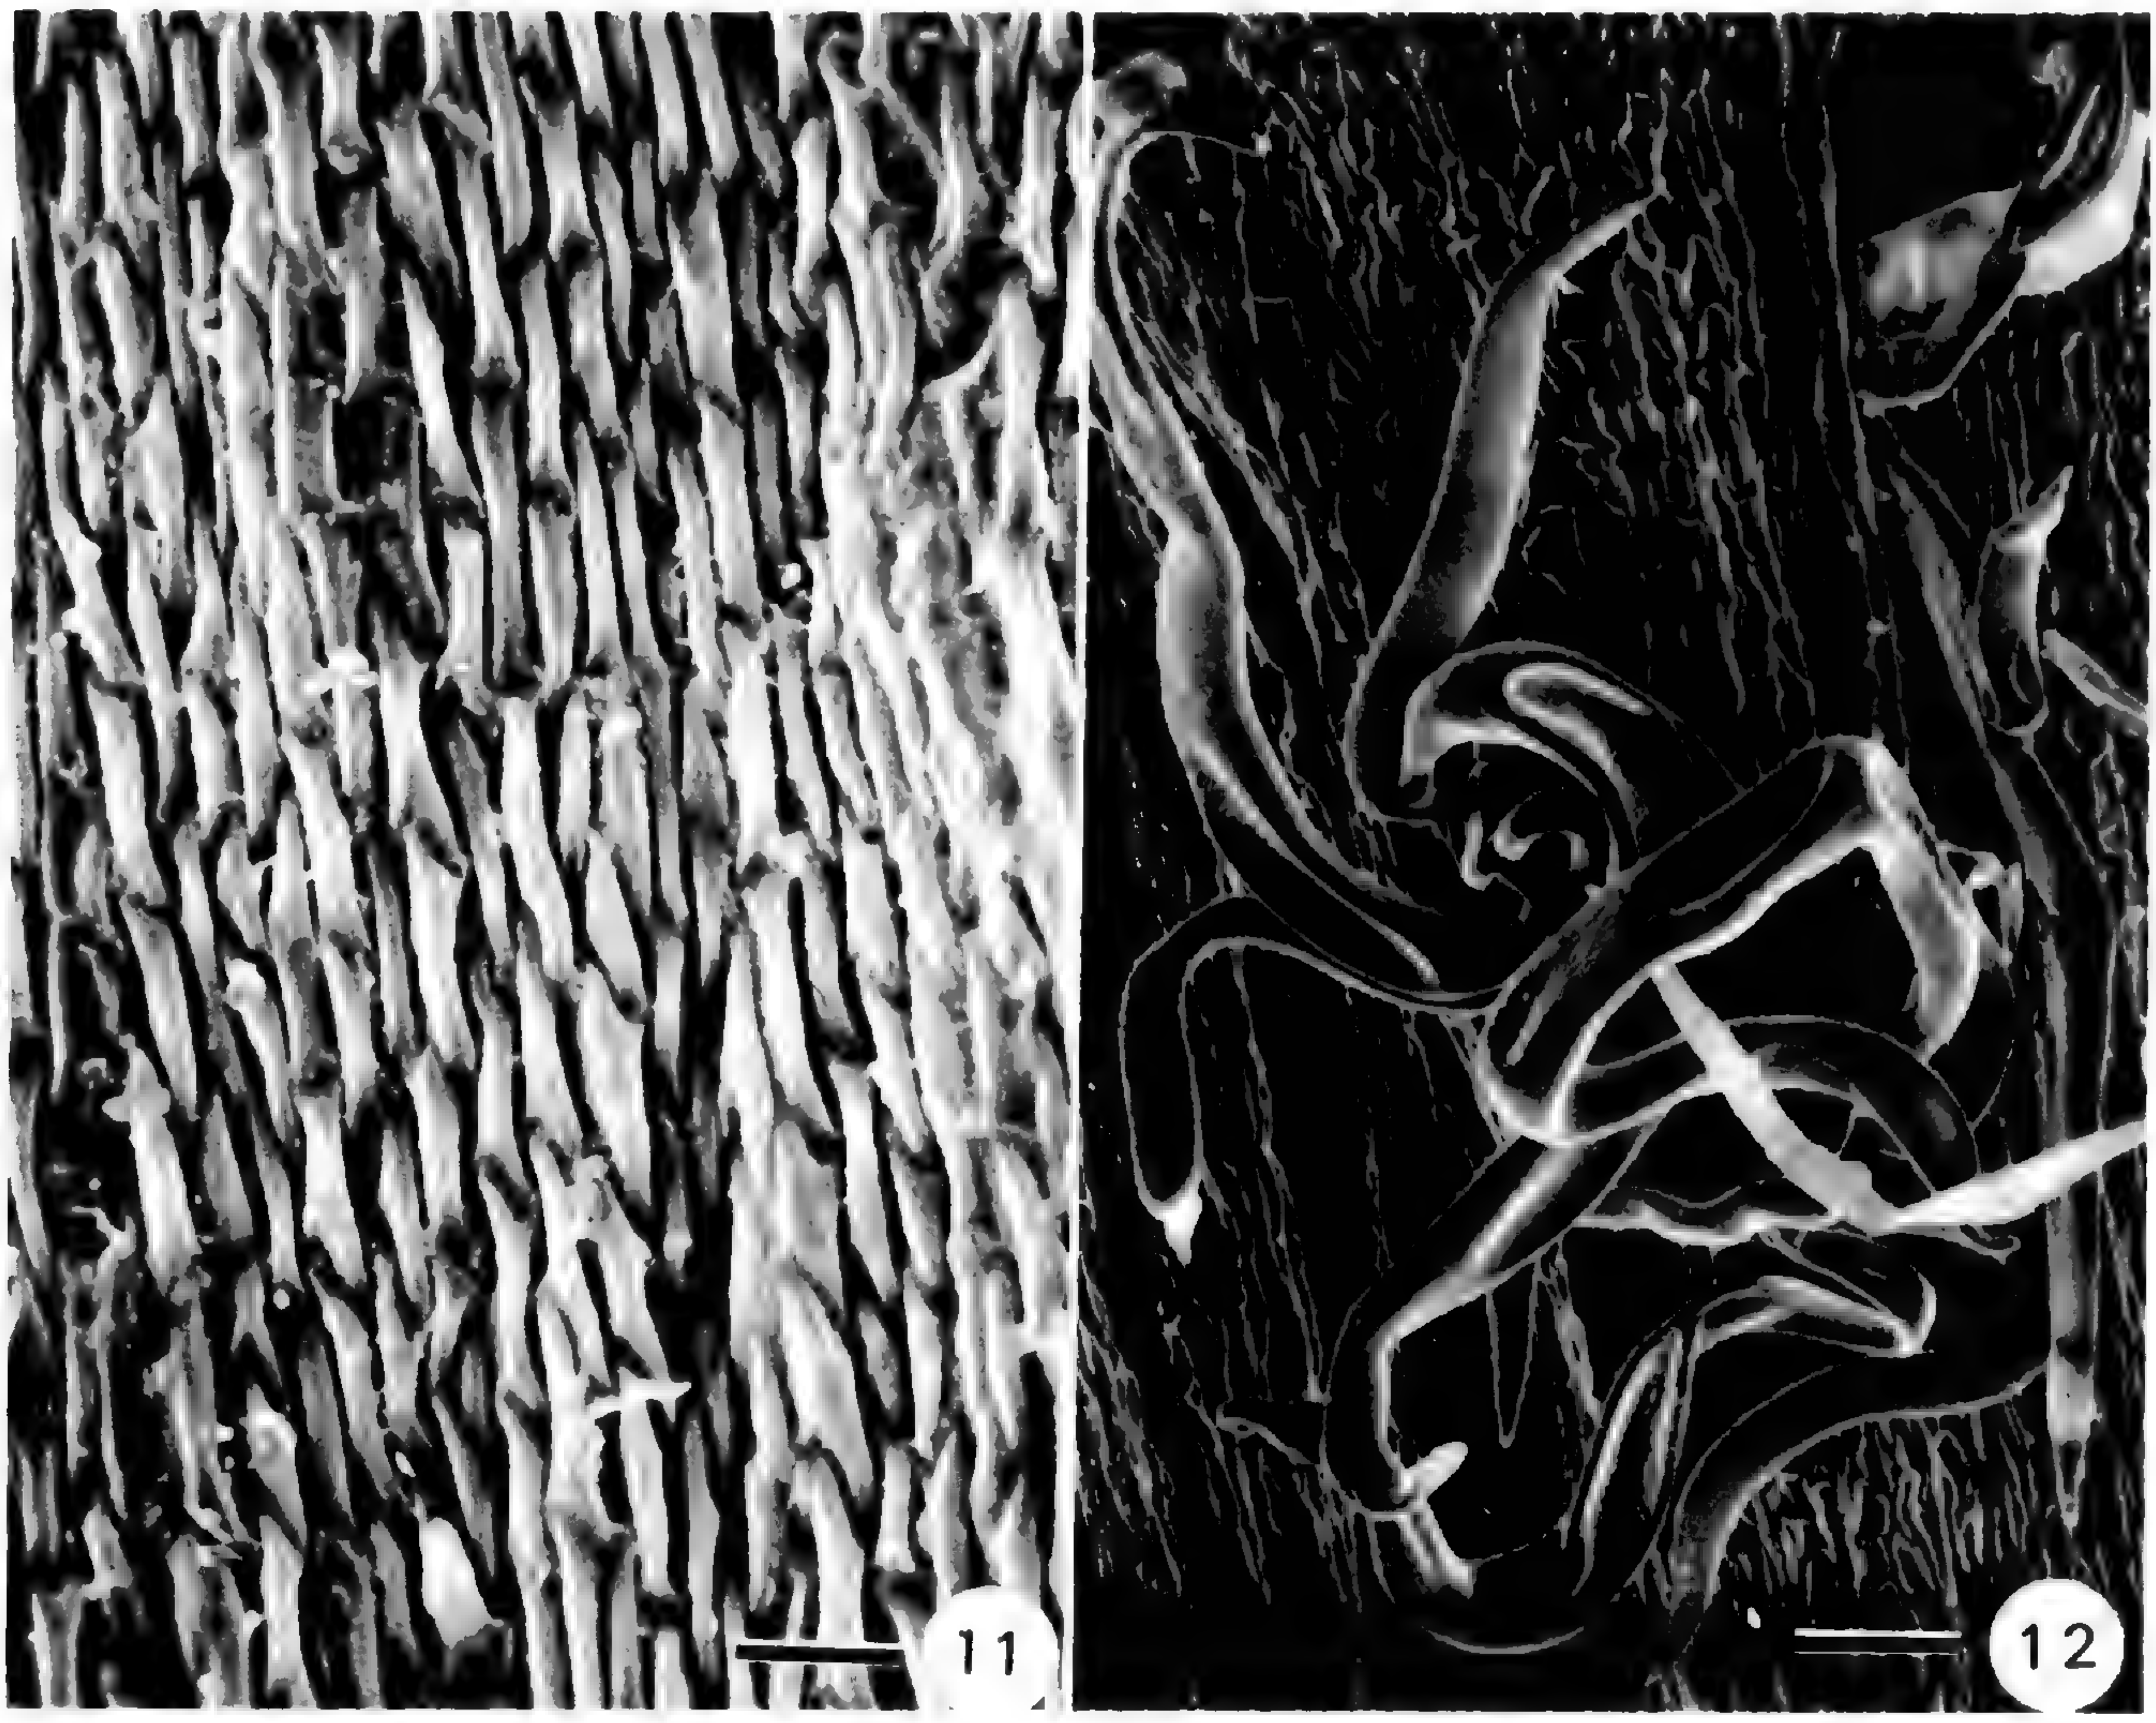
Distribution. Known from central Panama (Chiriquí, Coclé, Comarca de San Blas, Colón), 100–1,100 m. This species is also reported from coastal Ecuador by Dodson & Gentry (1978). Other specimens from Ecuador (e.g., *Balslev & Henderson 62107*) are clearly referable to this species, and it presumably occurs in intervening Colombia.

Additional specimens examined. PANAMA. CHIRIQUÍ: Fortuna dam area, road from Gualaca to Chiriquí Grande, continental divide trail west of road, 1,150 m, 8°45'N, 82°15'W, 18 Jan. 1986, *de Nevers & McPherson 6849* (MO, NY). COLÓN: trail from Alto Pacora to Cerro Brewster, 9°18'N, 79°16'W, 700 m, 18 Nov. 1985, *de Nevers et al. 6223* (MO, NY). COCLÉ: El Valle de Antón, La Mesa, ca. 1,000 m, 2 Sep. 1941, *Allen 2740* (paratype) (BH, MO). COMARCA DE SAN BLAS: Cerro Brewster, 9°18'N, 79°16'W, 850 m, 25 Apr. 1985, *de Nevers et al. 5541* (MO, NY). PANAMÁ: 3 mi. N of Cerro Azúl, 26 July 1970, *Croat 11589* (MO); Cerro Jefe, ca. 700 m, 20 Jan. 1980, *Moore et al. 10522* (BH); Río Pequení, slopes of Cerro San Francisco, 150–300 m, 9°22'N, 79°31'W, 29 Nov. 1985, *de Nevers & Henderson 6411* (CAS, MO, NY); road to Alto Pacora from Cerro Jefe, 700 m, 28 Nov. 1985, *Henderson & Brako 505* (MO, NY); Gorgas Memorial Lab's yellow fever research camp, ca. 25 km NE of Cerro Azúl on Río Piedras, 550 m, 20–22 Nov. 1974, *Mori & Kallunki 3454* (BH, MO).

Among the specimens examined, there appear to be two ecotypes, which may turn out to represent distinct taxa. At higher altitudes (900–1,200 m) in premontane rain forest (Holdridge et al., 1971), the inflorescence is straight and erect in bud (Fig. 13) and relatively long and thick (1.5–2.1 m × 3–5 cm). At lower altitudes (10–200 m) in tropical moist forest and tropical wet forest (Holdridge et al., 1971), the inflorescence is curved and horizontal in bud (Fig. 14) and is relatively short and thin (75–80 × 1.2–2.5 cm). When Bailey described *P. sejuncta*, he cited two specimens, one of each ecotype. The holotype is the short-inflorescence ecotype, and the paratype, *Allen 2740*, is the long-inflorescence ecotype. Although letters accompanying *Allen 2740* from Paul Allen to Bailey clearly outlined this variation, Bailey included only the dimensions of the smaller Madden Lake plant.

8. **Prestoea semispicata** de Nevers & A. J. Henderson, sp. nov. TYPE: Panama. Comarca de San Blas: Cerro Brewster, 9°18'N, 79°16'W, 800 m, premontane rain forest, 19 Nov. 1985, *G. de Nevers, A. Henderson, H. Herrera, G. McPherson & L. Brako 6290* (holotype, MO; isotypes, AAU, BH, CAS, COL, FTG, K, NY, PMA). Figures 15, 16.

Ab omnibus congeneribus inflorescentia simplice vel pauciramosa necnon seminum endospermate subruminato diversa.



FIGURES 11, 12. Prestoea.—*11.* P. roseospadix, *part of rachilla, showing absence of hairs (*Woodson 623*).* *Scale bar = 400 µm.*—*12.* P. sejuncta, *part of rachilla, showing long, loosely intertwined hairs (*de Nevers & Henderson 6411*). Scale bar = 500 µm.*

Stems cespitose, only one well-developed, to 145 cm long, 3.5–9 cm diam., often procumbent and partly subterranean; roots visible above ground, spiny and occasionally swollen. Leaves 4–10, arching to erect; sheaths not forming a crownshaft, 17–20 cm long, brown, persistent; petiole 29–100 cm long, densely covered with closely appressed, brown hairs; rachis 52–180 cm long; pinnae 12–20 per side, elliptic, abruptly and asymmetrically long-apiculate, glossy green adaxially, lighter green abaxially; middle pinnae 19–51 × 2.5–6 cm. Inflorescence infrafoliar, protandrous, arching, borne at or near ground level; peduncle 6–50 cm long, 1.5–3 mm diam., terete, with scattered brown scales; prophyll erect and persistent in leaf axil, inserted at base of peduncle, (1.2–)4.5–19 cm long, 1.1–1.8 cm wide, dorsiventrally compressed, ancipitous, splitting apically; peduncular bract (9–)29–90 cm long, 1–2 cm wide at middle, inserted (0.7–)1.5–7 cm above insertion of prophyll, terete in bud, apically pointed, brown at anthesis, soon dropping; rachillae 1(–4), 8–30 cm long, glabrous; peduncle and rachis white at anthesis and becoming red in fruit; triads densely crowded and borne to apex of rachillae, slightly sunken, subtended by a low bract; staminate flowers 4 mm long, sessile or borne on a short, flattened pedicel, white; sepals 3, triangular, gibbous, imbricate below, 1 mm long, ciliate; petals 3, free, lanceolate, valvate, 4 mm long; stamens 6; filaments slightly flattened, with long reflexed apex in bud, 3 mm long; anthers dorsifixed, latrorse, 2 mm long; pistillode prominent, as long as stamens in bud, briefly trifid at apex; pistillate flower 3 mm long, surrounded by 2 low bracteoles; sepals 3, free, imbricate, minutely ciliate; petals 3, free, val-

FIGURES 13, 14. Prestoea sejuncta.—*12. Straight inflorescence bud and long inflorescence with elongate peduncle and numerous rachillae (*Henderson & Brako 505*).—14. Curved inflorescence bud and small inflorescence with short peduncle and few rachillae (*de Nevers & Henderson 6411*).*

vate above, imbricate below; gynoecium ovoid, pseudomonomerous, 2 mm long, the ovule attached laterally; stigmas sessile, elongate, not recurved at anthesis; staminodes dentiform; fruit spherical, 8 mm diam., with lateral stigmatic residue, black; epicarp smooth; mesocarp fleshy; seed spherical, 7 mm diam., the endosperm homogenous to slightly ruminate; embryo basal.

Common name. "Siler burwi" (Kuna, Panama).

Distribution. Known only from the low mountains of Central Panama, from the western end of the Serranía de San Blas to El Copé in Coclé, where it is uncommon between 350 and 850 m. It grows on steep slopes and ridge tops in premontane rainforest and tropical wet forest.

Additional specimens examined. PANAMA. COCLÉ: El Valle de Antón, Cerro Gaital, 8°37′N, 80°6′W, 1,000 m, 26 Nov. 1985, *de Nevers et al. 6351* (CAS, MO, NY); continental divide above El Copé, 900 m, 19 Jan. 1978, *Hammel 967* (MO); 27 Nov. 1985, *de Nevers et al. 6381* (MO, NY, PMA, other duplicates to be distributed). de Nevers & Herrera 8029 (CAS, MO); Cerro Obu, 78°48'W, 9°23'N, 25 June 1986, *de Nevers & Herrera 8055* (CAS, MO).

Prestoea semispicata is unusual in the genus by the usually spicate inflorescence, seeds with homogenous to slightly ruminate endosperm, and shape of the pinnae. In populations where individuals with branched inflorescences occur, spicate inflorescences are also found. In fact, branched and spicate inflorescences form on the same plants. *Prestoea semispicata* appears morphologically similar to that group of *Prestoea* characterized by a weakly developed stem, absence of crownshaft, markedly unequal prophyll and peduncular bract, short rachis with few rachillae, and seeds with either homogenous or ruminate endosperm (Henderson, 1986). In this group, *P. semispicata* shares with *P. cuatrecasasii* and *P. schultzeana* (Burret) H. Moore seeds with homogenous endosperm but differs in the shape of the pinnae and in having usually spicate inflorescences. Some specimens of *P. longipetiolata* from Nicaragua and *P. pubens* H. Moore from Colombia have two or three rachillae on the inflorescence, but these are densely tomentose and not glabrous as in *P. semispicata*.

KARYOTYPE VARIATION IN *PANCRATIUM HIRTUM* A. CHEV. (AMARYLLIDACEAE)[1]

S. O. Oyewole[2]

ABSTRACT

Natural populations of Pancratium hirtum *A. Chev. from different ecological niches show definable morphological variation. Samples were grown in an experimental garden and investigated karyotypically. Five morphological variants (morphotypes) were identified and were confirmed as showing karyotype differences. Karyotype differentiation involves at least: (1) chromosomal breakages, and (2) differences in the total length of chromatin material per nucleus. The chromosome basic number of x = 11 is confirmed for the species, while the presence of accessory chromosomes in one morphotype is reported for the first time in the genus. Population divergence is less pronounced than karyotypic divergence.*

Pancratium L. is represented in West Tropical Africa by two species, *P. hirtum* A. Chev. and *P. trianthum* Herb. Their taxonomy was well documented by Morton (1965), who reported the somatic chromosome number of $2n = 22$ for them. Morton did not include analysis of the karyotypes. *Pancratium hirtum*, with large chromosomes, is especially suitable for study of chromosome morphology.

MATERIALS AND METHODS

Pancratium hirtum grows in a variety of niches in savanna vegetation, where it exhibits minor but definable differences in leaf size, leaf color, extent of pubescence, length and form of the peduncle, and texture of the outermost tunic of the bulb (Table 1).

Five morphological groups (morphotypes, Fig. 1) were recognized during field study and samples were collected. Not fewer than 40 bulbs of each morphotype were grown separately on adjacent beds in the experimental garden. Their habitats are described in Table 2.

Each bulb in each morphotype was examined cytologically using root tip squashes as outlined in Darlington & LaCour (1969). Chromosome counts were made from several metaphase plates in each preparation. Measurement of chromosomes using calibrated micrometer eyepiece graticule was impracticable due to their unusual lengths. Photographs of metaphase plates were taken at ×7.5 ocular and ×40 objective of the Olympus (Vanox model) Research Microscope. Chromosomes were measured from the photomicrographs. The measurements were pooled from 15–20 complements for each morphotype, and average lengths were determined. Chromosome morphological determinations were according to Levan et al. (1964) as modified by Adhikary (1974). Evidence of chromosomal changes was manifested in unequalness of members of homologous chromosome pairs (such changes usually affect one arm of a member). In such instances, the unaffected arm length was employed to identify the members, and the chromosome index was based solely on the length of the longer member of the pair. Idiograms were constructed from enlarged photomicrographs.

RESULTS

Karyotype data are summarized in Table 3. Figure 2 shows metaphase plates of the somatic complements, and Figure 3 presents the idiograms. All morphotypes have a somatic chromosome number of $2n = 22$, except E, in which the complement is $2n = 22 + 4$ B-chromosomes.

Morphotype A. The chromosomes vary in length from 5.5 μm to 19 μm, with a total length of chromatin material of 216.5 ± 6.5 μm. The complement (Figs. 4A, 5A) consists of four pairs with median to submedian centromeres (1st, 2nd, 3rd, and 11th), one telocentric pair (8th), and six pairs with terminal to subterminal centromeres (4th–7th, 9th and 10th). The longest two pairs have unequal members, one member of each having lost a portion of its long arm.

Morphotype B. Chromosomes vary in length from 11.38 μm to 41.75 μm, with an average total chromatin length of 439.5 ± 18.5 μm. The complement (Figs. 4B, 5B) consists of three pairs (1st, 2nd, and 11th) with median to submedian centromeres, and eight (3rd–10th) with terminal to subterminal centromeres. The second- and third-longest pairs have unequal members: a member of the former having lost a portion of the long arm, while one member of the latter lost a portion of its short arm.

Morphotype C. Chromosomes vary in length from 6.3 μm to 19.14 μm, and the total chromatin length averages 237.3 ± 23.3 μm. The complement (Figs. 4C, 5C) consists of three pairs (1st, 2nd, and 11th) with median to submedian centromeres and eight pairs (3rd–10th) with terminal to subterminal centromeres. The third-longest pair has unequal members—the shorter member has a shorter second arm. One member of the shortest pair also shows loss of a portion of one arm.

Morphotype D. Chromosome length varies between 8.6 μm and 27.3 μm, with an average total chromatin length of 340.4 ± 49.8 μm. The complement (Figs. 4D, 5D)

TABLE 1. *Summary of the external morphology of* Pancratium hirtum *morphotypes.*

	A	B	C	D	E
Peduncle	4–7 cm long, flattened, puberulous	2–4.5 cm long, elliptic, fluted, faintly puberulous	4–7 cm long, cylindrical, glabrous	10–13 cm long, cylindrical, glabrous	4–6 cm long, slightly flattened, shortly puberulous
Fruit	2.5–3.5 cm long, 3–3.6 cm circumference, oblong-elliptic, obtuse apex, trigonal in transverse section, green, glabrous, receptacle 1–3 mm high	2–4 cm long, 2–3.3 cm circumference, lanceolate, obtuse apex, trigonal in transverse section, green, glabrous, receptacle 1–3 mm high	1.7–2 cm long, 2–3.6 cm circumference, oblong, apex 4–5 mm high, trigonal in transverse section, green, glabrous, receptacle 1–3 mm high	1.4–2 cm long, 2.5–3.5 cm circumference, cylindrical, apex 2–4 mm high, trigonal in transverse section, green, glabrous, receptacle 1–3 mm high	2–2.5 cm long, 3–4 cm circumference, spindle shaped, apex 1–5 mm high, obtusely trigonal, green, glabrous, receptacle 1–3 mm high

consists of five pairs (1st–3rd, 10th, and 11th) with median to submedian centromeres and six pairs (4th–9th) with terminal centromeres. Five of the eleven pairs (1st, 2nd, 3rd, 8th, and 10th) show evidence of loss of portions from one member of each pair. First and 10th pairs show loss in the long arm; the second and third pairs show loss in the short arm, and the eighth shows loss in one of the two equal arms.

Morphotype E. The autosomes vary in length from 5.6 μm to 17.9 μm, and the B-chromosomes vary between 1 μm and 1.5 μm. The average total chromatin length is 219.14 ± 2.5 μm. The complement (Figs

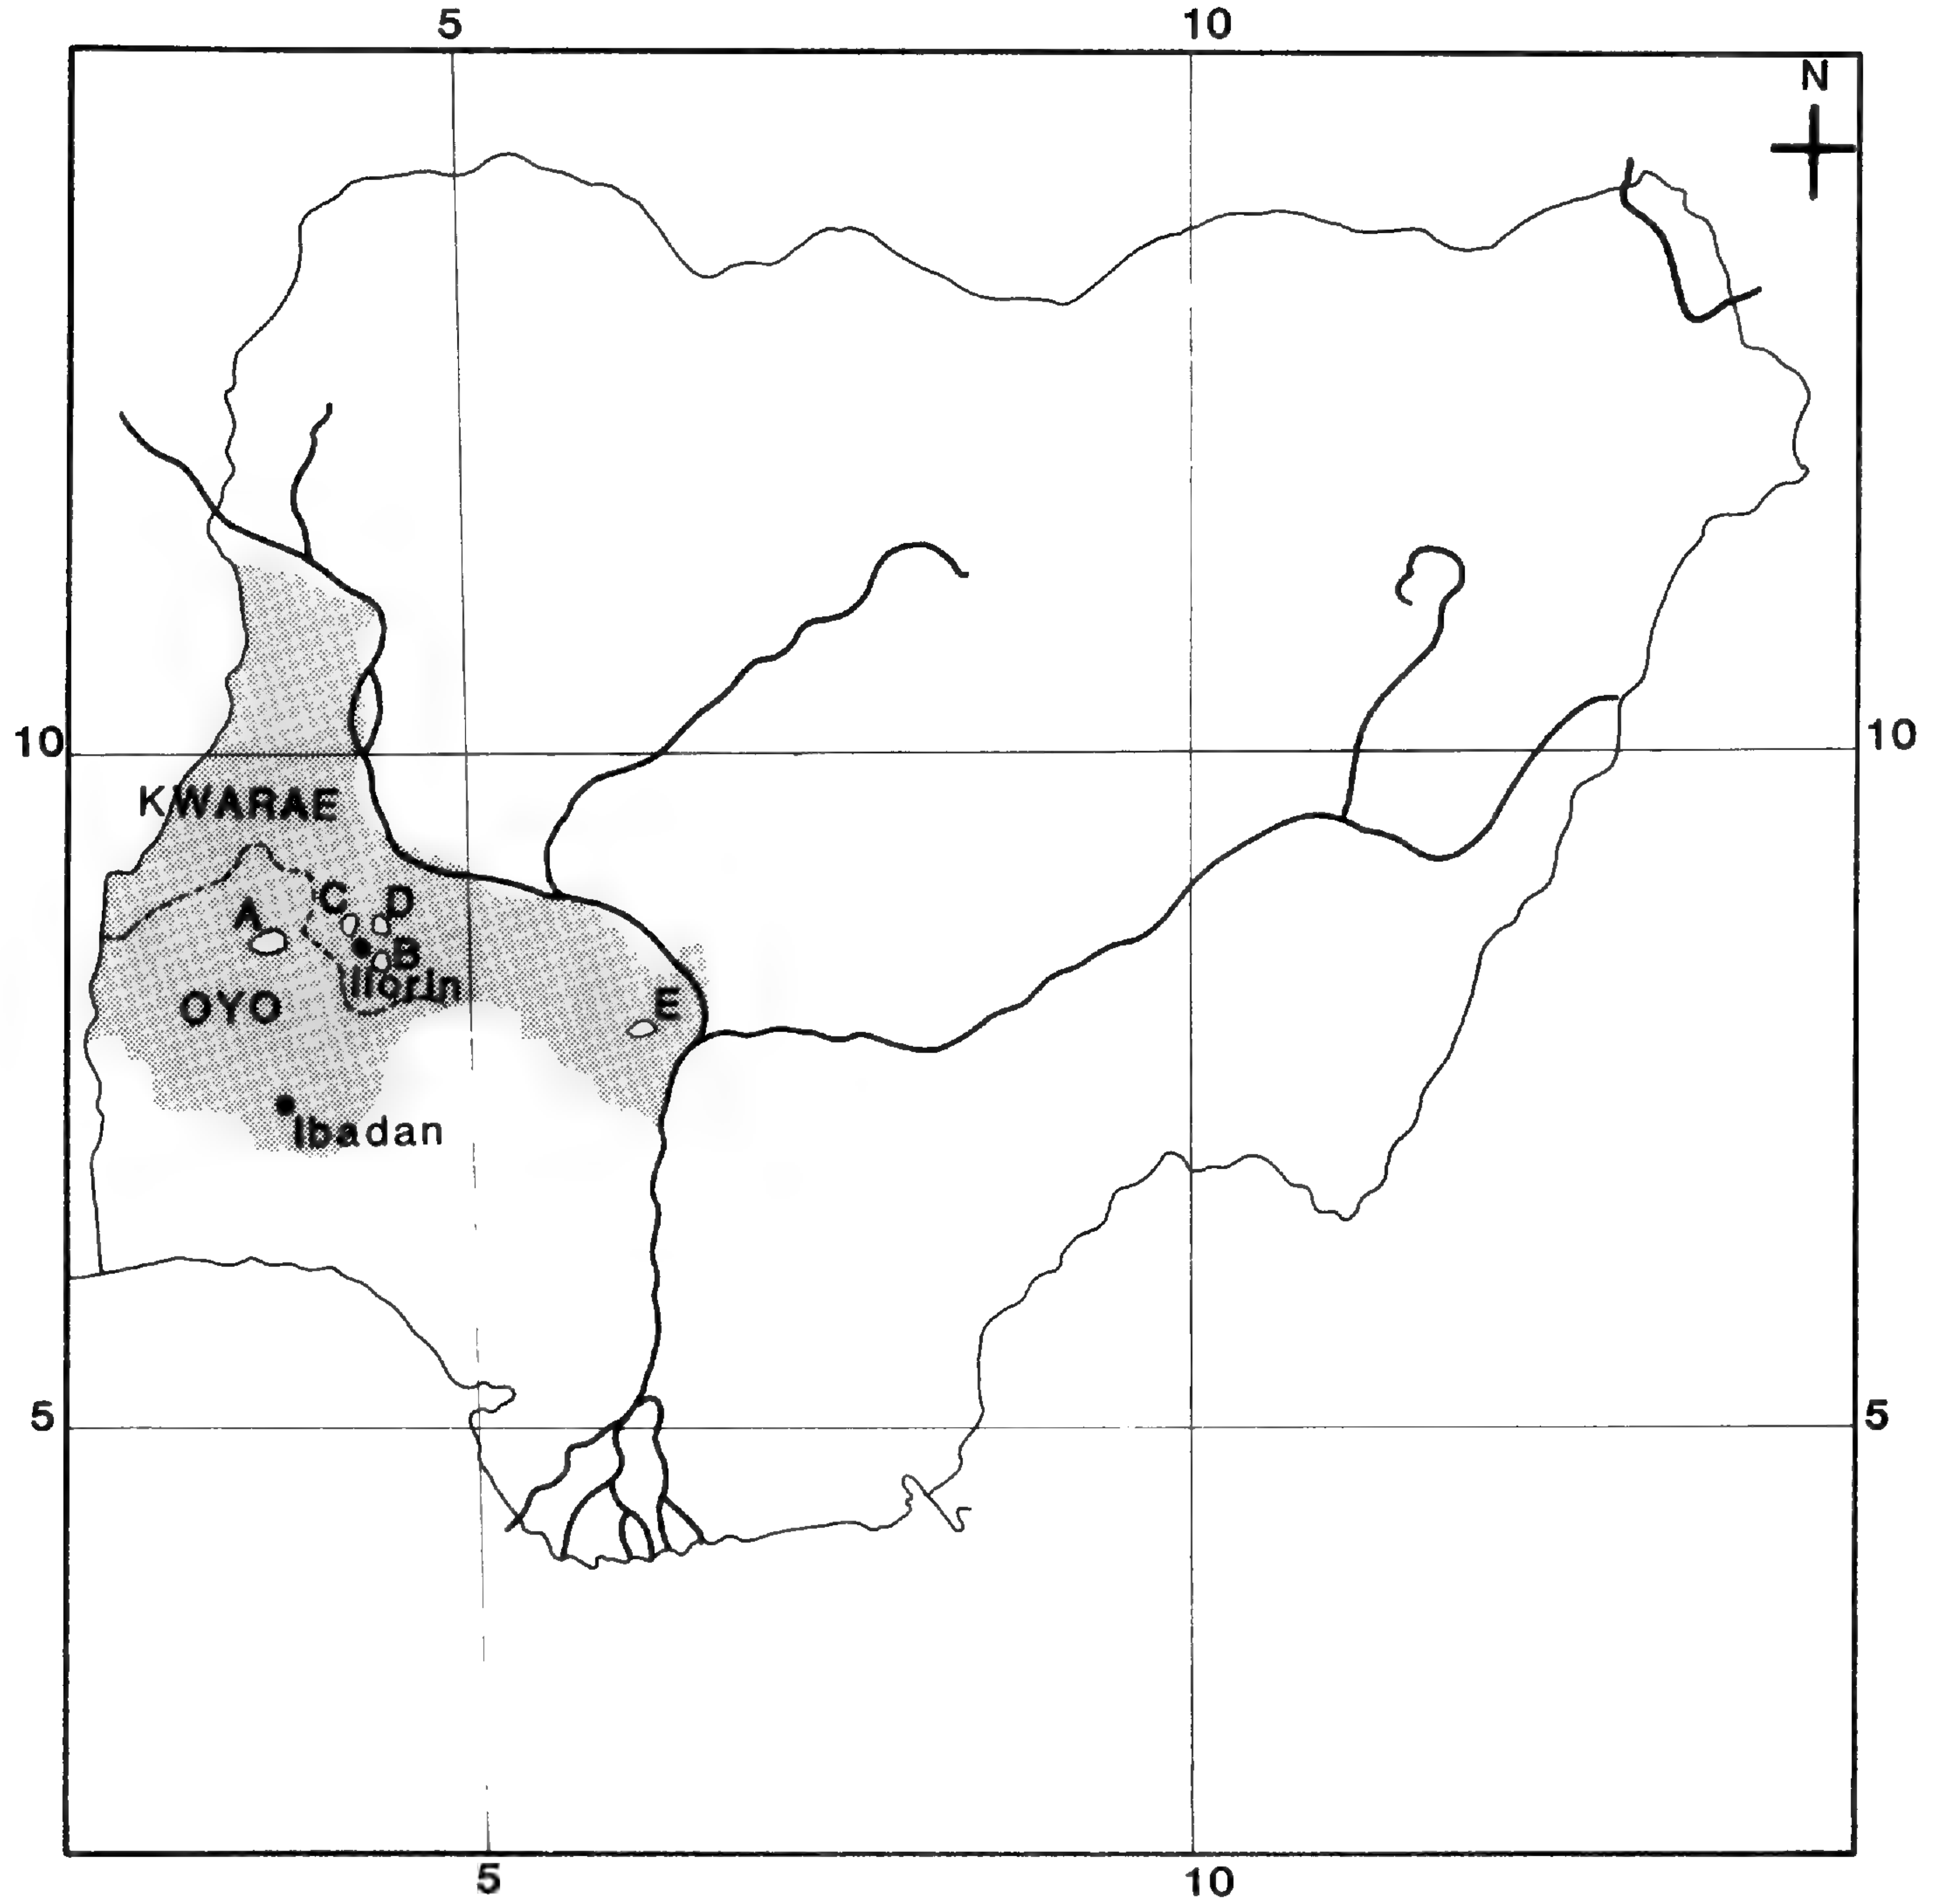

FIGURE 3. *Map of Nigeria showing locations where* Pancratium hirtum *populations were sampled in Oyo and Kwara States. Broken line = state boundary; circles = state capital city; solid lines = rivers.*

4E, 5E) consists of five pairs (1st, 2nd, 4th, 8th, and 11th) with median to submedian centromeres, and six pairs (3rd, 5th, 6th, 7th, 9th, and 10th) with terminal to subterminal centromeres. All the B-chromosomes are telocentric. One member of the second-longest autosomal pair has chromosome loss in the long arm, while one member of each of the eighth and ninth pairs shows loss in the short arm.

DISCUSSION

Previous chromosome counts in *Pancratium* show a chromosome number of $2n = 22$ (Ponnamma, 1978; Lakshmi, 1980). This number is confirmed here except that the presence of accessory chromosomes had not been reported previously in the genus.

The five karyotypes share a basic plan: the largest two and the smallest pairs of chromosomes are metacentric while all the others are acrocentric. Deviations from this plan consist of increase in the number of metacentrics (A, D, and E with an increase of one, two, and two pairs, respectively). Apart from these, there is evidence of structural changes in the chromosomes as a result of loss or gain of segments. This is common to all the karyo-

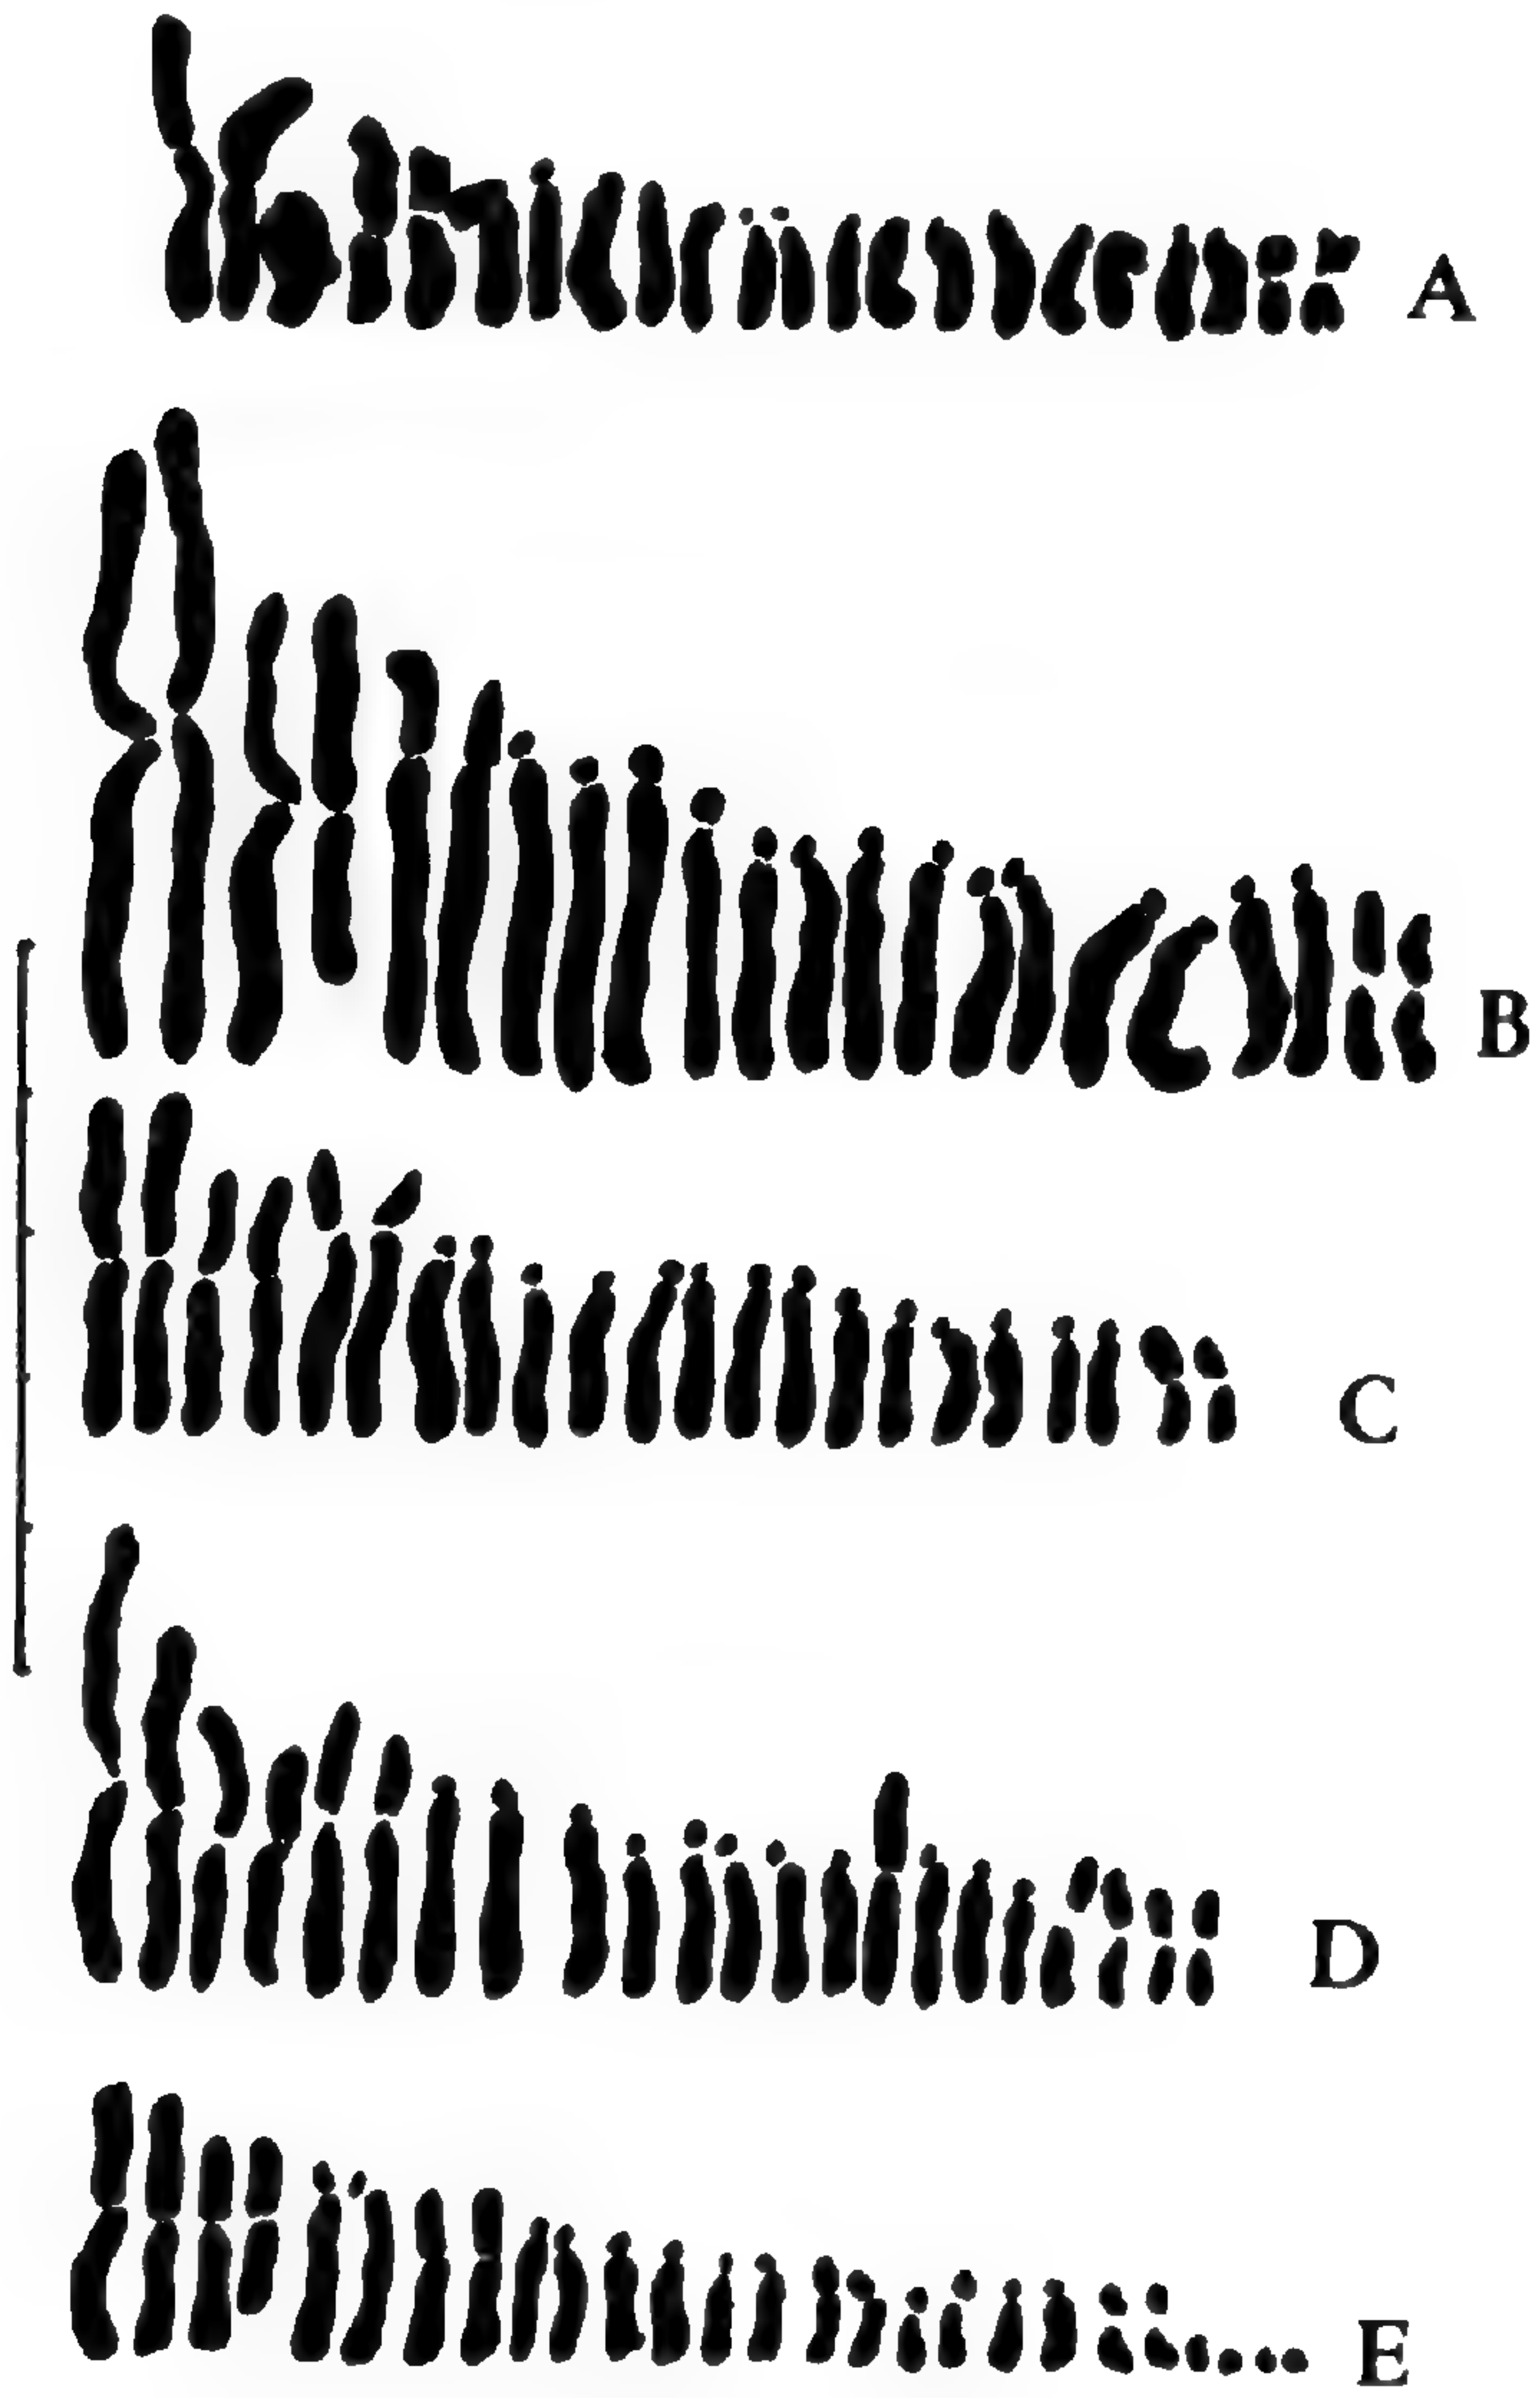

FIGURE 5. *Idiograms of the somatic chromosome complements of* Pancratium hirtum *morphotypes.*

types. Further deviation is the presence of B-chromosomes in E.

One way of generating genetic variation is by changes in chromosomal morphology, which are reflected in the karyomorphology of the population or the species (Coates, 1979; Coates & James, 1979). Another way is by genic changes that may not be immediately detectable (see Linhart et al., 1981). Thus, while genic changes may not be as immediately detectable as changes in the karyotype, karyotype variation may not be immediately accompanied by morphological divergence.

Karyotype variation in *P. hirtum* is associated with population differentiation and ecological preference. Dickinson & Antonovics (1973) maintained that karyotypic differentiation is a direct response of various biotypes to differing habitat pressures. White (1973) opined that chromosome rearrangements underlie reproductive isolation and, hence, speciation. It is probable that the ancestral population of *P. hirtum* in West Africa was at some time afflicted by some drastic environmental events that left survivors whose genetic systems suffered some changes. Such survivors occupied different ecological niches to which each had adapted for continued survival. Each has thus become ecologically isolated. Such a situation would be reinforced further by environmental barriers to long-distance pollen dispersal. The smallness of the population that would initially inhabit each ecological niche would enhance both chromosomal evolution and speciation, as asserted by Wright (1940), Bush et al. (1977), and Bengtsson (1980). These events would lead to reproductive isolation and thereby lay the foundation for further divergence of the population, culminating, in time, in the formation of several species. Again, the effects of the environment, especially edaphic factors, may be the major driving force in the karyotypic differentiation in this species. For instance, Morton's (1965) pl. 14, fig. 1 is similar to the karyotypes reported here, but it is not identical with any of them. All of Morton's materials were collected from Ghana. It is therefore possible that other karyotypes may still be encountered within the tropical West African region.

In conclusion, karyotype differentiation in *P. hirtum* has involved: (i) changes in chromosomal morphology resulting from loss or gain of chromosomal segments, which might have been accompanied by changes involving rearrangements of genes and/or gene blocks in inversions and translocations; and (ii) variations in the length of total chromatin material per somatic nucleus. Therefore, it seems likely that ecotype differentiation at the morphological level appears genetically fixed, and this is accompanied by varying degrees of karyotypic change, which presumably originated once the ecotypes had become established.

THE ARCHITECTURE OF INFLORESCENCES IN THE MYRTALES[1]

Focko Weberling[2]

In Memory of Dorothea Weberling,
April 25, 1928–February 2, 1988.

ABSTRACT

In the Myrtales a great variety of inflorescences are found. In some families such as Oliniaceae or Alzateaceae (formerly included into Lythraceae) the inflorescences are exclusively of the more primitive monotelic type. In others gradual transitions from the monotelic to the polytelic type can be observed. Within the Lythraceae the genera Lawsonia, Lagerstroemia, *and* Galpinia *and—if included as subfamilies—the Punicoideae and Sonneratioideae still represent the monotelic type, whereas in the majority of the genera polytelic inflorescences are found. These often show a botrytic ramification, although the basic type of ramification is a thyrse. Among the great diversity of forms the gradual specialization of a short shoot–long shoot system can be observed, especially in the genus* Ginorea. *The same can be seen within the Combretaceae, which are polytelic throughout. As in most Myrtales families, phylloscopic accessory buds or branches are frequently occurring and sometimes form a determinating factor for the shape of a flowering plant. In Onagraceae polytelic structure of inflorescences is also manifested throughout the family and florescences as botrya or spikes are known. On this basis an impressive diversity exists, especially in the variations of the proportions between the terminal main florescence and the extension of the enrichment zone, the number and size of paracladia, the length of the internodes, and the possibility of a reversion of the inflorescence apex to vegetative growth, commonly called proliferation. The latter often occurs in the inflorescences of Myrtaceae in which the "central type" and perhaps the phylogenetically primitive form is a monotelic thyrsoid or a panicle. Even in proliferating or in truncate synflorescences the monotelic character is evident by the fact that all paracladia, including those with more than one pair of flower-bearing branches, are provided with a terminal flower. The efforation of the proliferating inflorescence can be delayed for such a long time that the proliferating shoot may even form branches above the flower-bearing zone. Thus inflorescences of this shape sometimes were regarded as "intercalary inflorescences." In some cases (some species of* Eugenia*) the transition to the polytelic type seems to be complete. In the majority of the Penaeaceae the inflorescences forming thyrsoids or stachyoids follow the monotelic type. Some facultatively or constantly truncate synflorescences form a transition to taxa with polytelic synflorescences. In Psiloxylaceae the flower-bearing systems are brachyblasts reduced to their botrytic florescence and inserted on older axes. Variety of inflorescences in Melastomataceae corresponds to the size of the family but shows less diversity than Myrtaceae. The inflorescences are monotelic. Cases of complete transitions to polytelic structures were not found. Even truncation seems to be rare and only a single case is reported for* Medinilla magnifica. *On the other hand, proliferation is not rare.*

FUNDAMENTAL FEATURES OF INFLORESCENCE MORPHOLOGY

Since differences and conformities in the arrangement of flowers are characteristic for smaller or larger taxonomic groups, these criteria have been used in many ways since the very beginning of systematic botany. For this purpose an elaborate descriptive terminology is in use designating the different modes of foliation and especially of ramification by well-known terms such as raceme, spike, umbel, panicula, etc. Many efforts have been made to establish a natural system for the immense diversity of inflorescences. The results, however, remained insufficient, primarily because the empirical basis was too small. Above all, it does not follow that the flower-bearing parts

to which a term such as "spike," "umbel," or "dichasium" is applied are necessarily homologous. For that reason, one cannot achieve correct interpretation of the morphology of inflorescences by focusing exclusively on those flower-bearing ramification systems that by some conspicuous quality appear to be "units." One must also consider the position of these entities within the structural plan of the whole plant. Only in this way it is possible to ascertain which flower-bearing elements may legitimately be compared as identical structures. This, however, is connected with the elucidation of the structural plans of flowering plants and therefore needs a broad empirical basis. According to Troll (in Troll & Weber, 1955; Troll, 1964, 1969), the great diversity of inflorescences is due to the variation of two types only: the polytelic and the monotelic types.

In the *monotelic* inflorescence (Fig. 1 I), the apex of the inflorescence axis commonly ends with a *terminal flower*. This also applies to all the floral branches below the terminal flower. All of these branches, whether branched or not, are homologous elements, and they are all referred to by the term *paracladia* (pc; singular: paracladium), because these branches repeat the structure of the main axis of the flowering system. Accordingly, their ramifications are called paracladia of the second to n^{th} order. The whole area that produces flowering paracladia (Bereicherungstriebe, "enriching branches") may be designated as the *enrichment zone* (Bereicherungszone, "paracladial zone"). In the lower part of the flowering shoot this zone is commonly preceded by an *inhibition zone*, within which the development of paracladia is inhibited more or less abruptly (Figs. 1, 3 I). The same zonation can be recognized in the individual paracladia if these are not reduced in any way. In perennials the axillary buds at the base of the whole stem do not develop within the same season but will give rise to innovation shoots at the beginning of the following season. Therefore, this area has to be distinguished as an *innovation zone*.

In the *polytelic* type of inflorescence (Fig. 1 II), which is no less frequent in angiosperms, there is no terminal flower at the summit of the primary axis. The shoot apex remains *indefinite* after developing a smaller or greater number of lateral flowers, the last of which often do not complete their development but atrophy in the same way as the end of the axis. This apical flowering system, which is composed of lateral flowers only (or cymes, see below), is a characteristic feature of this type of inflorescence and is now referred to by the special term *florescence*. The term "florescence" should not be confused with the term "*in*florescence," which has no specified morphological signification and may be used to designate any flower-bearing ramification system. (The same applies to the term "partial *in*florescence," which can designate without any morphological relevance any part of a flowering system, while the term "partial florescence" means a distinct part of a florescence, namely a cymose branch.) Instead of ending in a single flower, as in the monotelic inflorescence, the floral axis here terminates in a multiflowered so-called polytelic florescence.

If the lateral flowers composing the florescences are provided with prophylls (Fig. 2 I), these may produce secondary flowers or dichasial or monochasial flowering systems from their axils (Fig. 2 II). This mode of ramification, in which the production of branches is restricted to the axils of prophylls of consecutive order, is called cymose (see Schimper, 1835; Wydler, 1851a: 305 ff.; Eichler, 1875: 34 ff., but not in the strict sense; Troll, 1957: 234 ff.; 1964: 63). The diverse sympodial ramification systems resulting from this mode of branching (Fig. 2 III–VI) are often briefly called cymes (cymae, see p. 231). In such cases the florescence consists of cymose *partial florescences* (pf) as, for example, in the inflorescences of most Scrophulariaceae and Labiatae (Fig. 3 III). Within both families, the derivation given here is verified by many transitional forms.

Below the florescence terminating the main axis there may be some branches that repeat the structure of the main stem by producing

FIGURE 1. *Diagrams of a (I) monotelic and (II) polytelic inflorescence. From Troll (in Troll & Weber, 1955), slightly modified.*

florescences themselves and that therefore are also called *paracladia.* Their florescences are termed *co-florescences* in order to distinguish them from the main florescence of the main axis. The apices of the co-florescences remain *indefinite* like those of the main florescence. Thus the whole flower-bearing ramification system appears as a system of florescences: a (polytelic) *synflorescence.* In the case of a monotelic inflorescence, the synflorescence consists of a terminal flower and (monotelic) paracladia.

Within the polytelic synflorescences, the same zonation can be observed as in monotelic flowering systems (Fig. 3 II, III): an *enrichment zone* (Bereicherungszone: Troll), which precedes the main florescence, an *inhibition zone* (Hemmungszone: Troll), and in perennials, an *innovation zone.* The three zones together form the so-called *hypotagma.* The florescence is separated from the paracladial zone by a *basal internode* (Grundinternodium: Troll), which may be of remarkable length.

It also proved to be useful to designate the ultimate internode preceding the terminal flower of a monotelic system by a special term: *final internode* (Grundinternodium, Fig. 1 I).

The polytelic type probably has been derived repeatedly from the monotelic during the evolution of angiosperms *by reduction of the terminal flower* and *specialization of the paracladia* of the monotelic system into either single lateral flowers or lateral cymes, which then constitute elements of the florescences, whereas the others are differentiated as par-

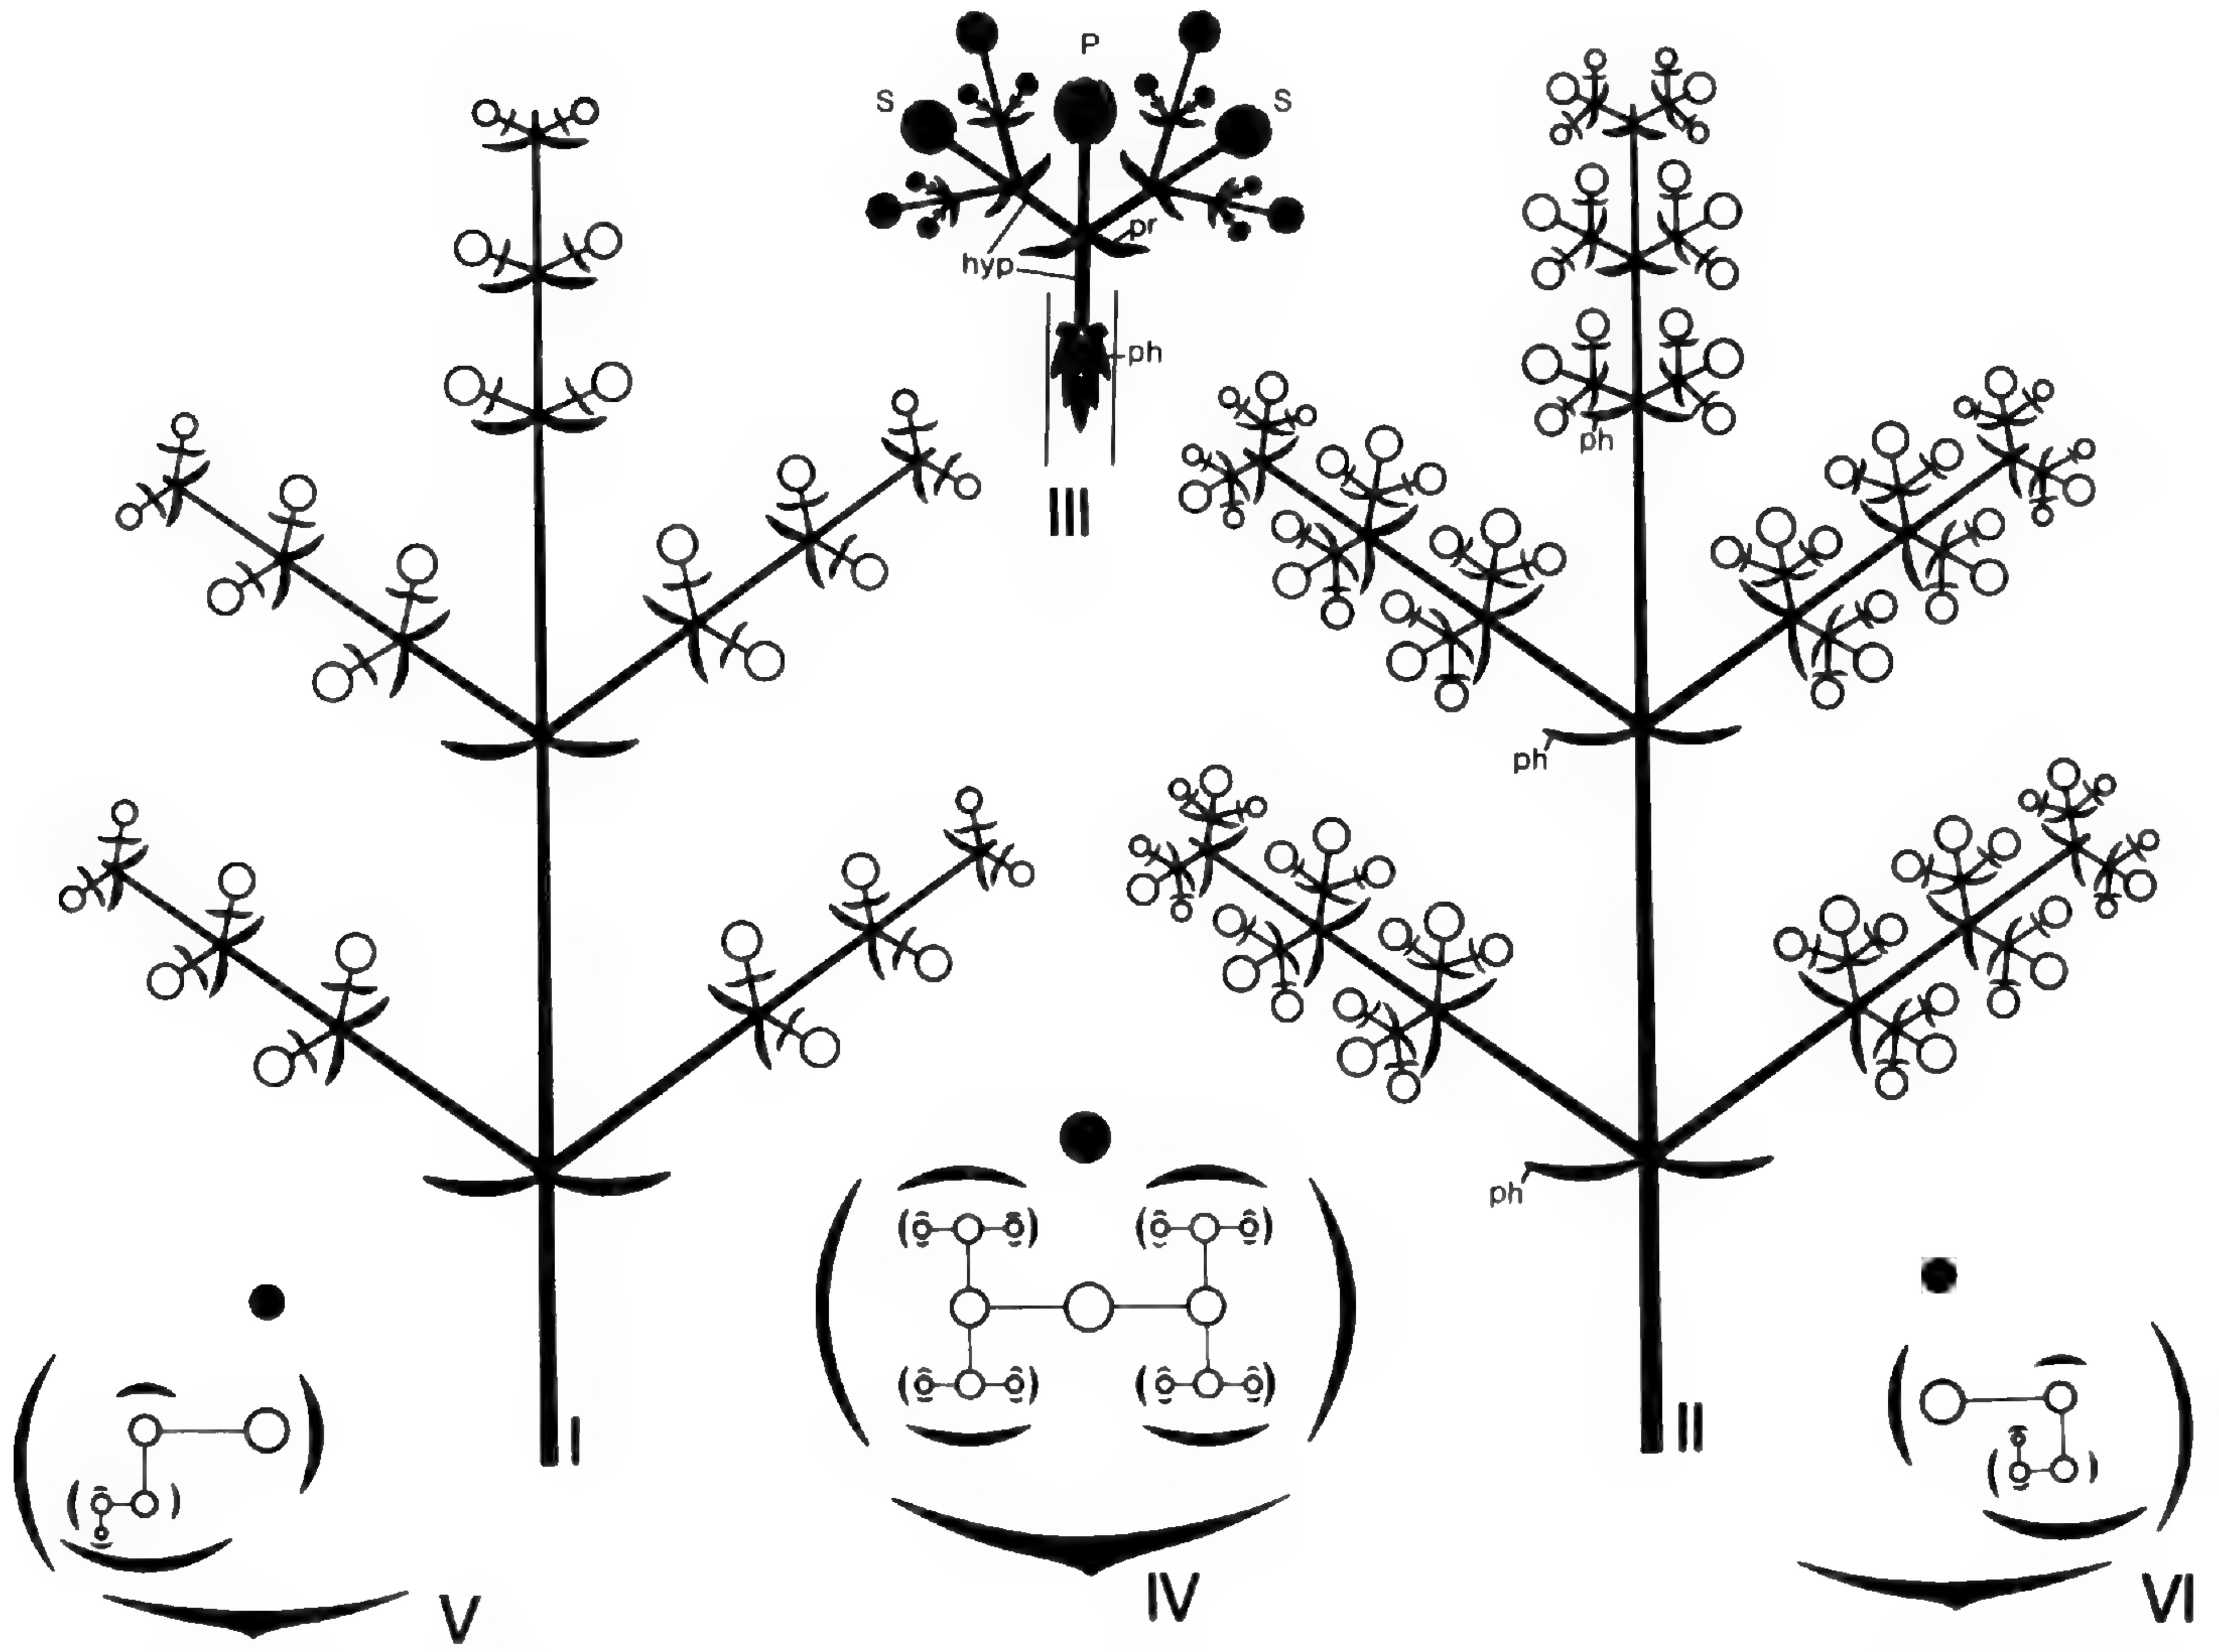

FIGURE 2. *I, II. Vertical diagrams of polytelic inflorescences.—I. Heterothetic diplobotrys.—II. acladia (of the polytelic type), which themselves form florescences (Weberling, 1961, 1965, 1983a, b; Troll & Weberling, 1966).

In both monotelic and polytelic types, the different elements may vary in many different quantitative respects according to the principle of variable proportions: in polytelic synflorescences, the main florescence may be extended and the number of its flowers may be increased in many ways, or it may be reduced or even be missing altogether (truncate polytelic synflorescences). In both cases the paracladia may be well developed or reduced, their number may be increased, or they may be missing or modified in different ways. The development of paracladia may be basitonic or acrotonic (see below). Variation also exists in the diversity of phyllotaxis and foliation, shortening or lengthening of the internodes in different parts of the plant, different intensity and different modes of ramification, and so on. Especially in woody plants the zonation of flowering systems can be altered extremely by, for example, the complete reduction of the inhibition zone.

An essential difference between the types seems to be that in inflorescences of the polytelic type the shoot apex of the inflorescence axis remains indeterminate. This also occurs, however, in some monotelic inflorescences in which the terminal flower aborts. In such *truncate monotelic synflorescences,* however, the paracladia usually end in terminal flowers, thus demonstrating the monotelic character of the whole system.

In many lianas, the growth of the main

axis is indefinite. Therefore the main axis, though it may produce lateral flower-bearing branches, never ends in a terminal flower. The sample applies to rosette geophytes with indefinite main axes, as in *Plantago* or *Phyllactis* (Valerianaceae). In the latter, the apex of the rosette changes periodically from the formation of absolutely sterile zones to the formation of fertile regions, in which thyrsoid "partial inflorescences" originate from the axils of the rosette leaves. (The same applies to the so-called *proliferating inflorescences* of many Myrtaceae.) In cases like these, the monotelic or polytelic character of the inflorescence is revealed by the monotelic or polytelic character of the paracladia.

Thus the question of whether the terms monotelic and polytelic correspond to the old classification of inflorescences into two groups called "indeterminate" (indefinite, racemose) and "determinate" (definite, cymose) must be answered in the negative. Apart from this answer, the statement given by Rickett (1955: 419), that "current usage" of this classification, "at least in English, is both confused and inaccurate," still refers to this classification in general. To a great extent this is due to the fact that the "cymose type" is often equated with an "overtopping" of the (somewhat sympodial) branching system (Rickett, 1955: 426; Goebel, 1931: 81 ff.).

However, it is neither necessary nor possible to renounce all the classical descriptive terms used for the description and distinction of flower-bearing ramification systems. Many of these terms can be used without any change, and some need to be clarified and specified in their application. This also has been done by Troll (1964: 33 f.), who partly referred to Eichler (1875: 34 f.) in his classification of descriptive terms, which may be repeated here:

I. *Simple inflorescences:* botrys (raceme), spike (stachys), spadix, umbella, capitulum.
II. *Complex (compound) inflorescences*
    a. with racemose partial inflorescences: diplobotrys (and related forms: bispica, bi-umbella, etc.), panicula.

b. with cymose partial inflorescences: thyrse (including thyrsoid), cymoid.

Among the compound inflorescences the panicle is distinguished by the main axis ending in a terminal flower (as do all of the branches). Thus the panicle is a determinate inflorescence, and this term never refers to any indeterminate inflorescence, as it often is used by English language authors.

If all branches of the panicle are reduced to single flowers (uniflorous paracladia), a botryslike system results that, however, still ends in a terminal flower and therefore is termed a "botryoid"; if the flowers are sessile, a spicoid. Complete reduction of all lateral flowers (all paracladia) leads to a uniflorous system (single terminal flower).

The term thyrse, which was often confused with the term panicle (Čelakovský, 1893: 45), needs some further comments too. (There is, of course, some connection between panicles and thyrsoids, as seen, e.g., in the so-called thyrso-paniculate systems of *Sambucus* and *Viburnum*: Troll & Weberling, 1966.) The term, used by Linnaeus for a "coarctate panicle of ovate form" (Rickett, 1955: 443), was specified by De Candolle (1827: 417) as "compound of small cymes along an axis of indefinite growth" (Rickett, 1955: 443; Bravais & Bravais, 1837: 197: "groupe de cimes disposées d'après l'évolution centripète comme les fleurs le sont dans l'épi"). It was applied, however, to determinate thyrsic branching systems as well (see Troll, 1964: 63 f.).

Briggs & Johnson (1979: 177, 247) restricted the term thyrse to a "blastotelic inflorescence with a multinodate main axis that bears lateral cymes"; thus a determinate thyrselike ramification system should be termed a thyrsoid (which appears consequent, as this term is comparable with terms such as botryoid, spicoid, cymoid in the terminology of Troll). Although we fear that a change of terminology used hitherto in so many publications might cause new confusion, we hesitantly follow this suggestion of Briggs & Johnson. Consequently, and in accordance with these authors, the adjective "thyrsoid" must be replaced by "thyrsoidal" (thyrsusartig), while the adjective thyrsic (thyrsisch) should be used now for a thyrse in the restricted sense.

The terms used here are illustrated by Figure 2 II–VI. The vertical diagram in Figure 2 II shows a diplo-thyrsic inflorescence. The distal part of it, comprising three pairs of lateral cymes, forms a simple thyrse (monothyrsus, haplothyrsus), whereas the branches originating from the two proximal nodes are thyrses themselves (named "Spezialthyrsen" by Troll, "special thyrses," infrathyrse). In this diagram, the lateral cymes are triadic, i.e., comprising three flowers only. They may, however, produce more flowers by continuous branching from the consecutive axes (Fig. 2 III). The characteristic trait of this mode of ramification is that each axis before ending in a terminal flower produces two and only two leaves: the *prophylls*, which are mostly transversal-opposite and identical with the prophylls (the first two leaves) of other branches. In monocotyledons there is frequently only one prophyll, often in adaxial position. The internode preceding the prophyllar node is the *hypopodium*, the internode following the prophyllar node and terminating in the flower is the *epipodium*. If the two prophylls are separated by another internode, this is called the *mesopodium*. From the axils of the prophylls of the primary flower arise branches that end in the secondary flowers and bear two prophylls of second order. From the axils of the prophylls of second order the ramification can continue in the same way. This mode of cymose ramification can result in a complete symmetrical dichasium as shown in Figure 2 IV. In many cases, however, the continuation of the ramification is limited at a certain stage to one of the two prophyllar axils, thus resulting in the formation of a monochasium, either a scorpioid cyme (cincinnus, Fig. 2 V) or a helicoid cyme (bostryx, Fig. 2 VI). In the monocotyledons a rhipidium or a drepanium can be formed.

In thyrsoidal inflorescences, as displayed in a great variety of forms within the Caryophyllaceae for example, a high degree of diversity can result from differences between paracladia in vigor of development. In many cases the paracladia are more extensively developed toward the base of the plant (*basitonic* ramification) or, if the paracladial zone is preceded by an inhibition zone, toward the middle of the plant (*basi-mesotonic*; in *mesotonic* ramification, vigor of the paracladia increases from both ends to the middle part of the flowering system), whereas in others the distal paracladia are the most vigorous (*acrotonic* ramification). Examples for these models can be found within the genus *Silene*.

In thyrsoids with decussate foliation and ramification (as in *Silene*), extreme acrotonic branching results in the exclusive development of the uppermost pair of cymose paracladia, which far overtop the main axis by vigorous development and copious branching. Such dichasia as represented, e.g., by *Silene vulgaris* (Moench) Garcke often have been regarded as ideal "cymose inflorescences." They are, however, connected by many transitional forms with basi-mesotonic thyrsoids as represented, e.g., by *Silene nutans* L. In other plants transitions can even appear in the same individual, if the subdistal pair of paracladia develops at a later stage. Thus these "dichasial" inflorescences do not represent an inflorescence type of their own but must be regarded as thyrsoids with acrotonic ramification. The complete inflorescence only simulates a cymose ramification, which actually takes place in the cymose paracladia. This induced Troll (1959a: 115; 1964: 102) to name this extreme form of an acrotonic thyrsoid a cymoid. In similar fashion, monochasial or pleiochasial overtopping of the main axis can be included in this term.

As is well known, foliation and phyllotaxis often change in the transition from the vegetative to the flower-bearing parts of a plant. The foliage leaves may be diminished from leaflike *frondose* to smaller *frondulose* organs or even convert by change of diverse proportions into *bracteose* organs (*bracts*), which are often more or less scalelike. The subtending leaves of the flower-bearing branches, the *pherophylls* (Briggs & Johnson, 1979: 179, 246; "Tragblatt," "Deckblatt"), may thus be frondose, frondulose, or bracteose.

The *mode of efflorescence* can, but need not be characteristic for the diverse forms of inflorescences. One should expect that anthesis of flowers follows the way of their initiation, advancing from, for example, the oldest flowers at the base of a botryoid to the top of this flowering system. In monotelic synflorescences, however, the terminal flower usually blooms before the neighboring laterals. To some extent this dominant position results from the fact that the organs of the terminal flower arise from the inflorescence apex immediately, whereas the lateral flowers are formed by lateral apices. Thus the terminal flower is somewhat in advance in relation to the ultimate lateral flowers. It is not rare for the flowers or partial inflorescences in the axils of the ultimate leaves preceding the terminal flower to be retarded or even to abort. Thus the terminal flower can be preceded by sterile leaves that are called "Zwischenblätter" (Nordhagen, 1937: 12; Troll, 1964: 15) or *metaxyphylls* (Briggs & Johnson, 1979: 179, 244). Beyond that, cases of a complete basipetal efflorescence—advancing from the top to the base of a flowering system—are not rare (*Meconopsis*). In the florescences of polytelic inflorescences, the efflorescence usually advances from base to apex (acropetal). For thyrses this means, of course, that an acropetal sequence of primary flowers that open first is followed and overlapped by a secondary sequence of the secondary flowers of the cymose partial florescences (Troll, 1957: 380 f.). There are also florescences with divergent effloration, the best known example may be *Dipsacus*. However, the sequence of paracladia in polytelic systems mostly unfolds in a basipetal order. Starting with the paracladia immediately below the main florescence, the progression of unfolding usually depends on the vigor of the individual and the length of the flowering period, thus determining the extension of the paracladial zone and the inhibition zone (Troll, 1950). Nevertheless, in annual or hapaxanthic plants this progression can reach the base of the plant, and the most basal paracladia can, if they are fully developed, be the most vigorous.

ONAGRACEAE

Polytelic structure of inflorescences is manifested throughout the Onagraceae. The florescences are botrya or spikes. Even when the pedicels remain undeveloped, the inflorescences frequently (e.g., *Oenothera biennis* L., Fig. 4) look like botrya, because pedicels are simulated by the long gynoecium of the epigynous flowers. In some taxa, e.g., *Epilobium alsinoides* Cunn. subsp. *tenuipes* (Hook. f.) Raven & Engelhorn, the pedicels lengthen after anthesis. Plants in the flowering state, as shown for the case of *Epilobium angustifolium* (Fig. 3 II), usually show a clear zonation: below the main florescences there is a more or less extended enrichment zone (paracladial zone, pz) which stretches down the primary axis until the development of paracladia is inhibited. Transition between this "inhibition zone" (inh.z., Hemmungszone) and the paracladial zone may be more or less abrupt. In perennials the axillary buds at the base of the whole stem do not develop within the same season but will give rise to innovation shoots at the beginning of the following season ("innovation zone," inn.z., Innovationszone).

Diversity in appearance of the different genera and species depends highly on quantitative variations of these zones, different lengths of the internodia, and different foliation of the florescences.

The phyllotaxis can be alternate or decussate, sometimes even verticillate mostly with three leaves at the same node. It is not rare to find that in the transition from the hypotagma to the main florescence the position of the leaves changes from decussate to alternate (e.g., *Epilobium montanum* L.).

The subtending leaves of the flowers can be quite different within the same genus. They can be bracteose as in *Fuchsia arborescens* Sims (Fig. 15 II) or foliaceous as in *Fuchsia magellanica* Lam. (Fig. 14), giving the inflorescence a "naked" or "leafy" shape. In many species of *Epilobium* or, for example, in *Oenothera biennis* (Fig. 4), they are leafy in the basal part of the florescences, diminishing distally, and finally becoming bracteose (frondo-bracteose foliation). Only in *Circaea* are the subtending leaves of the flowers missing. With the exception of the genus *Ludwigia*, the flowers do not bear prophylls.

Many representatives of the family are half-rosette plants, which means that the primary

FIGURE 4. *Onagraceae.* Oenothera biennis.—*Top, left. Flowering plant.—Top, center. The same plant with the flowers cut off to show the frondo-bracteose foliation.—Top, right. FIGURE 5. *Onagraceae.*—*I.* Oenothera rosea.—*II.* O. stricta.—*III.* O. fruticosa.

axis starts with the formation of a leafy rosette and continues its development with elongated internodes. In *Oenothera biennis*, *O. muricata* L., and some other species, the rosette leaves that develop during the first year of the biennial life cycle do not persist until the plant is flowering. This plant in full development shows a large main florescence, a preceding paracladial zone, and a long zone of inhibition. This basi-mesotonic support of ramification is shown for *O. biennis* in Figure 4. In vigorous plants of *O. biennis* the paracladia can develop strongly and in great number (Fig. 4). In species forming typical half-rosette plants, such as *O. indecora* Cambess., *O. rosea* L'Hér., and *O. stricta* Ledeb., the development of vigorous "rosette shoots" (Rosettentriebe) can be observed (Fig. 5). They form a second series of paracladia separated from the upper paracladia by the zone of inhibition.

Usually the extension and the stoutness of the p.z. depends on the vigor and age of the plants. In the annual *Camissonia scapioidea* (Torrey & A. Gray) Raven and *C. walkeri* (A. Nelson) Raven subsp. *tortilis* (Jepson) Raven, the paracladial zone can be extended over the whole elongated part of the main shoot, leaving no residuum of the zone of inhibition between the upper paracladia and the rosette shoots ("simple or branching from the base . . . the stems quite simple above," Abrams, 1951: 206). These plants show a pronounced basitonic support in the development of the paracladia and a scapelike prolonged internode that precedes the main florescence. Especially within the *Oenothera* alliance (in tribe Onagreae), the proportions of the main florescence, the paracladial zone, and the inhibition zone and the development of the internodes can be modified in different ways and can be very characteristic for some taxa. Sometimes, in *Camissonia cheiranthifolia* (Hornem. ex Sprengel) Raven, for example, the development of paracladia can be restricted to the basal rosette. The reason is often that this rosette comprises the whole hypotagma while the main florescence is the only part of the axis with elongated internodes. The early development of these basal paracladia is shown for *O. fruticosa* L. in Figure 5.

FIGURE 6. *Onagraceae.* Oenothera laciniata, *showing a small main florescence, a short inhibition zone, and vigorous rosette shoots. (USA. Texas: Brazos Co.,* N. Bean 331 *(M, as* O. sinuata*).)*

In some species, for example, *Oenothera laciniata* (L.) Hill (Fig. 6), *Camissonia hirtella* (Greene) Raven, and *Calylophus hartwegii* (Benth.) Raven, even the main florescence often or always remains relatively short and few flowered. In *O. caespitosa* Nutt., *Camissonia palmeri* (S. Watson) Raven, and many other species, the internodes of the primary axis, including the main florescence, are undeveloped throughout ("Caespitose perennial, acaulescent or nearly so," Abrams, 1951: 195). Among these species, *O. triloba* Nutt. (*O. rhizocarpa* Sprengel, *Lavauxia triloba* Spach), a hapaxanthic taprooted plant, is of special interest because of its basicarpous hygrochastic capsular fruits (Sernander, 1927: 73 ff.). In such cases the paracladia, however, can be well developed, forming plagiotropic (Figs. 7, 8) or ascendent branches with frondose (co-)florescences.

In other rosette plants, for example, *Camissonia graciliflora* (Hook. & Arn.) Raven (Fig. 15 III), even the paracladia, if developed, remain short, the whole plant forming a single rosette (also *Oenothera ovata* Nutt., *O. xylocarpa* Cav., *O. nana* Griseb., Figure 9, *C. tanacetifolia* (Torrey & A. Gray) Raven, Figure 10, *C. subacaulis* (Pursh) Raven, and *O. formosa* Brandegee), or a cespitose tuft.

In contrast to *Oenothera triloba*, which always retains its rosette stage, *O. macrocarpa* Nutt. subsp. *macrocarpa* (*O. missouriensis* Sims) is a perennial tap-rooted geophyte. After the juvenile rosette stage, it grows with slightly prolonged internodes and can develop innovation shoots, which can innovate secondarily. The same could possibly apply to *O. californica* (S. Watson) S. Watson, which Abrams (1951: 195) described as "perennial from underground rootstalks, rather coarse stemmed, rarely simple."

In the fruiting plant of *Oenothera triloba* (Fig. 8), the top of the primary axis is crowned by a bunch of foliage leaves as a result of the proliferating growth of the florescence axis. This proliferation may occur repeatedly in the same primary axis, thus forming zones with buds of paracladia alternating with single flowers in the axils of more or less foliaceous leaves. Proliferation can be observed in many additional species of *Oenothera*, for instance, *O. macrocarpa* and *O. biennis* (Fig. 4), and in many other members of the family, since the predisposition if frequently given by a strong florescence axis with more or less leafy pherophylls.

FIGURE 7. *Onagraceae.* Oenothera triloba. *(USA. Texas: Tarrant Co., Fort Worth,* A. Ruth 70 *(M).)*

In *O. triloba*, *O. macrocarpa*, and *O. biennis*, it is the apex of the main florescence that returns to vegetative growth (Spätprolifikation, Troll, 1960: 116, prolification of the florescence, retarded proliferation), whereas *O. multicaulis* Cav. (Figs. 11, 12) does not form a main florescence at all. Rather, it develops long paracladia from the axils of rosette leaves (Frühprolifikation), which can grow straight upright (Fig. 11) or more or less ascendent (Fig. 12).

In most herbaceous genera of Onagraceae the same architecture and zonation as described for the basi-mesotonic ramified *Epilobium angustifolium* (Fig. 3 II) and for *Oenothera biennis* (Fig. 4) can be observed. This applies to many species of *Epilobium* and all or most species of *Boisduvalia*, *Clarkia* (except species with decumbent or prostrate stems), *Gaura* and allied genera, *Lopezia*, and *Circaea*, although some species of *Boisduvalia*, e.g., *B. densiflora* (Lindley) S. Watson (Troll, posthumous notices), can be branched from the base.

Plagiotropic growth, often connected with proliferation, is also characteristic for *Clarkia*

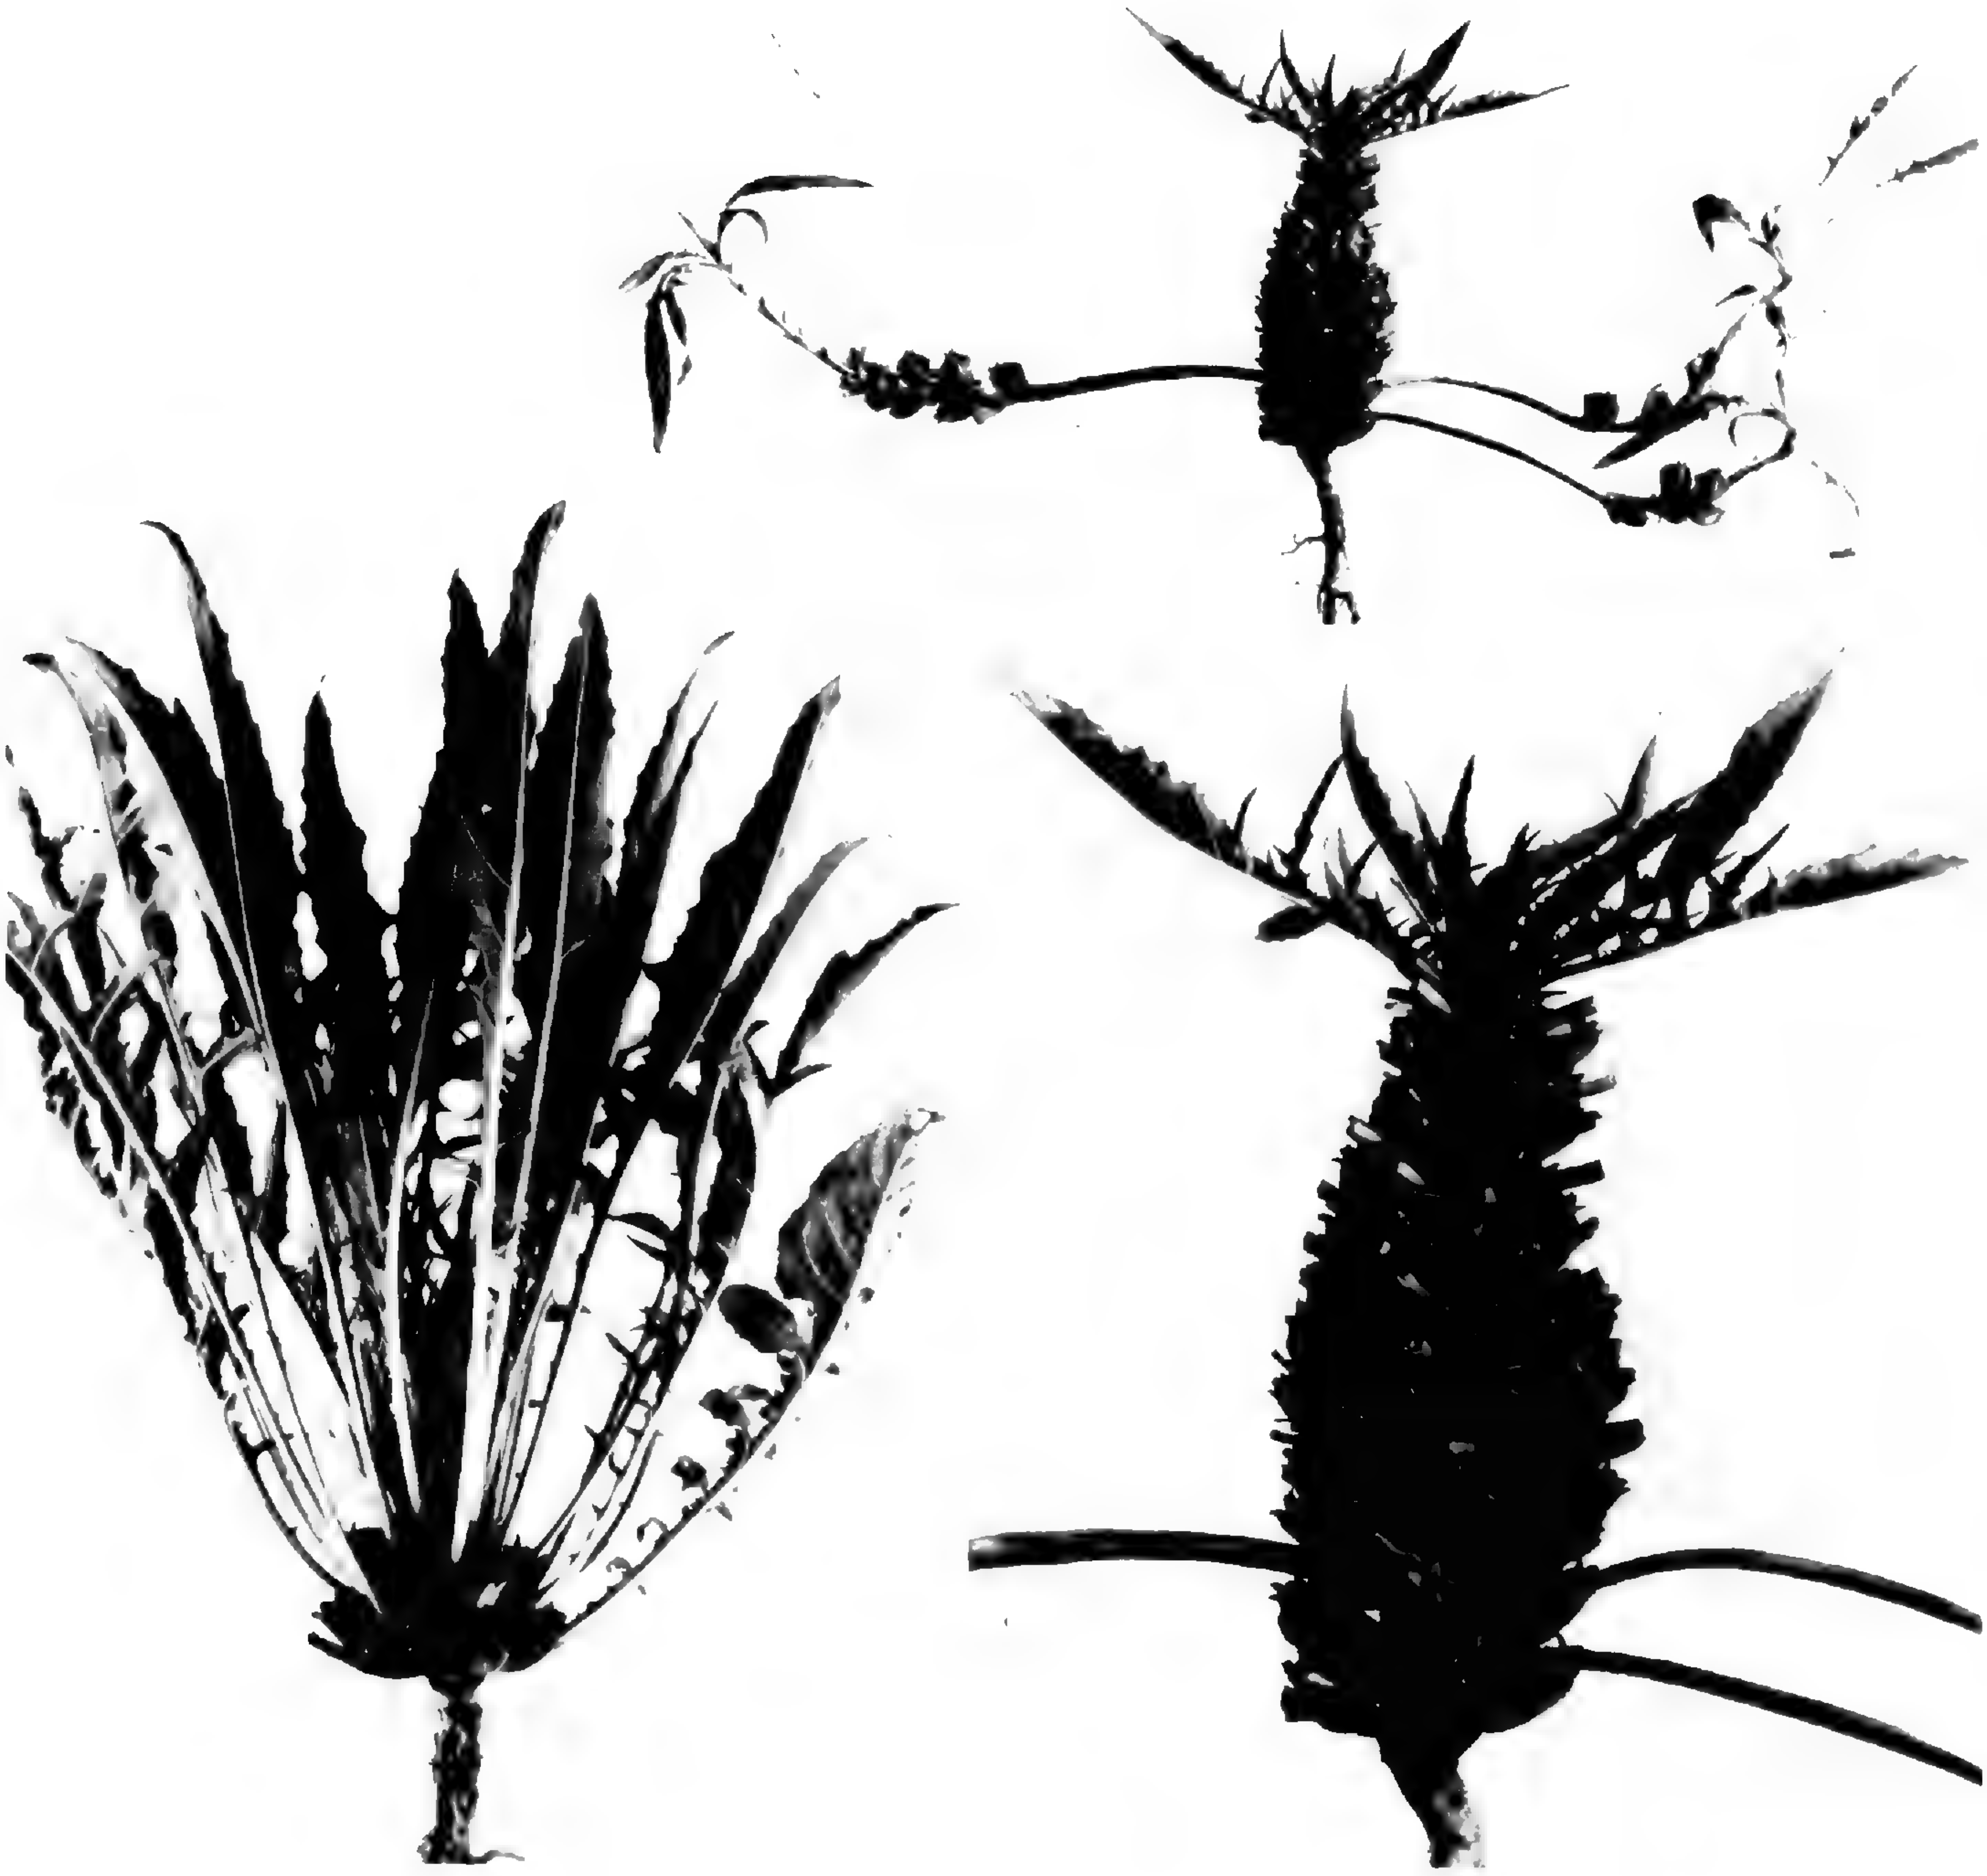

Figure 8. *Onagraceae.* Oenothera triloba.—*Left. Fruiting plant with proliferating main axis.—Top, right. Fruiting plant with terminal vegetative rosette and stolonlike fruiting and proliferating paracladia.—Bottom, right. Detail. (Original photographs from Troll.)*

prostrata Lewis & Lewis, *C. davyi* (Jeps.) Lewis & Lewis (Lewis & Lewis, 1955, fig. 11b, c), *Camissonia strigulosa* (Fischer & Meyer) Raven, and many species of *Ludwigia.*

Plants growing under severe environmental stresses may develop reduced inflorescences only. This is especially common in annuals. Often only the main florescence is formed, and in extreme but not uncommon cases only the lowermost flower of the main florescence comes to anthesis. *Clarkia bottae* (Spach) Lewis & Lewis (Fig. 13 I) is an example. In such cases this lowermost flower can be erected in pseudoterminal position, which also is characteristic for *Epilobium alpinum* L. f. *pusillum* Hausskn. The same occurs facultatively in *E. montanum* (Fig. 13 II).

For the genus *Epilobium* two features must be mentioned, each of them characteristic for a great number of species. In many species the buds of the innovation zone develop more or less proleptically into epigeal or subterranean stolons. If these stolons creep at the surface of the soil, their leaves are more or less foliaceous, as in *E. alpinum* L. The subterranean stolons bear scalelike cataphylls.

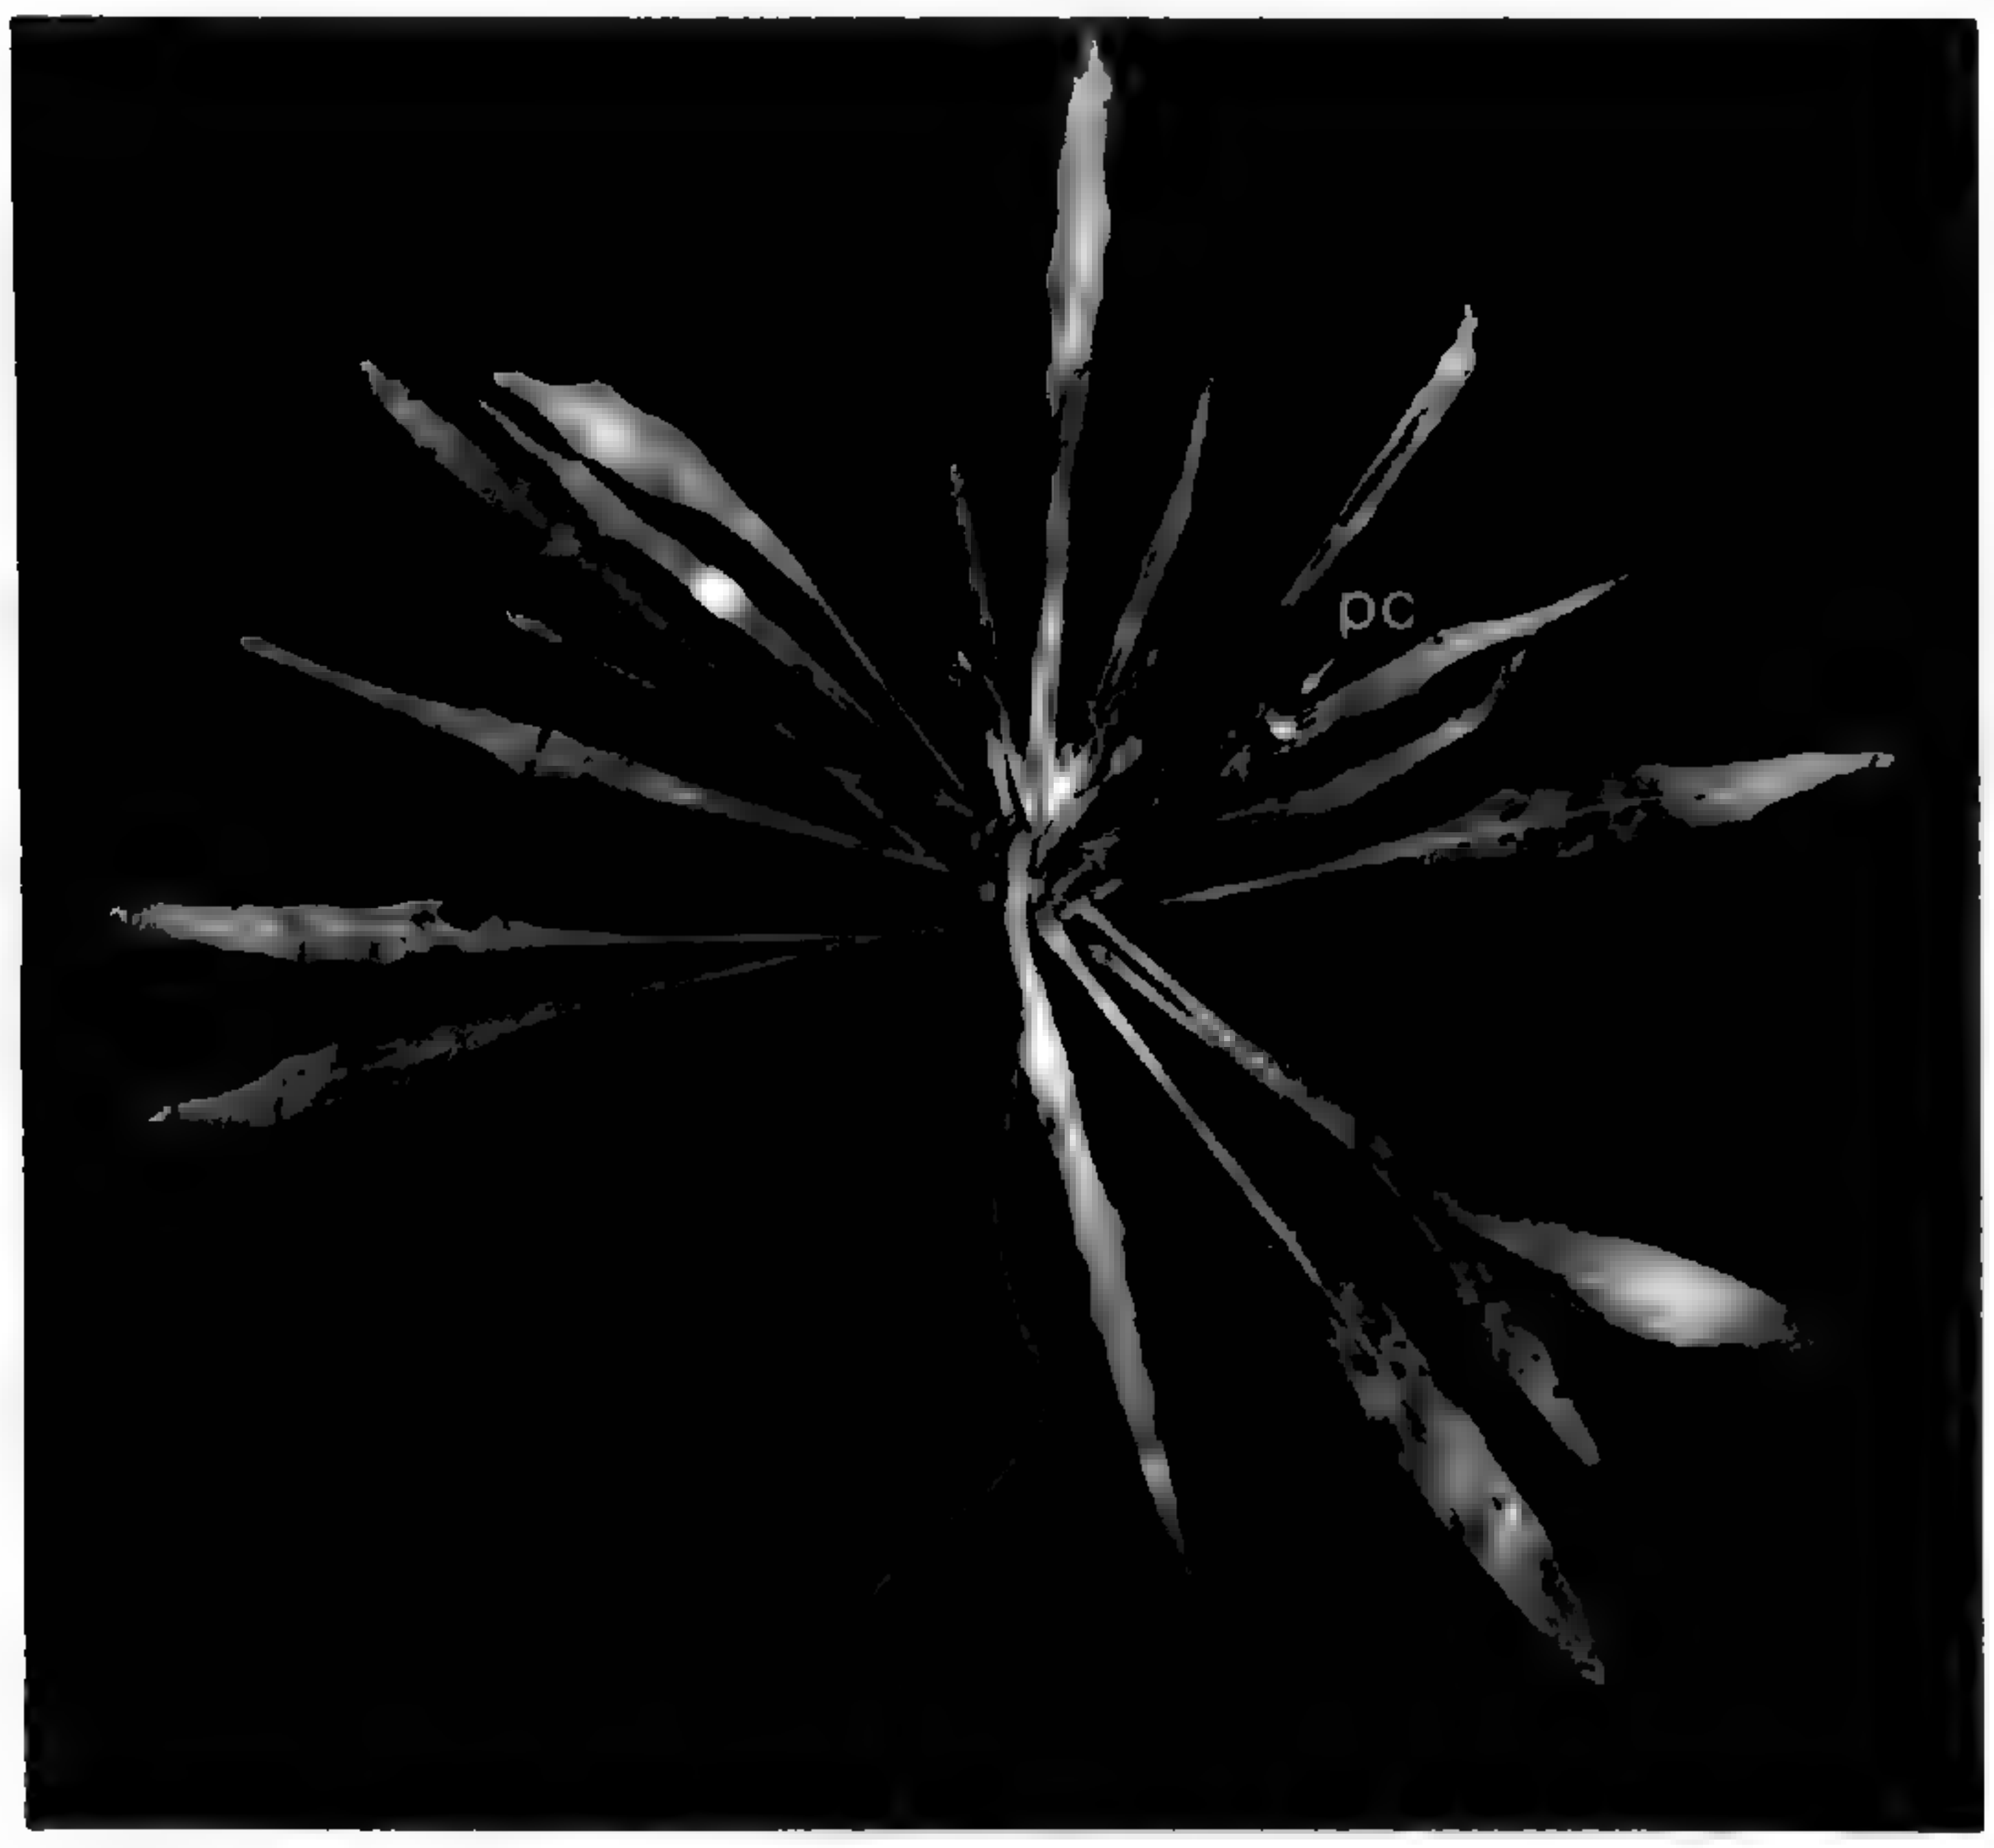

FIGURE 9. *Onagraceae.* Oenothera nana. *All internodes of the primary axis, including the main florescence, remain short; this also applies to the paracladia (pc). (Peru. Puno: above Chimu,* K. A. Santarius 2056/364 *(M).)*

FIGURE 10. *Onagraceae.* Camissonia tanacetifolia. *(USA. Washington: Spokane Co., July 1884,* Suksdorf s.n. *(M).)*

FIGURE 11. *Onagraceae.* Oenothera multicaulis. *Plant with rosette-leaved proliferating main shoot and flowering paracladia. (Peru: between Huancayo and Jarpa,* Müller 2345/75 *(M).)*

Their internodes may be very slender (*E. lineare* Muhlenb., *E. obscurum* Schreber) and often form small bulbs at their ends, especially well developed in *E. palustre* L. (Irmisch, 1847; Warming, 1918: 348; Troll, 1937: 811, fig. 639). In others the stolons are somewhat thickened, forming storage organs in this way (*E. hirsutum* L., Fig. 14). There are also many transitional forms between subterranean and epigeal stolons, which then develop foliaceous leaves in place of scales (*E. hirsutum*), and between stolon-forming innovation buds and those that remain short (the latter in *E. montanum*, *E. collinum* Gmelin, *E. roseum* Schreber, transitional in *E. parviflorum* Schreber, and *E. lanceolatum* Seb. & Mauri). In *E. palustre* there occur also transitional ascendent shoots with foliaceous leaves coming to flower in the same year as the main shoot and thus forming proleptical-

FIGURE 12. *Onagraceae.* Oenothera multicaulis. *Plant with proliferating main shoot with rosetted leaves and ascendent paracladia with co-florescences. (Peru: Huancayo.* Santarius 2204/717 *(M).)*

anthetical (see Müller-Doblies & Weberling, 1984) innovation shoots, while normally it takes until the next season for the stolonlike or short remaining innovation shoots to develop into a new flowering system. (For discussion of different modes of perennation in *Epilobium*, see Keating et al., 1982.)

A second peculiarity is especially characteristic for a number of species belonging to the series Similes, Microphyllae, and Sparsiflorae Hausskn., distributed in Australia, Tasmania, and New Zealand. These species show a more or less plagiotropic growth correlated with proliferation of the florescence apex, which seems to be a constant feature within the three series. "All of the leaves are opposite" (Raven & Raven, 1976: 15), and "the stem creeps and roots at the nodes, and continues growing vegetatively beyond the area where the flowers are produced." Thus the apex of the florescence regularly returns to a vegetative phase in which paracladia are developed and returns again to the production of a certain number of flowers. In *Epilobium nummulariifolium* R. Cunn., a node bearing a pair of flowers may be followed by two nodes with paracladia, but more frequently one of the axils of a pair of leaves produces a flower,

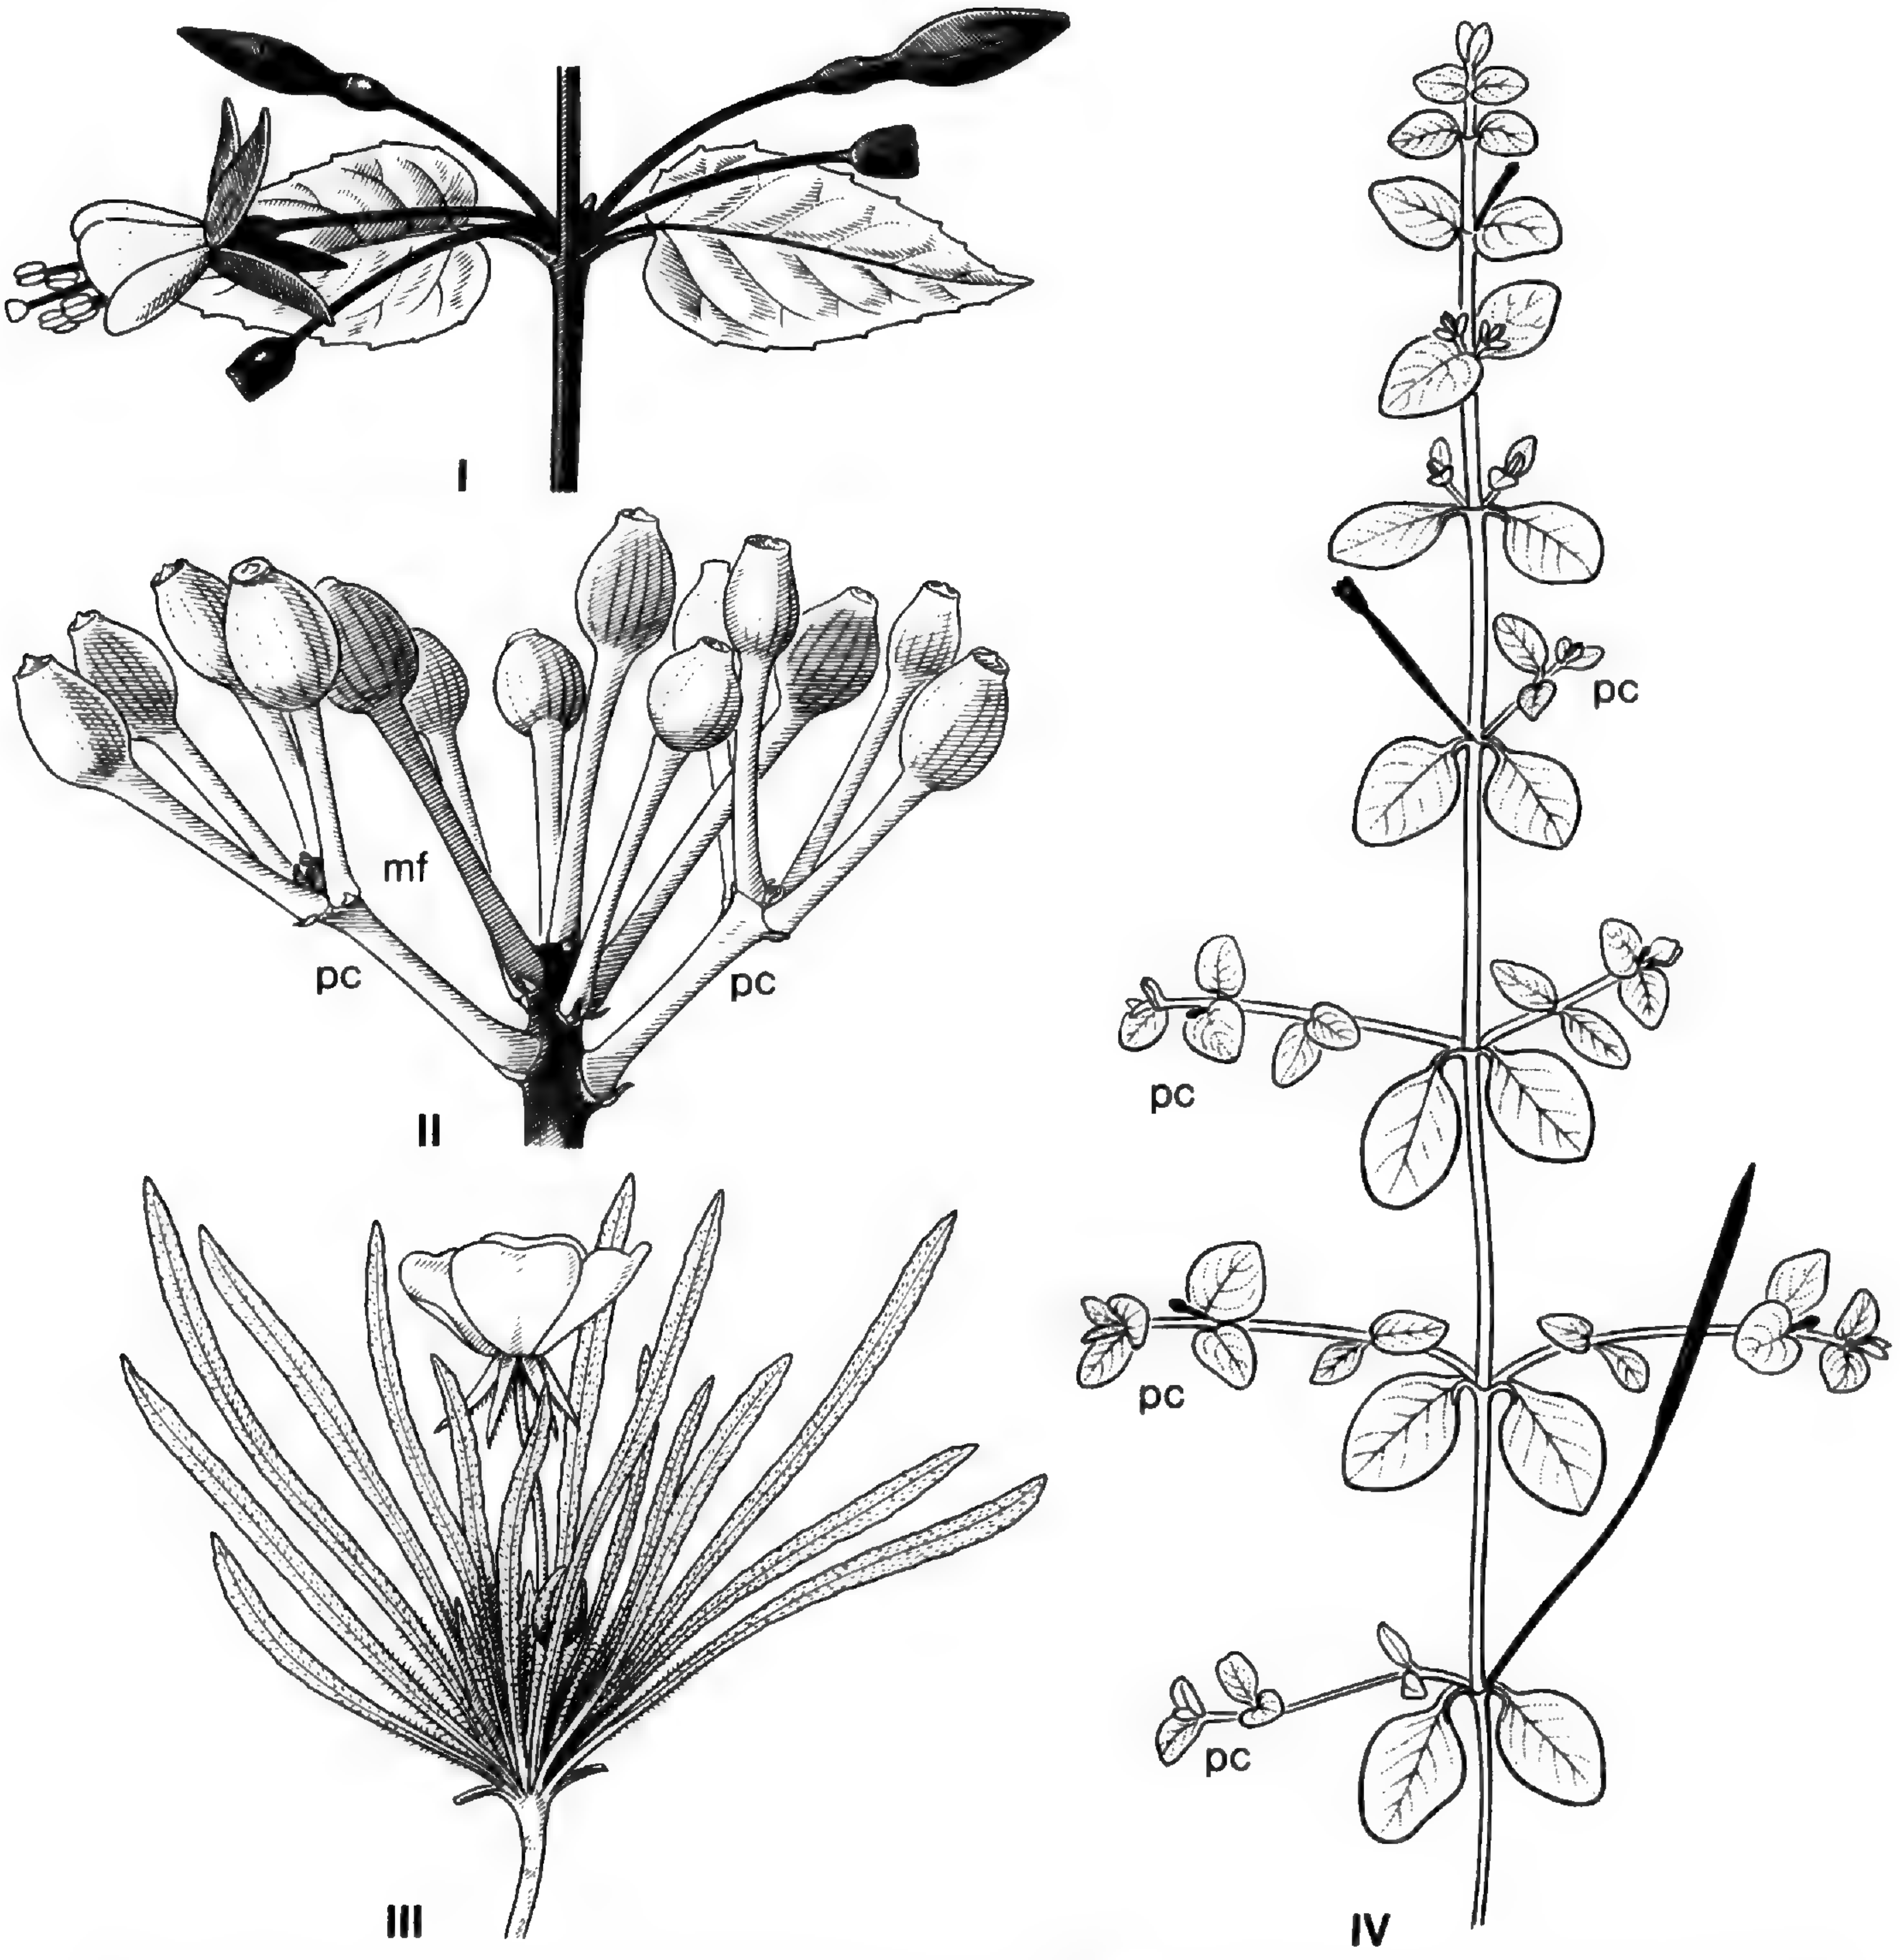

FIGURE 15. *Onagraceae.—I.* Fuchsia coccinea; *node of the florescence with regular and accessorial flowers.—II.* F. arborescens; *inflorescence with main florescence (mf) and paracladia (pc).—III.* Camissonia graciliflora; *habit (after J. W. Hook.).—IV.* Epilobium nummulariifolium. *(I, II, IV original drawings from Troll.)*

while the other one bears a paracladium (Fig. 15 IV). Troll (unpubl. notes) found the primary axis passing over to plagiotropic growth after the unfolding of the cotyledons. The axils of the cotyledons produced paracladia. According to Raven & Raven (1976: 15) this "habit has evolved independently on at least seven occasions among the Australasian species, as indicated by the morphological, genetic, and geographical relationships of the species involved: 1) *E. willisii*; 2) *E. macropus*; 3) *E. pedunculare*; 4) *E. crassum*; 5) *E. margaretiae*; 6) *E. brunnescens*, *E. pernitens*, *E. nerteroides*, and *E. nummulariifolium*; and 7) *E. komarovianum* and *E. angustum*. There is presumably an ecological solution as to why this peculiar plant form, unknown elsewhere in the world, should have evolved repeatedly in Australasia."

Within the genus *Ludwigia* (including *Jussieua)* one can find species that show the typical zonation as described for polytelic

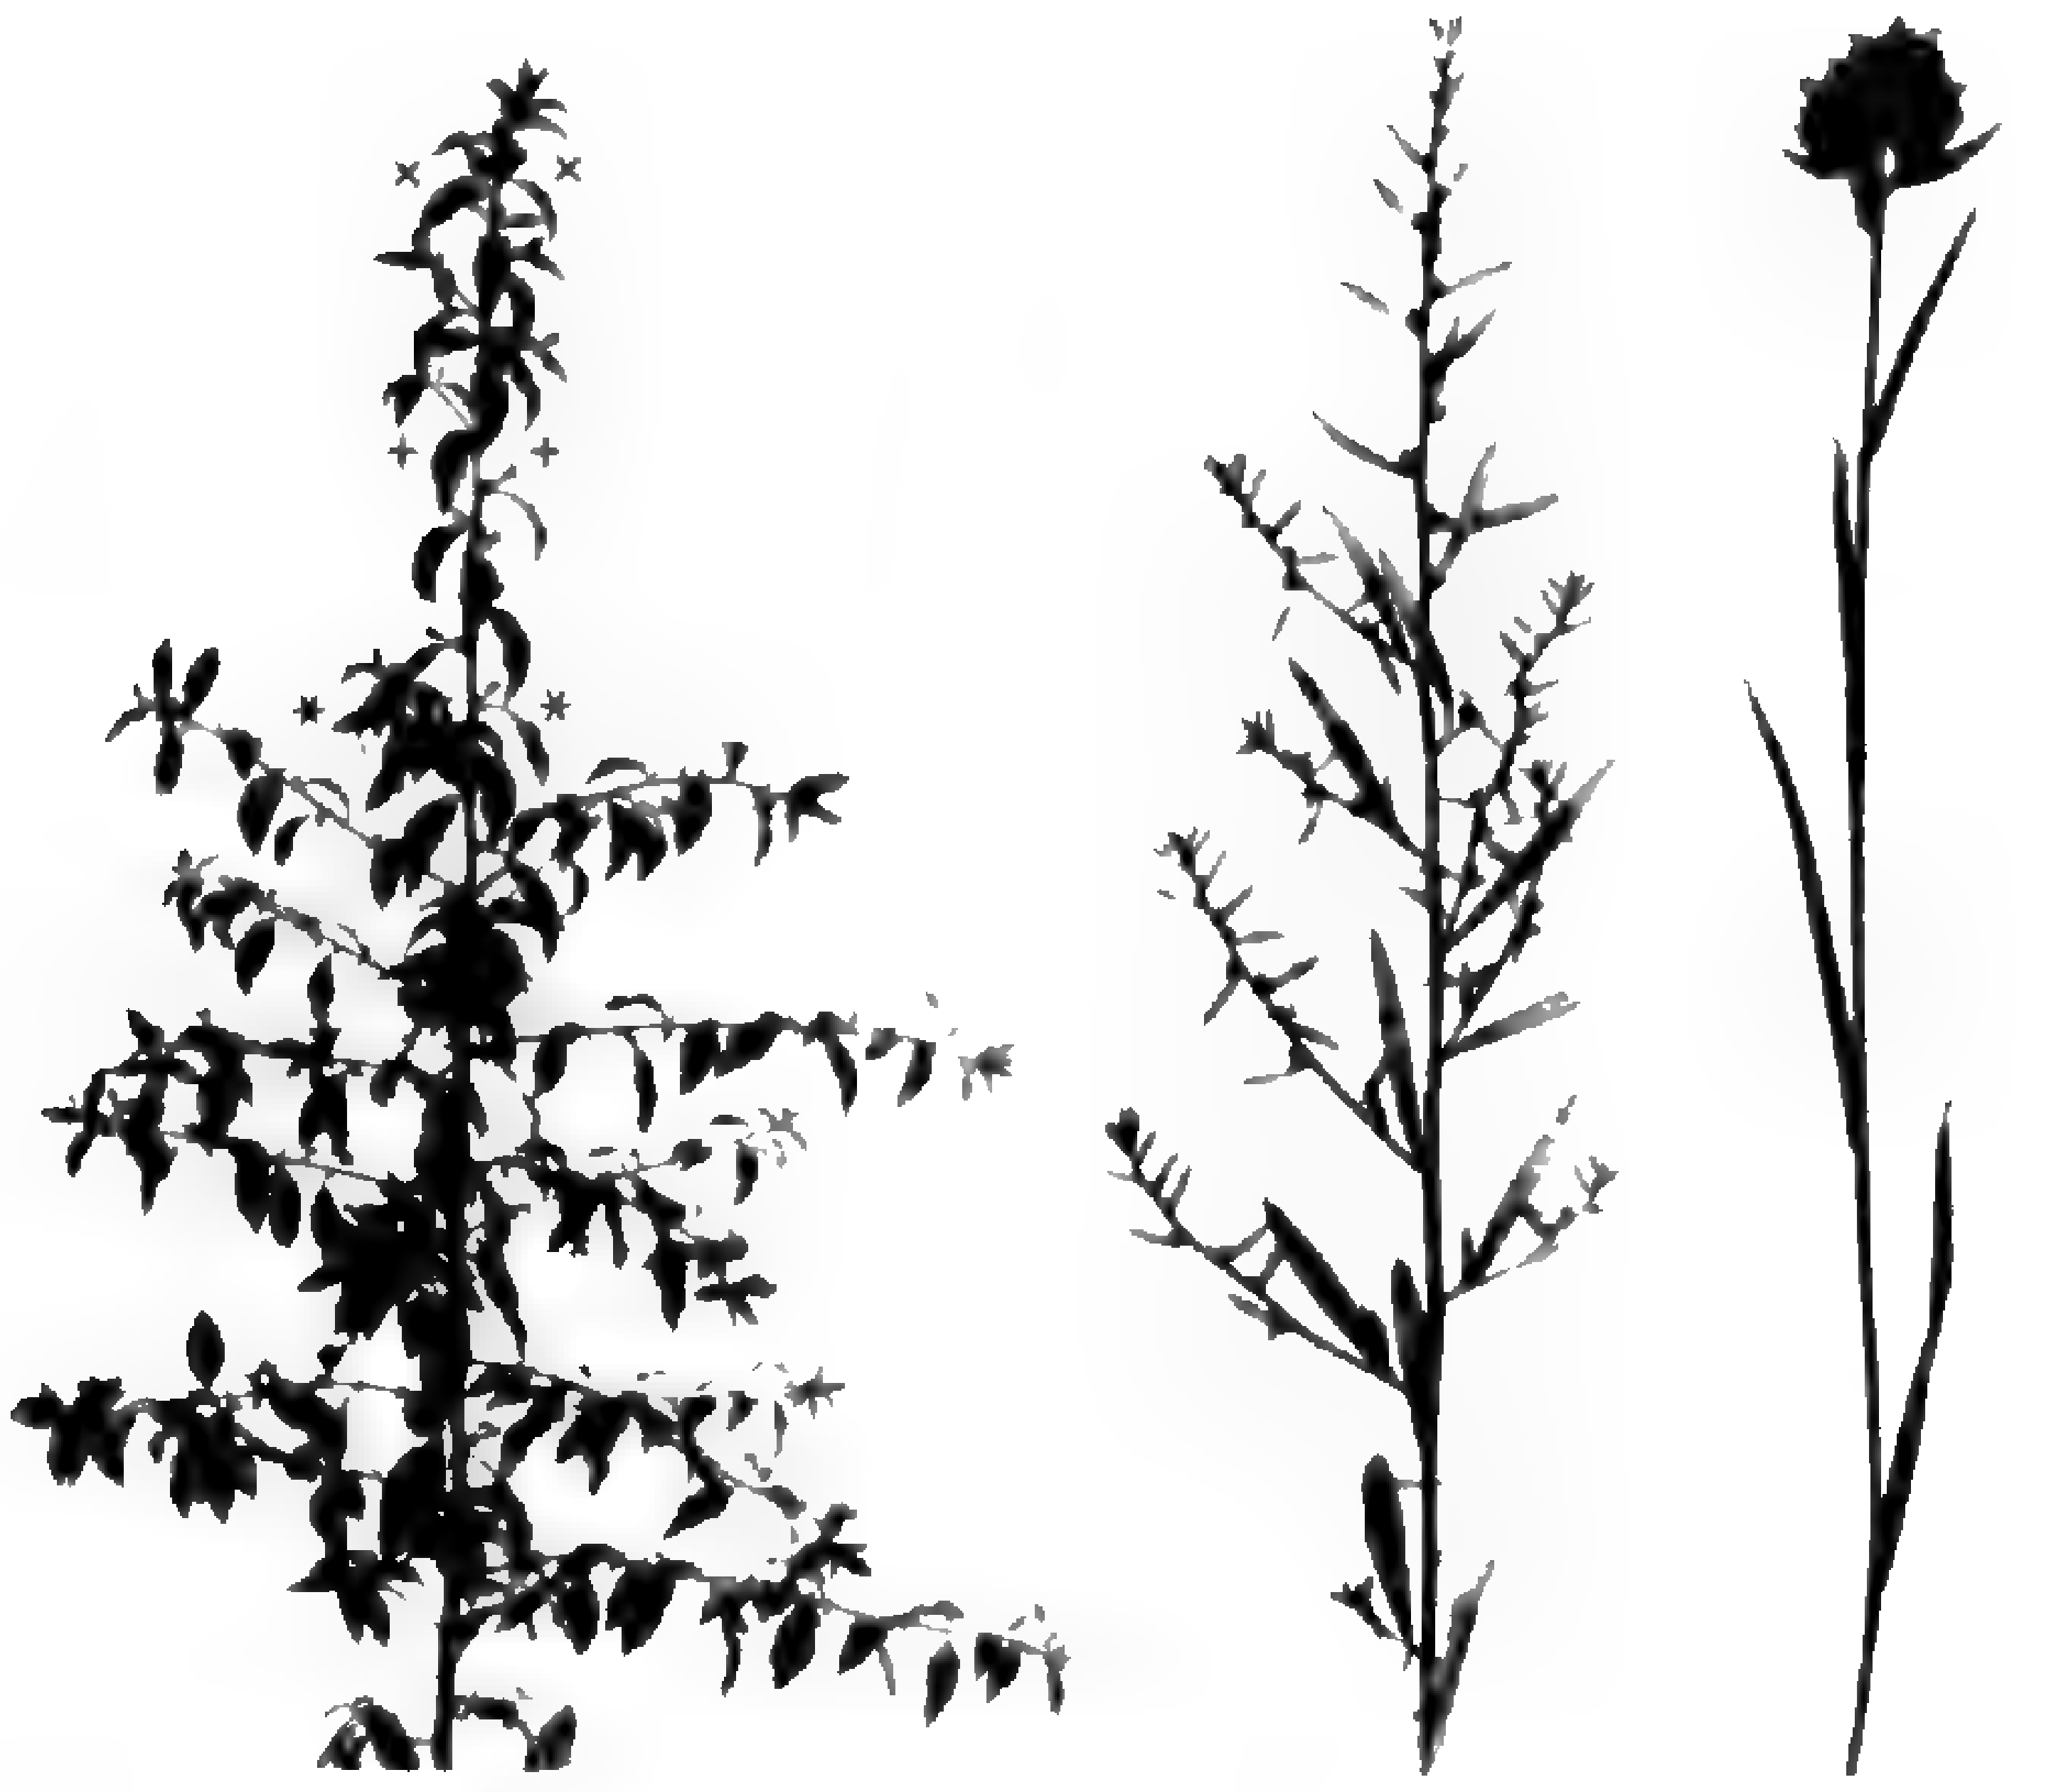

FIGURE 16. *Onagraceae.—Left.* Ludwigia suffruticosa.—*Center.* L. alata.—*Right.* L. octovalvis (L. capitata). *(Original photographs from Troll.)*

plants with botrytic florescences. *Ludwigia suffruticosa* (L.) Gomez serves as an example (Fig. 16). The main inflorescence is a frondose botrys. The same applies to the paracladia, which are preceded by an inhibition zone. Axoscopic accessorial buds can be observed accompanying the paracladia as well as the single flowers of the florescences. The apex of the inflorescence axis proliferates repeatedly: after having produced single lateral flowers forming the main florescence, it develops a paracladial zone and then returns to produce single flowers again. This zonation found in *L. octovalvis* is also found in *L. alata* Ell. (Fig. 16) and *L. perennis* L. In the latter the pherophylls within the florescences are somewhat smaller than in the preceding paracladial zone. Here the paracladia mostly comprise a co-florescence only, since the prophylls bear flowers in their axils already. The axoscopic accessorial buds within the florescence form small flower-bearing branches, while those that accompany the paracladia remain undeveloped.

In *Ludwigia virgata* Michaux, development of the paracladia usually is suppressed. The plants are extremely heterophyllous, bearing lanceolate leaves in the proximal part of the hypotagma and linear leaves in the distal part, whereas the foliation of the main florescence consists of small bractlike leaves. *Ludwigia octovalvis* (Jacq.) Raven resembles *L. virgata* in the suppression of the paracladia, but the flowers of the main florescence of *L. octovalis* (= *L. capitata* Michaux) usually are condensed into a head by suppression of internode development (Fig. 16). At the base of the plants, Troll (unpubl. notes) sometimes observed stolonlike innovation shoots.

FIGURE 17. *Trapaceae.* Trapa natans; *flowering rosette. (Deutsch-Mühlenweiher, Saarbrücken, 1904,* Ruppert s.n. *(M).)*

On the other hand, we could not find a main florescence in herbarium specimens of *Ludwigia abyssinica* A. Rich. The specimens investigated only had paracladia ending in a botrytic florescence, their foliation being bracteose in the upper paracladia and frondobracteose in the lower paracladia. If this preliminary result proves to be true, *L. abyssinica* has a truncate polytelic synflorescence.

Ludwigia palustris Ell. differs from the preceding species by having plagiotropic growth. The plant, which grows in stagnant or slow-flowing water or on muddy soil, develops roots from the nodes and different forms of leaves depending on ecological conditions. In these features *L. palustris* resembles species such as *L. helminthorrhiza* (Martius) Hara (*Jussieua natans* Humb. & Bonpl.) and *L. adscendens* (L.) Hara (*J. repens* L.), which are well known for peculiar respiratory roots that develop at the nodes in addition to normal roots. They also show a more or less pronounced heterophylly. Here again the inflorescence apex regularly proliferates and returns to flower formation. In *L. peduncularis* (Wright ex Griseb.) Gomez (*L. clavellina*) a pair of flowers often is followed by a pair of paracladia. In the picture of *L. helminthorrhiza* given by Humboldt & Bonpland (1805, t. 3, under *Jussieua natans*), each flower is accompanied by a vegetative accessorial branch.

The most interesting species of *Ludwigia* is *L. sedoides* (Kunth) Hara, an aquatic herb in which the branches end in floating rosettes. The rosettes are formed by alternate leaves that gradually differ in the length of their petioles, thus forming a configuration similar to a rosette window.

Usually the flowers are described as solitary in the axils of the foliage leaves. Actually they all form a botrytic main florescence which proliferates, however, after the formation of only a few flowers, forming a vegetative flowerless zone and then returns to flower production. Thus the flower-bearing zones are interrupted by vegetative zones. Paracladia that repeat the architecture of the main shoot seem to develop rarely only from the more remote parts of the stem.

In all of these respects *Ludwigia sedoides* is completely congruent with *Trapa natans* L., Trapaceae (Fig. 17). The submerged leaves of *Trapa*, however, are pinnatifid and thus differ from the floating leaves that have a rhombic lamina and somewhat inflated petioles, which keep the rosette floating.

In the ligneous (*Fuchsia, Hauya*) or suffruticose Onagraceae, the architecture of the inflorescences does not differ fundamentally from that of the herbaceous genera.

In *Fuchsia* the diversity of inflorescences mainly depends on differences of foliation, development of the internodes, and degree of ramification within the flower-bearing parts. As was shown already, the difference between the bracteose and the leafy character of the pherophylls (Figs. 14, 15 II) has a great effect on the appearance of the plants. In *F. magellanica* the leafy botrytic florescences proliferate frequently and often repeatedly, giving the impression that there are "flowers solitary in the axils of leaves." From the vegetative zones of the "interrupted florescences" paracladia can develop. Accessorial flowers can occur in a phylloscopic sequence (Fig. 15 I). Quite a different impression is given by the botrytic florescences of *F. triphylla* L., *F. coccinea* Sol., and *F. fulgens* Mociño & Sessé (see Raimann, 1893b, fig. 94A), the foliation of which is bracteose or frondo-bracteose. In *F. boliviana* Carr. the pendant botrytic frondo-bracteose main florescence and co-florescences are hanging by the inclination of their prolonged basal internodes, while the flower-bearing zone is more or less condensed (Fig. 18). The bracteose inflorescence terminating the foliaceous shoots of *F. arborescens* Sims (Fig. 18) is often called a panicle but comprises a botrytic main florescence and a smaller or greater number of paracladia, which are restricted to their coflorescences. The inflorescences of *Hauya elegans* DC. subsp. *cornuta* (Hemsley) Breedlove & Raven is a leafy proliferating few-flowered spike. Although the structure of the inflorescences within the woody Onagraceae seems to be clear, the position of the flower-bearing branches within the whole ramification system should be examined in comparative investigations regarding the different growth forms of the ligneous plants.

LYTHRACEAE

The diverse forms of ramification found in the inflorescences of Lythraceae have been carefully investigated and described by Koehne (1883). Thus we only need to treat some new fundamental and comparative aspects here. The phyllotaxis is usually decussate, rarely alternate; sometimes verticils with three or many (e.g., species of *Rotala*) leaves are formed. With some exceptions (*Cuphea* sect. *Lythrocuphea* and some other species) prophylls are nearly always present within the inflorescences. Eichler (1878b: 478) named as the only exceptions *Cuphea* subgen. *Cuphea* (subgen. *Lythrocuphea* Koehne) and the secondary flowers within the cymes of *Lythrum* species.

FIGURE 18. *Onagraceae. Inflorescences of* Fuchsia arborescens *(left) and* F. boliviana *(right). (Original photographs from Troll.)*

Within the family only the genera *Galpinia*, *Lagerstroemia*, *Lawsonia*, *Rhynchocalyx* (now treated as Rhynchocalycaceae), and *Woodfordia* are characterized by monotelic inflorescences.

The inflorescence of the ligneous *Lagerstroemia indica* L. (Figs. 19 I, 20 I) is a diplothyrsoid (a diplothyrse with terminal flower) with three- to seven-flowered cymes. A remarkable feature of this inflorescence is that effloration takes place from base to top, though the terminal flower of the whole system precedes the neighboring lateral ones. The same applies to the terminal flowers of the thyrsoid paracladia in the proximal part of the inflorescence. Correlated with this mode of effloration is the delay in the formation of the ultimate lateral flowers below the terminal flower, which can be more or less impeded (Fig. 20 Ia). In case of complete reduction of the uppermost paracladia their subtending bracts appear as metaxyphylls.

Generally *Lagerstroemia tomentosa* Presl shows the same mode of ramification as *L. indica*. In *L. calyculata* Kurz, *L. hypoleuca* Kurz, and *L. speciosa* Pers., however, the distal part of the inflorescence bears a considerable number of uniflorous paracladia forming a botryoidlike zone. This also occurs in the thyrsoid paracladia at the base of the inflorescence, which apparently are more numerous and vigorously developed in these species. In any case, a careful comparative examination of the inflorescences of the numerous species of this genus is needed in order to find out if the peculiarities mentioned here are useful for diagnostic and systematic aims.

The mode of effloration found in *Lagerstroemia indica* can also be observed in *Lawsonia inermis* L. (Fig. 19 II), which differs from *L. indica* in that the ramification of the cymes does not exceed the three-flowered stage (Fig. 20 II). On the other hand, the number of flowers of the inflorescence fre-

FIGURE 19. *Lythraceae.—I.* Lagerstroemia indica.*—II.* Lawsonia inermis; *flowering branches. (After Koehne, 1893.)*

quently is increased by accessory phylloscopic branches of first (as_1) and second (as_2) order. They can form a single flower provided with two prophylls, as in pc_2 to pc_4, or can develop into triads (pc_5) and even into thyrsoids (pc_6). The highest degree of ramification and most vigorous development of accessory branches takes place at the base of the whole inflorescence. The formation of accessory branches can be repeated within the paracladia (pc_5, pc_6) and even within the accessory branches themselves (as_1 in pc_6). The diagrams in Figure 20 III–V give additional information about the serial position of the accessory branches. Accessory branches or flowers are very common within the whole family.

Lagerstroemia parviflora Presl (Fig. 21 I) has advanced to the differentiation of a

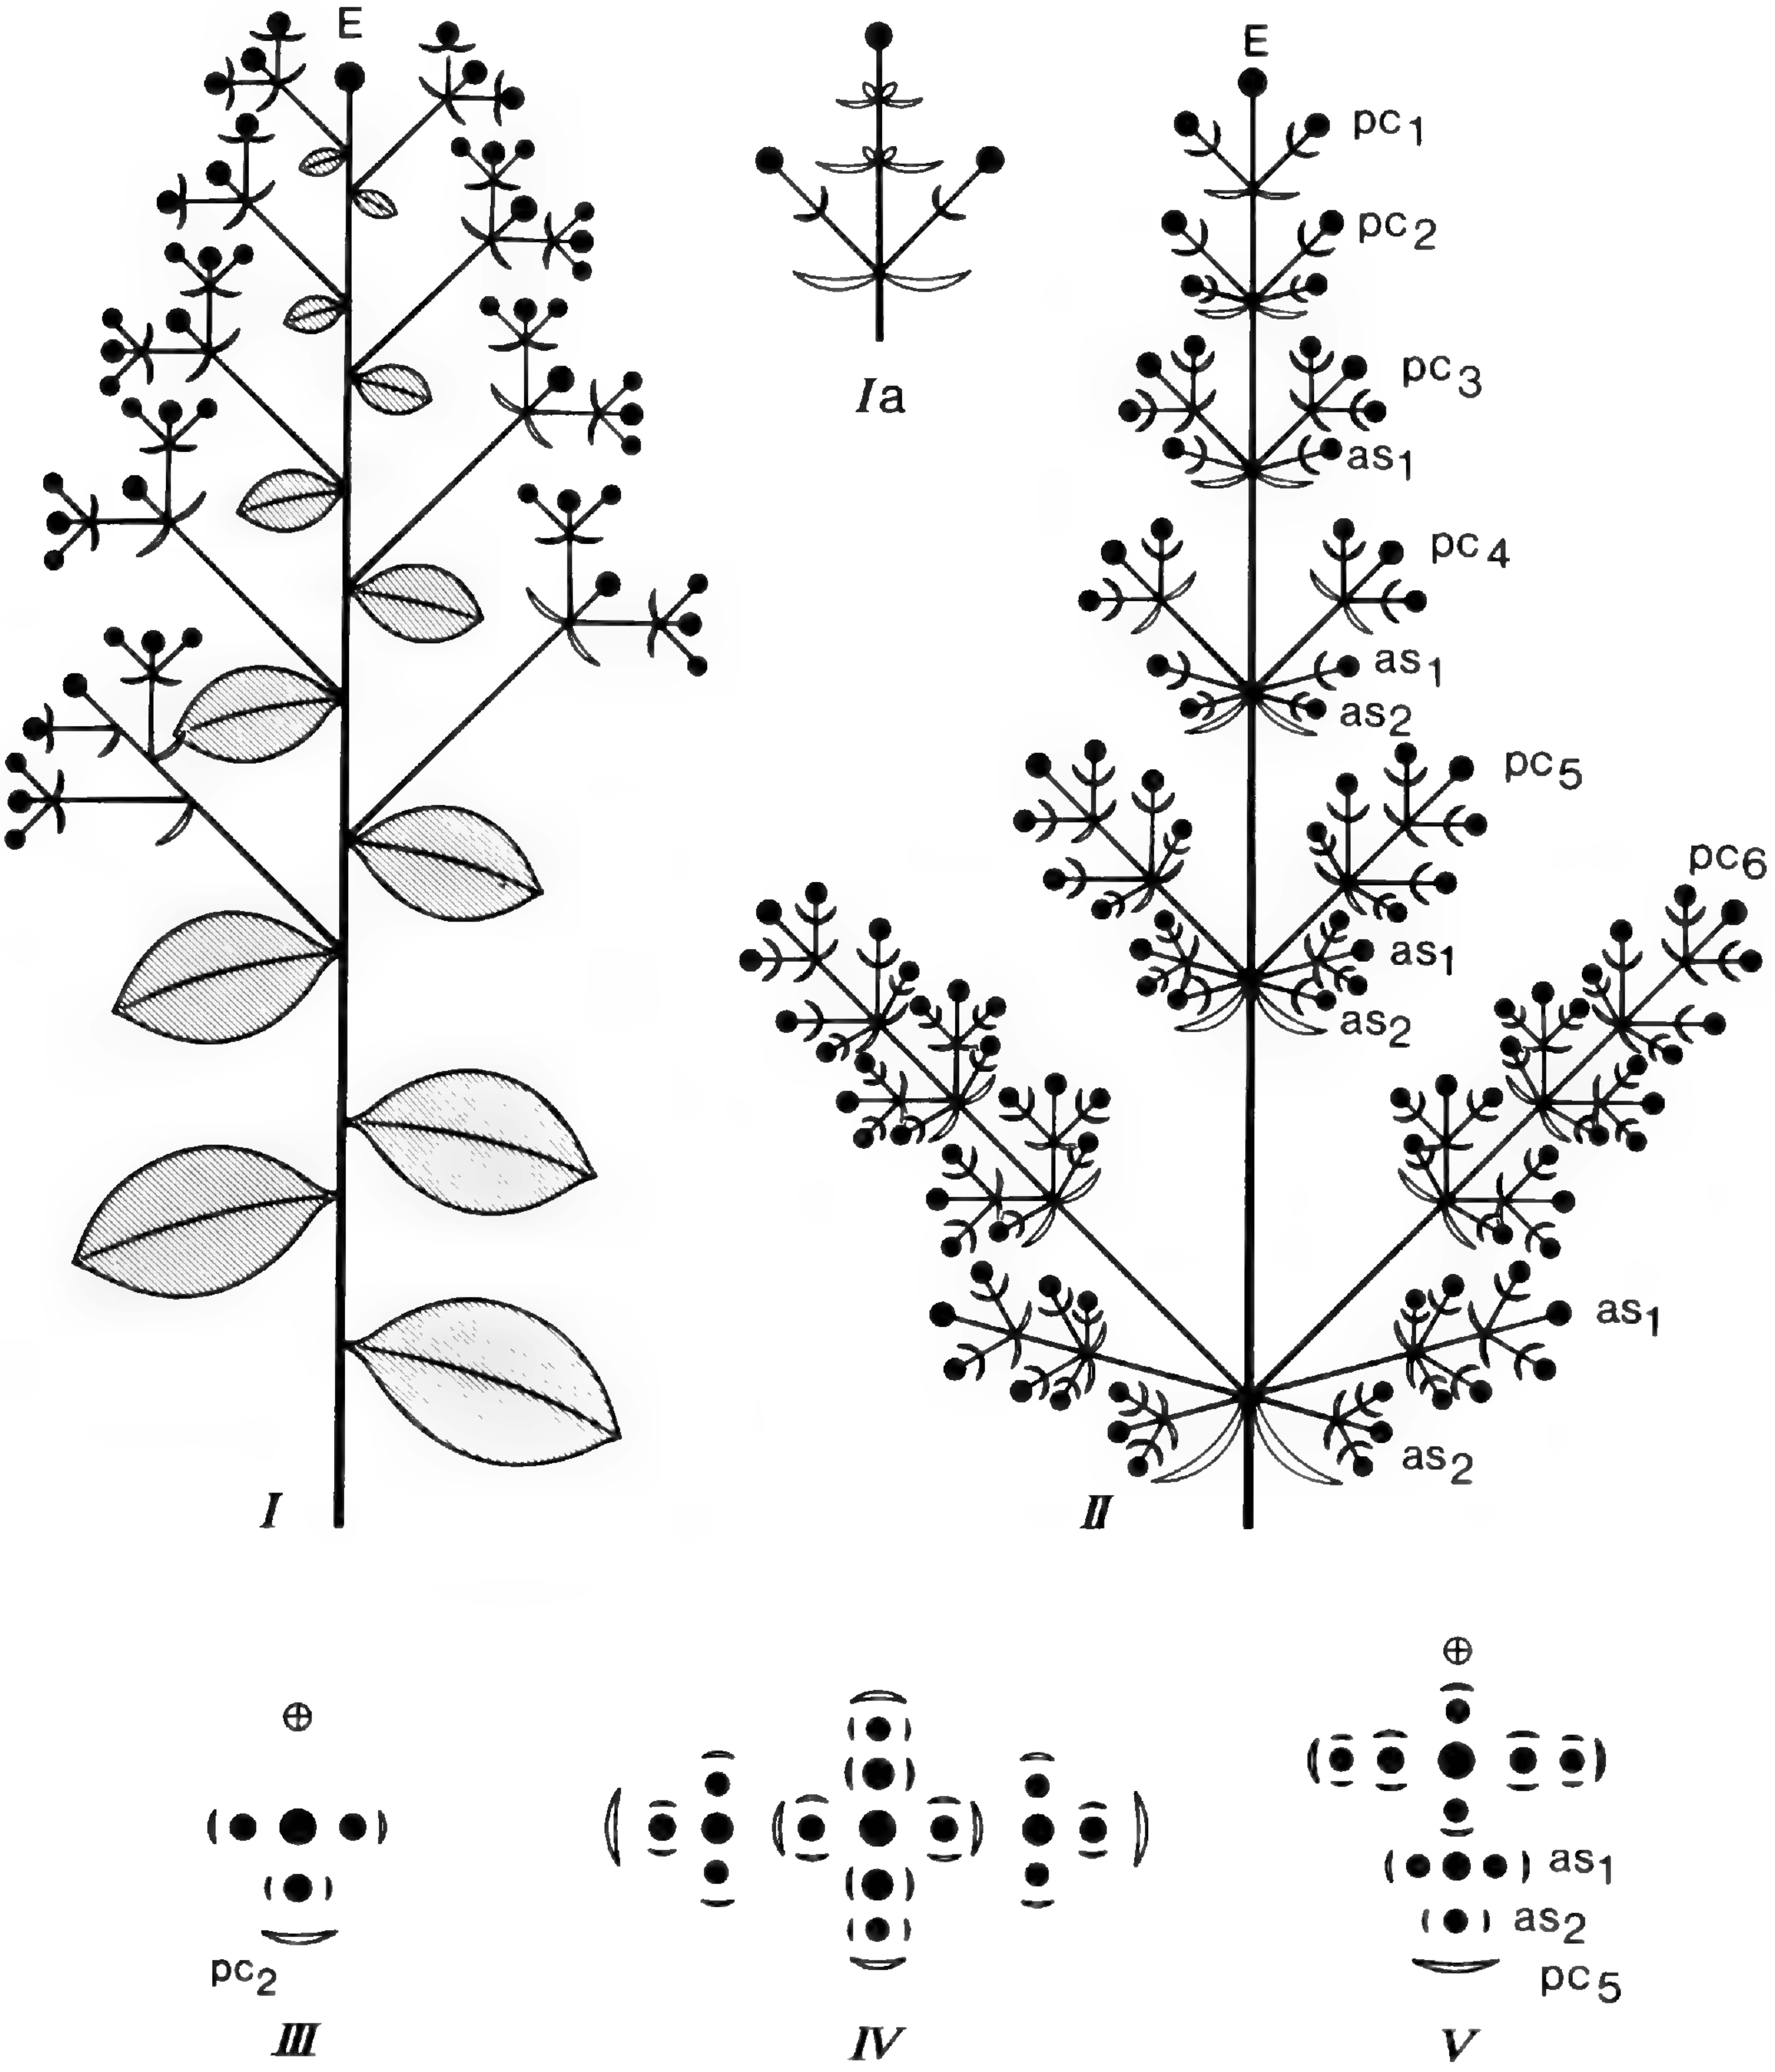

FIGURE 20. *Lythraceae.* Lagerstroemia indica *(I, Ia) and* Lawsonia inermis *(II–V). Vertical projections of flowering branches (I, II) and horizontal projections of* pc_2 *(III),* pc_5 *(V) with accessory branches* as_1 *and* as_2*, the distal part* (pc_1–pc_2) *of the inflorescence in II (IV). Ia is terminal flower of another inflorescence of* Lagerstroemia indica *with two preceding pairs of bracts with undeveloped axillary buds. (From posthumous notices of W. Troll, except Ia.)*

long shoot–short shoot system in which flower formation is restricted to the short shoots (brachyblasts), while the long shoots (macroblasts) continue the vegetative growth. In this case the buds of the short shoots are protected by a series of bud scales and kept undeveloped until the next vegetation period. At the moment of their unfolding and flowering the long shoot has lost its leaves already. The flowering short shoot proliferates. Thus the inflorescence consists of paracladia only, which form botryoids rising from the axils of normally

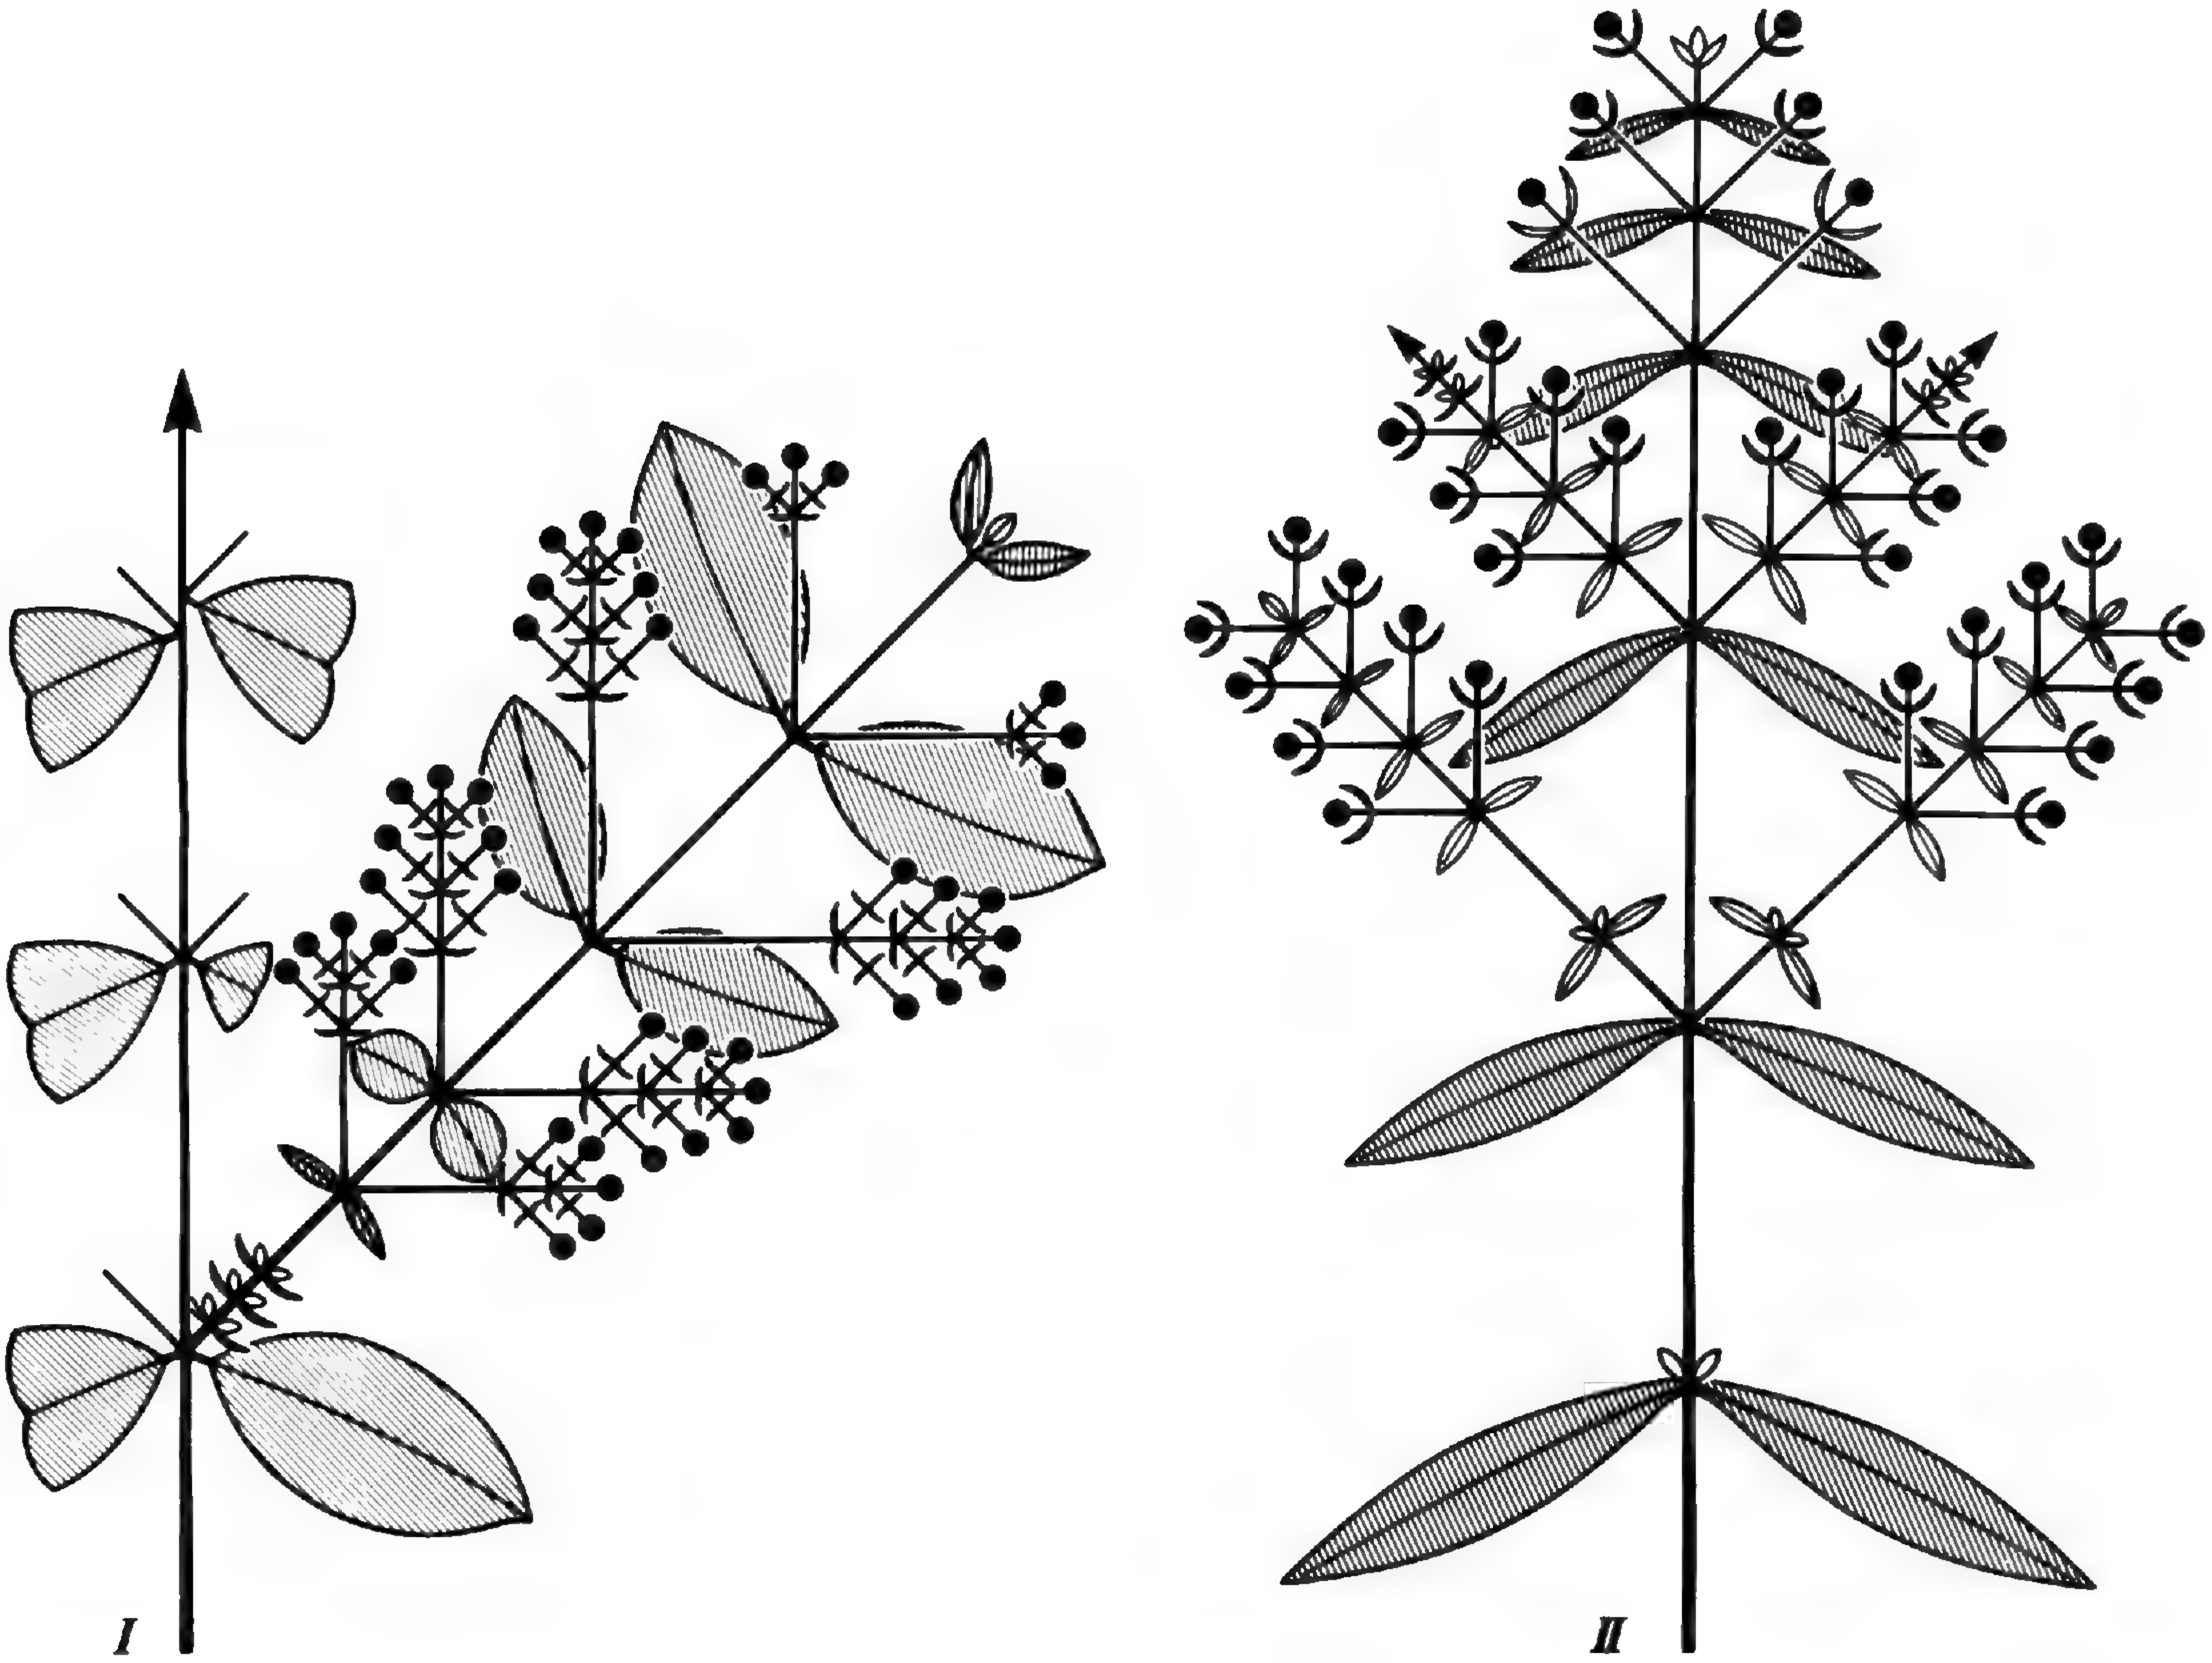

FIGURE 21. *Lythraceae. Vertical projections of flowering branches.—I.* Lagerstroemia parviflora; *piece of a last year's vegetative long shoot with a flowering short shoot.—II.* Lafoensia replicata. *(From posthumous notices of W. Troll.)*

developed or, at the base of the short shoots, very small foliaceous leaves. The basis of the brachyblast that bears bud scales may be interpreted as a zone of inhibition or perhaps also as an innovation zone.

If *Punica* (formerly Punicaceae) ought to be included in Lythraceae, forming subfamily Punicoideae, it could be placed close to *Lagerstroemia* for its monotelic inflorescences. These inflorescences, however, are highly reduced and frequently limited to their terminal flower. They may develop one or two decussate pairs of uniflorous paracladia originating from the axils of bracteose leaves. The uniflorous paracladia bear prophylls that are inserted immediately below the flower. Most of these lateral flowers degenerate sooner or later.

Sonneratia (formerly Sonneratiaceae), which is regarded now to form subfamily Sonneratioideae within the Lythraceae, also has monotelic inflorescences: terminal botryoids with two or three decussate pairs of uniflorous paracladia that bear large prophylls immediately below the flowers. At least the lowermost paracladia arise from the axils of foliage leaves. Sometimes only the terminal flower develops (*S. acida* L. f.).

The genus *Duabanga*, which was formerly included in Sonneratiaceae and now is regarded to represent subfamily Duabangoideae of the Lythraceae, has terminal few-flowered panicles in which ramification only somtimes goes beyond the formation of Pc′.

Crypteroniaceae, formerly sometimes joined with Sonneratiaceae, differ fundamentally from *Sonneratia* by polytelic di- to pleiobotrytic inflorescences of paniclelike appearance with frondo-bracteose (*Axinandra* Thwaites, *Dactylocladus* Oliv.) or mainly bracteose (*Crypteronia* Bl.) foliation and many-flowered botrya. In the axils of the lowermost and foliaceous leaves of the flowering system we could observe well-developed botrytic accessory branches.

Sometimes we found the terminal flower of the inflorescence of *Lagerstroemia speciosa* missing, though terminal flowers still were present in all paracladia. One might overestimate this fact, however, if one interprets this occurrence of truncate monotelic inflorescences as first indication of a gradual transition to the polytelic type within the family. In any case polytelic inflorescences occur in most Lythraceae.

The inflorescence of *Galpinia transvaalica* N. E. Br. resembles those of *Lagerstroemia* in the terminating leafy branches and in its paniclelike structure: the inflorescence axis and all floriferous branches end in terminal flowers. Its foliation, however, is frondulose to bracteose.

In contrast to *Galpinia*, *Lawsonia*, and most species of *Lagerstroemia*, the flower-bearing systems of the shrubby genus *Woodfordia* (*W. floribunda* Salisb., *W. uniflora* (A. Rich.) Koehne) are brachyblastlike branches originating in the axils of foliaceous leaves that are still present during anthesis. They are thyrses or diplo-thyrses (in the narrow sense, cf. Fig. 2 II) with frondulose leaves on their main axes. Since they often bear a series of cataphylls at their bases, it seems likely that they do not unfold immediately after initiation but remain as buds for a while, perhaps to endure an unfavorable season. Frequently these brachyblasts are accompanied by phylloscopic accessory branches of similar shape.

In the flowering systems of *Lafoensia*, another ligneous genus comprising large trees or shrubs, all axes bearing more than one pair of leaves proved to be auxotelic or anauxotelic (see p. 290). The inflorescence of *L. replicata* Pohl, which may serve here as an example (Fig. 21 II), shows a complete reduction of cymose branching. Thus a terminal and several pairs of lateral botryslike structures with acropetal effloration are formed. They can be interpreted as the terminal main florescence and the co-florescences of a polytelic system. The same applies to *L. acuminata* DC., *L. pacari* St. Hil., *L. punicifolia* DC., and *L. densiflora* Pohl. The deciduous prophylls of the flowers are situated immediately at the base of the flowers. In other species, as in *L. nummulariifolia* St. Hil., the number of flowers is diminished.

While in the *Lafoensia* species treated here the subtending leaves within the inflorescences are more or less foliaceous, *Physocalymma scaberrimum* Pohl is characterized by bracteous foliation throughout the whole flower-bearing system that terminates vegetative branches. This system is a diplo- or pleiobotryum with a large paracladial zone (Fig. 22 I). The axes of all botrya end in a vegetative bud. According to Koehne (1893), flowering of this tree takes place when the plants have lost their leaves. In the shrubby *Pemphis madagascariensis* (Baker) Koehne, the production of flowers seems to be limited to brachyblastlike branches which, however, proliferate like the macroblastic main axis. The botrytic flower-bearing zones comprise a few flowers only (Fig. 22 II). *Pemphis acidula* Forster, the second species of the genus, is similar.

A gradually progressing differentiation of the ramification system into flower-bearing short shoots and vegetative long shoots can be seen within the genus *Ginoria* Jacq. As reported by Koehne (1883: 115) in *G. americana* Jacq., the flower-bearing branches arise from the axils of foliaceous leaves. After the appearance of a pair of bud scales, these twigs develop several pairs of foliaceous leaves that bear single flowers in their axils (Fig. 23 I). At a later stage the twigs pass over to vegetative growth. *Ginoria spinosa* and *G. glabra* Griseb. are reported to be similar, but the flowering branches are shorter with fewer flowers and do not proliferate regularly.

In *Ginoria curvispina* Koehne, the flower-bearing brachyblasts unfold in the season after their initiation, when their pherophylls are already lost (Fig. 23 IIa). Their foliation begins with one to three pairs of cataphylls

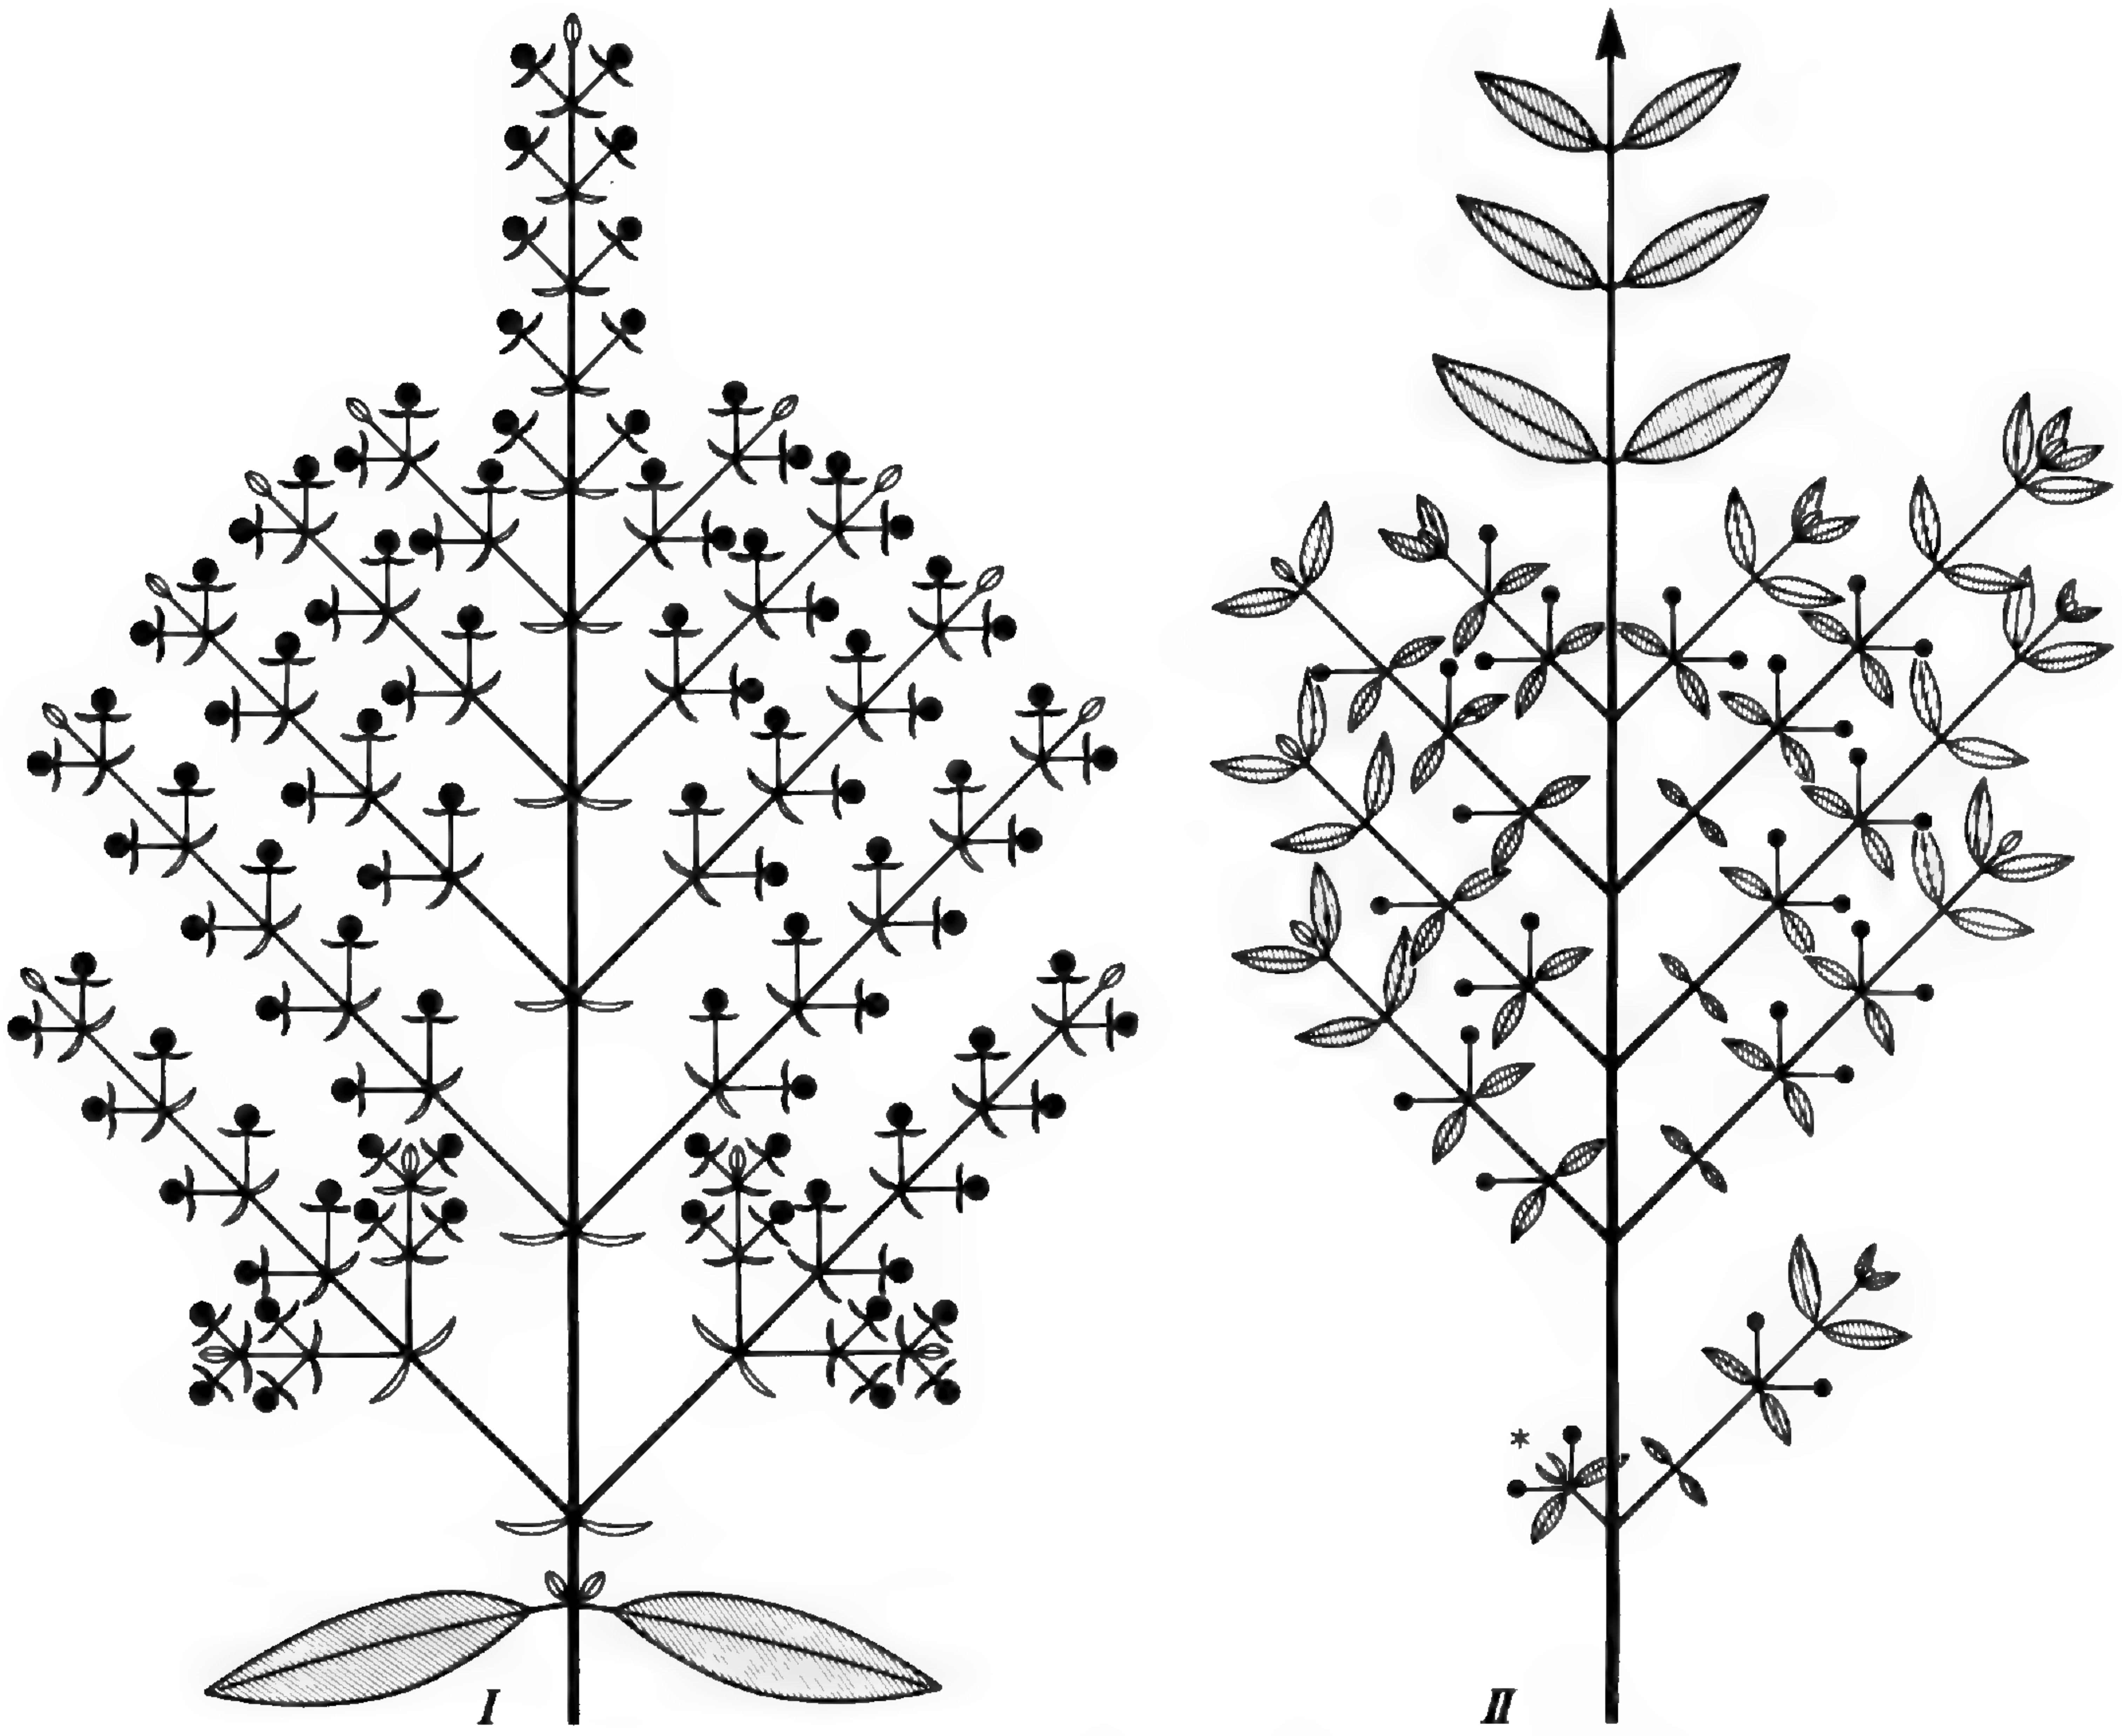

FIGURE 22. *Lythraceae. Vertical projections of flowering branches.—I.* Physocalymma scaberrimum.—*II.* Pemphis madagascariensis. *(From posthumous works of W. Troll.)*

followed by foliaceous leaves. The whole brachyblast can bear one to four pairs of single flowers that can originate in the axils of the cataphylls as well as in the axils of the foliaceous leaves. Finally the brachyblasts proliferate.

According to Koehne (1883: 116), the foliaceous leaves of the brachyblasts resemble those of the macroblasts but measure only one-fourth of their size.

Thus the brachyblasts with their botrytic main florescences contrast conspicuously with the vegetative macroblasts, which at their distal end can continue growth with the development of a new annual shoot. According to the observations of Koehne, these new shoots can also bear single flowers in the axils of their lowermost foliaceous leaves (Fig. 23 IIb). Koehne also reported that two similar long shoots can originate at the very base of the annual shoot and also bear up to four pairs of flowers (Fig. 23 IIc). Thus the limitation of flower production to the short shoots seems not to be complete yet.

In *Ginoria diplusodon* Koehne (Fig. 23 III), the brachyblasts remain shorter, their foliation consists of scales, one to three pairs of which can bear flowers in their axils, thus forming a short botrys. (Sometimes the prophylls of these flowers bear secondary flowers.) Even here the annual shoots continuing the macroblasts (Fig. 23 V) develop one to three pairs of single flowers originating in the axils of cataphylls at the base of the annual shoots (Koehne, 1883). *Ginoria rohrii* (Vahl) Koehne is similar, but the brachyblasts are shorter and the two- to eight-flowered florescence is umbel-shaped (Figs. 23 IV, 24);

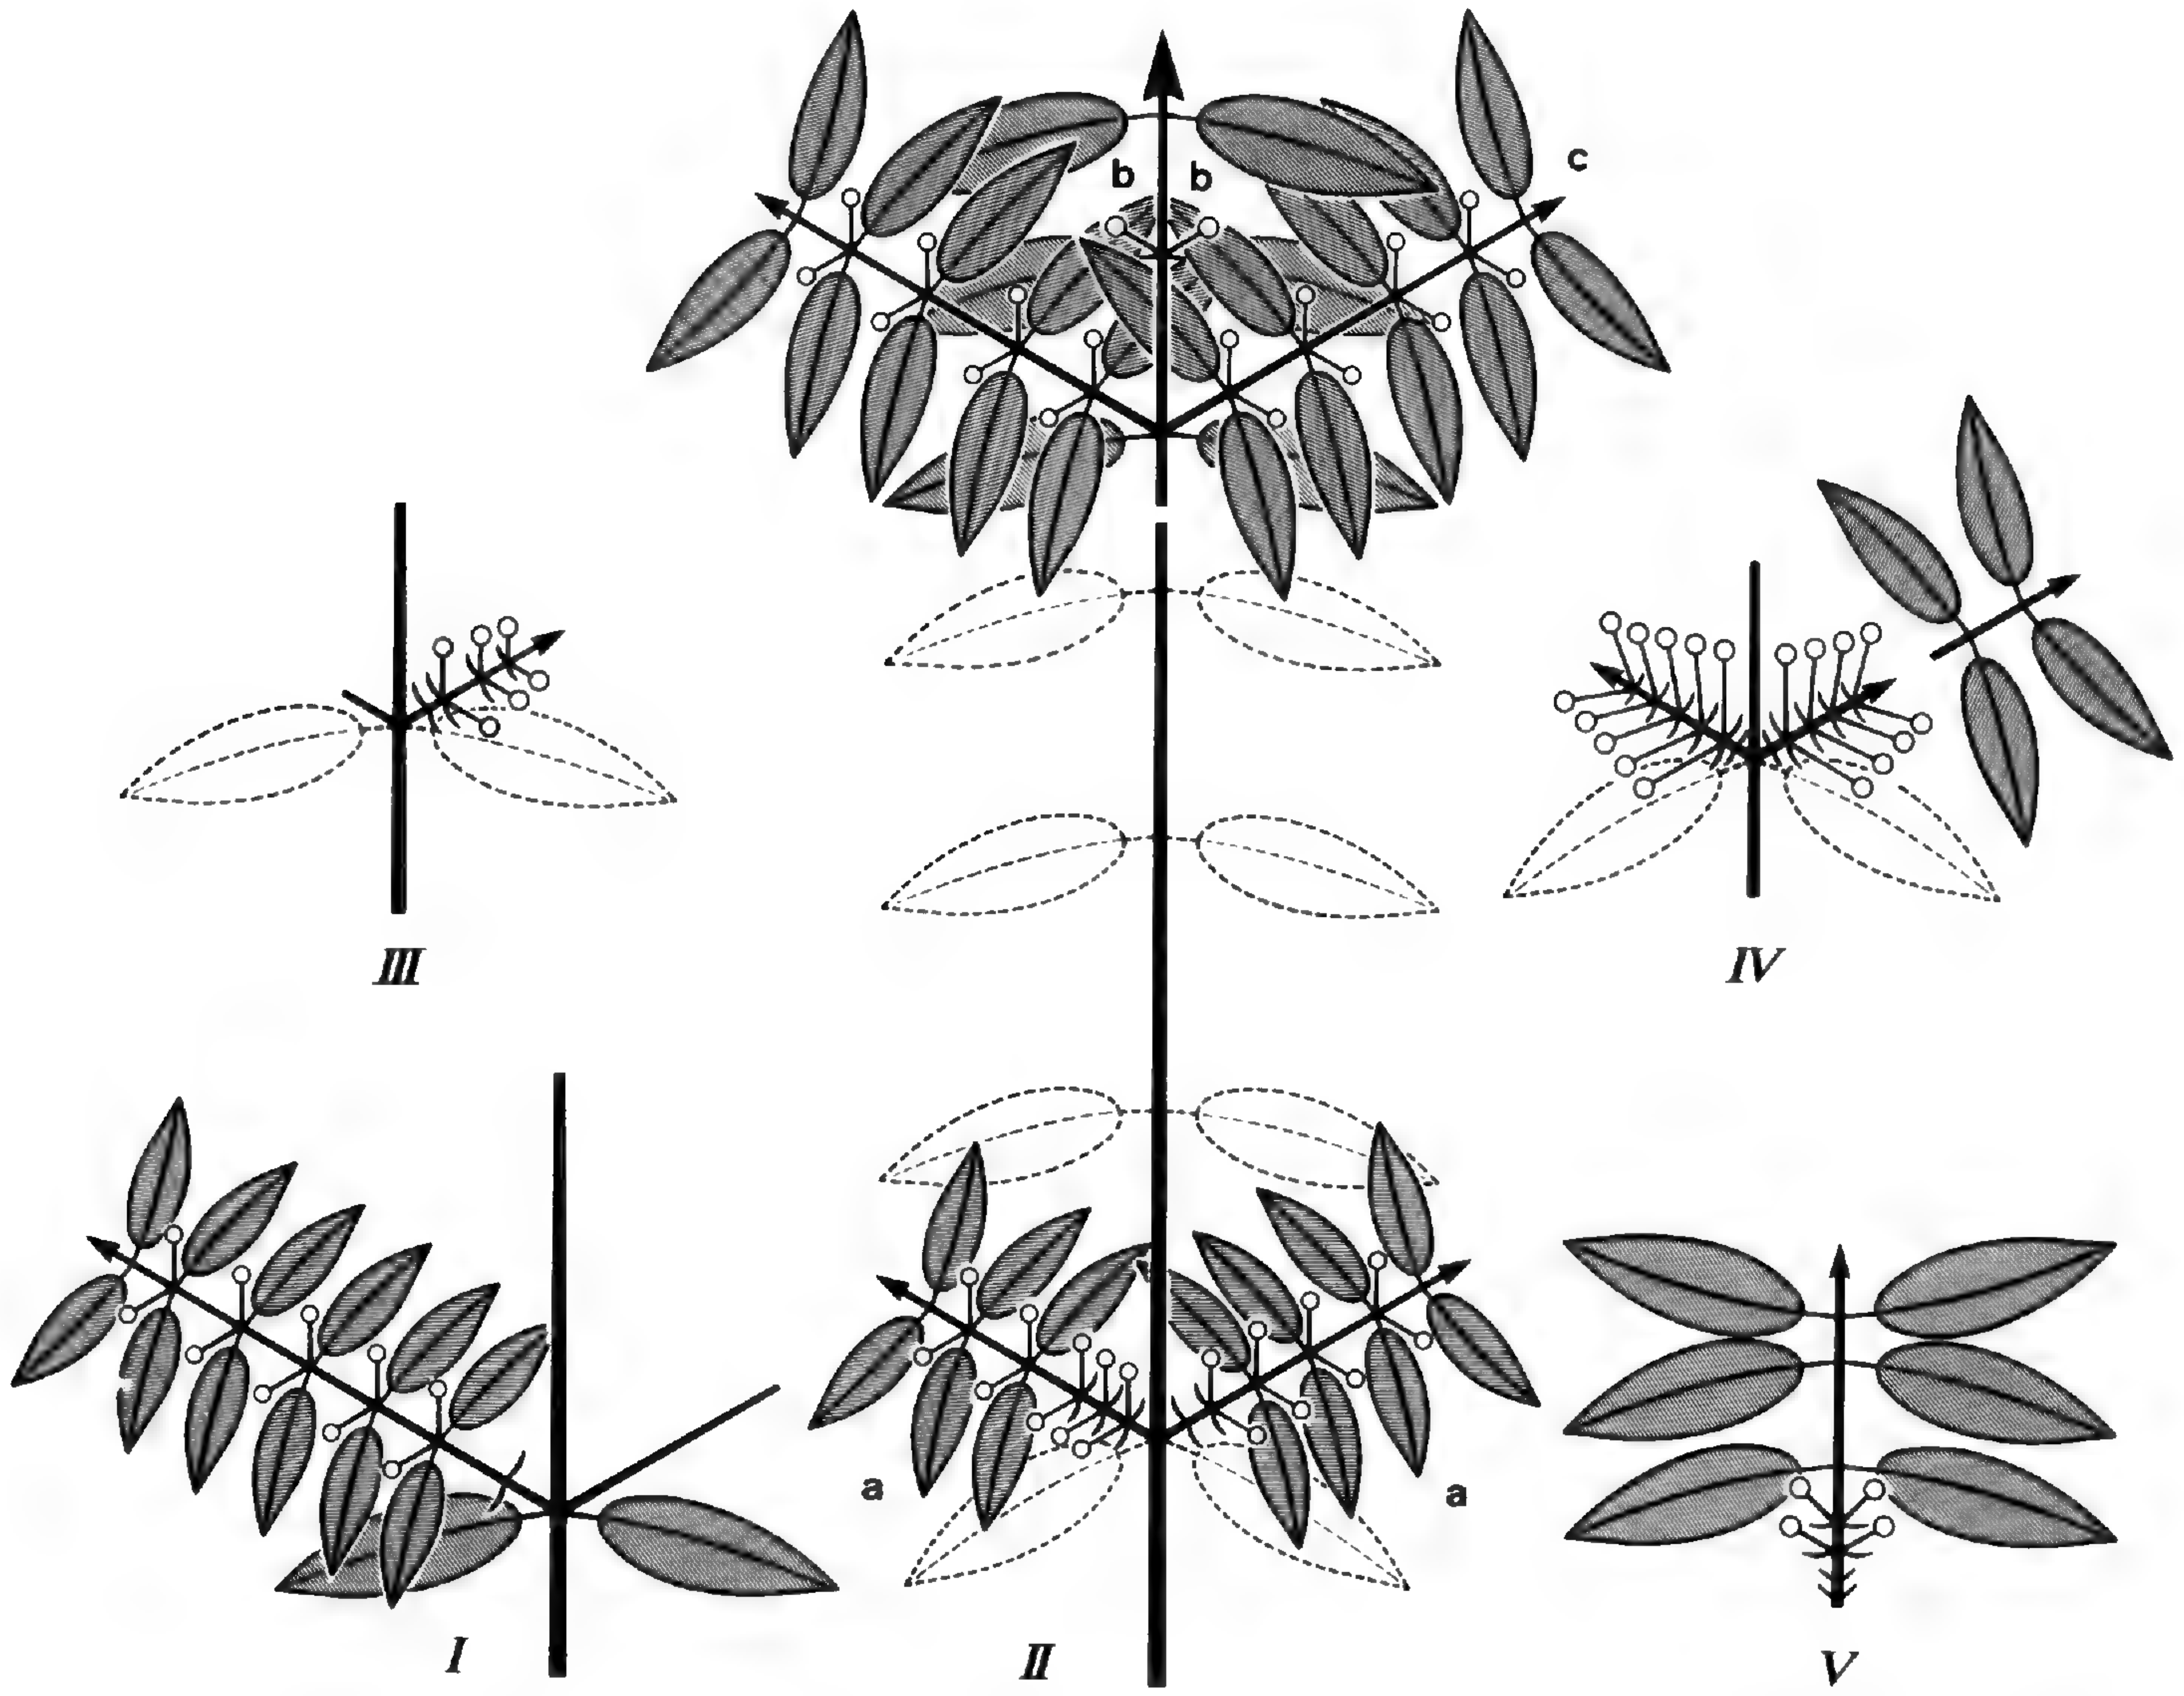

FIGURE 23. *Lythraceae. Vertical diagrams of flowering shoots.—I.* Ginoria americana; *proliferating brachyblast.—II.* G. curvispina; *last year's macroblast with flowering and proliferating brachyblasts (a), single flowers in the axils of proximal foliaceous leaves of the new annual shoot (b), and lateral macroblasts (c) developing from the axils of proximal foliaceous leaves of the new annual shoot. These lateral macroblasts can also bear single flowers in the axils of their proximal foliage leaves.—III.* G. diplusodon; *bracteose flowering brachyblasts in the leaf axils of a last year's macroblast.—IV.* G. rohrii; *brachyblasts which later can proliferate.—V.* G. diplusodon; *base of an annual shoot (macroblast) with flowers in the axils of the uppermost (bud) scales. Prophylls of the flowers omitted. (Construction according to report by Koehne (1883) and to our results.)*

the prophylls are sterile. The brachyblasts unfold when the macroblast is already defoliated. The uppermost brachyblasts are reported to proliferate occasionally. According to Troll (unpubl.), the terminal bud of the macroblast often fails. Then the macroblast is continued by the development of the uppermost lateral buds. Their foliation begins with two or three pairs of bud scales. The distal pair can be frondulose; according to Koehne (1883: 117), the flowers originating in the axils of the bud scales may bear a second flower in the axil of one of their prophylls.

Although the florescences of the ligneous Lythraceae such as *Ginoria*, *Lafoensia*, *Pemphis*, and *Physocalymma* present themselves as botrya or spikes, the basic form of the florescence in the polytelic Lythraceae is a thyrse (in the narrow sense, i.e., without terminal flower). Among the ligneous taxa this is demonstrated by *Adenaria*: in *A. floribunda* Kunth, the flower-bearing twig is a foliaceous, proliferating thyrse with many-flowered cymes, which by abbreviation of all internodes except the epipodia become umbel-shaped or headlike (Fig. 25). *Pehria* (= *Grislea*), as seen in *P. compacta* (Rusby) Sprague, is said to be similar in this respect (Koehne, 1893); the same applies to *Decodon verticillatus* (L.) Ell.

Within the suffruticose and herbaceous taxa

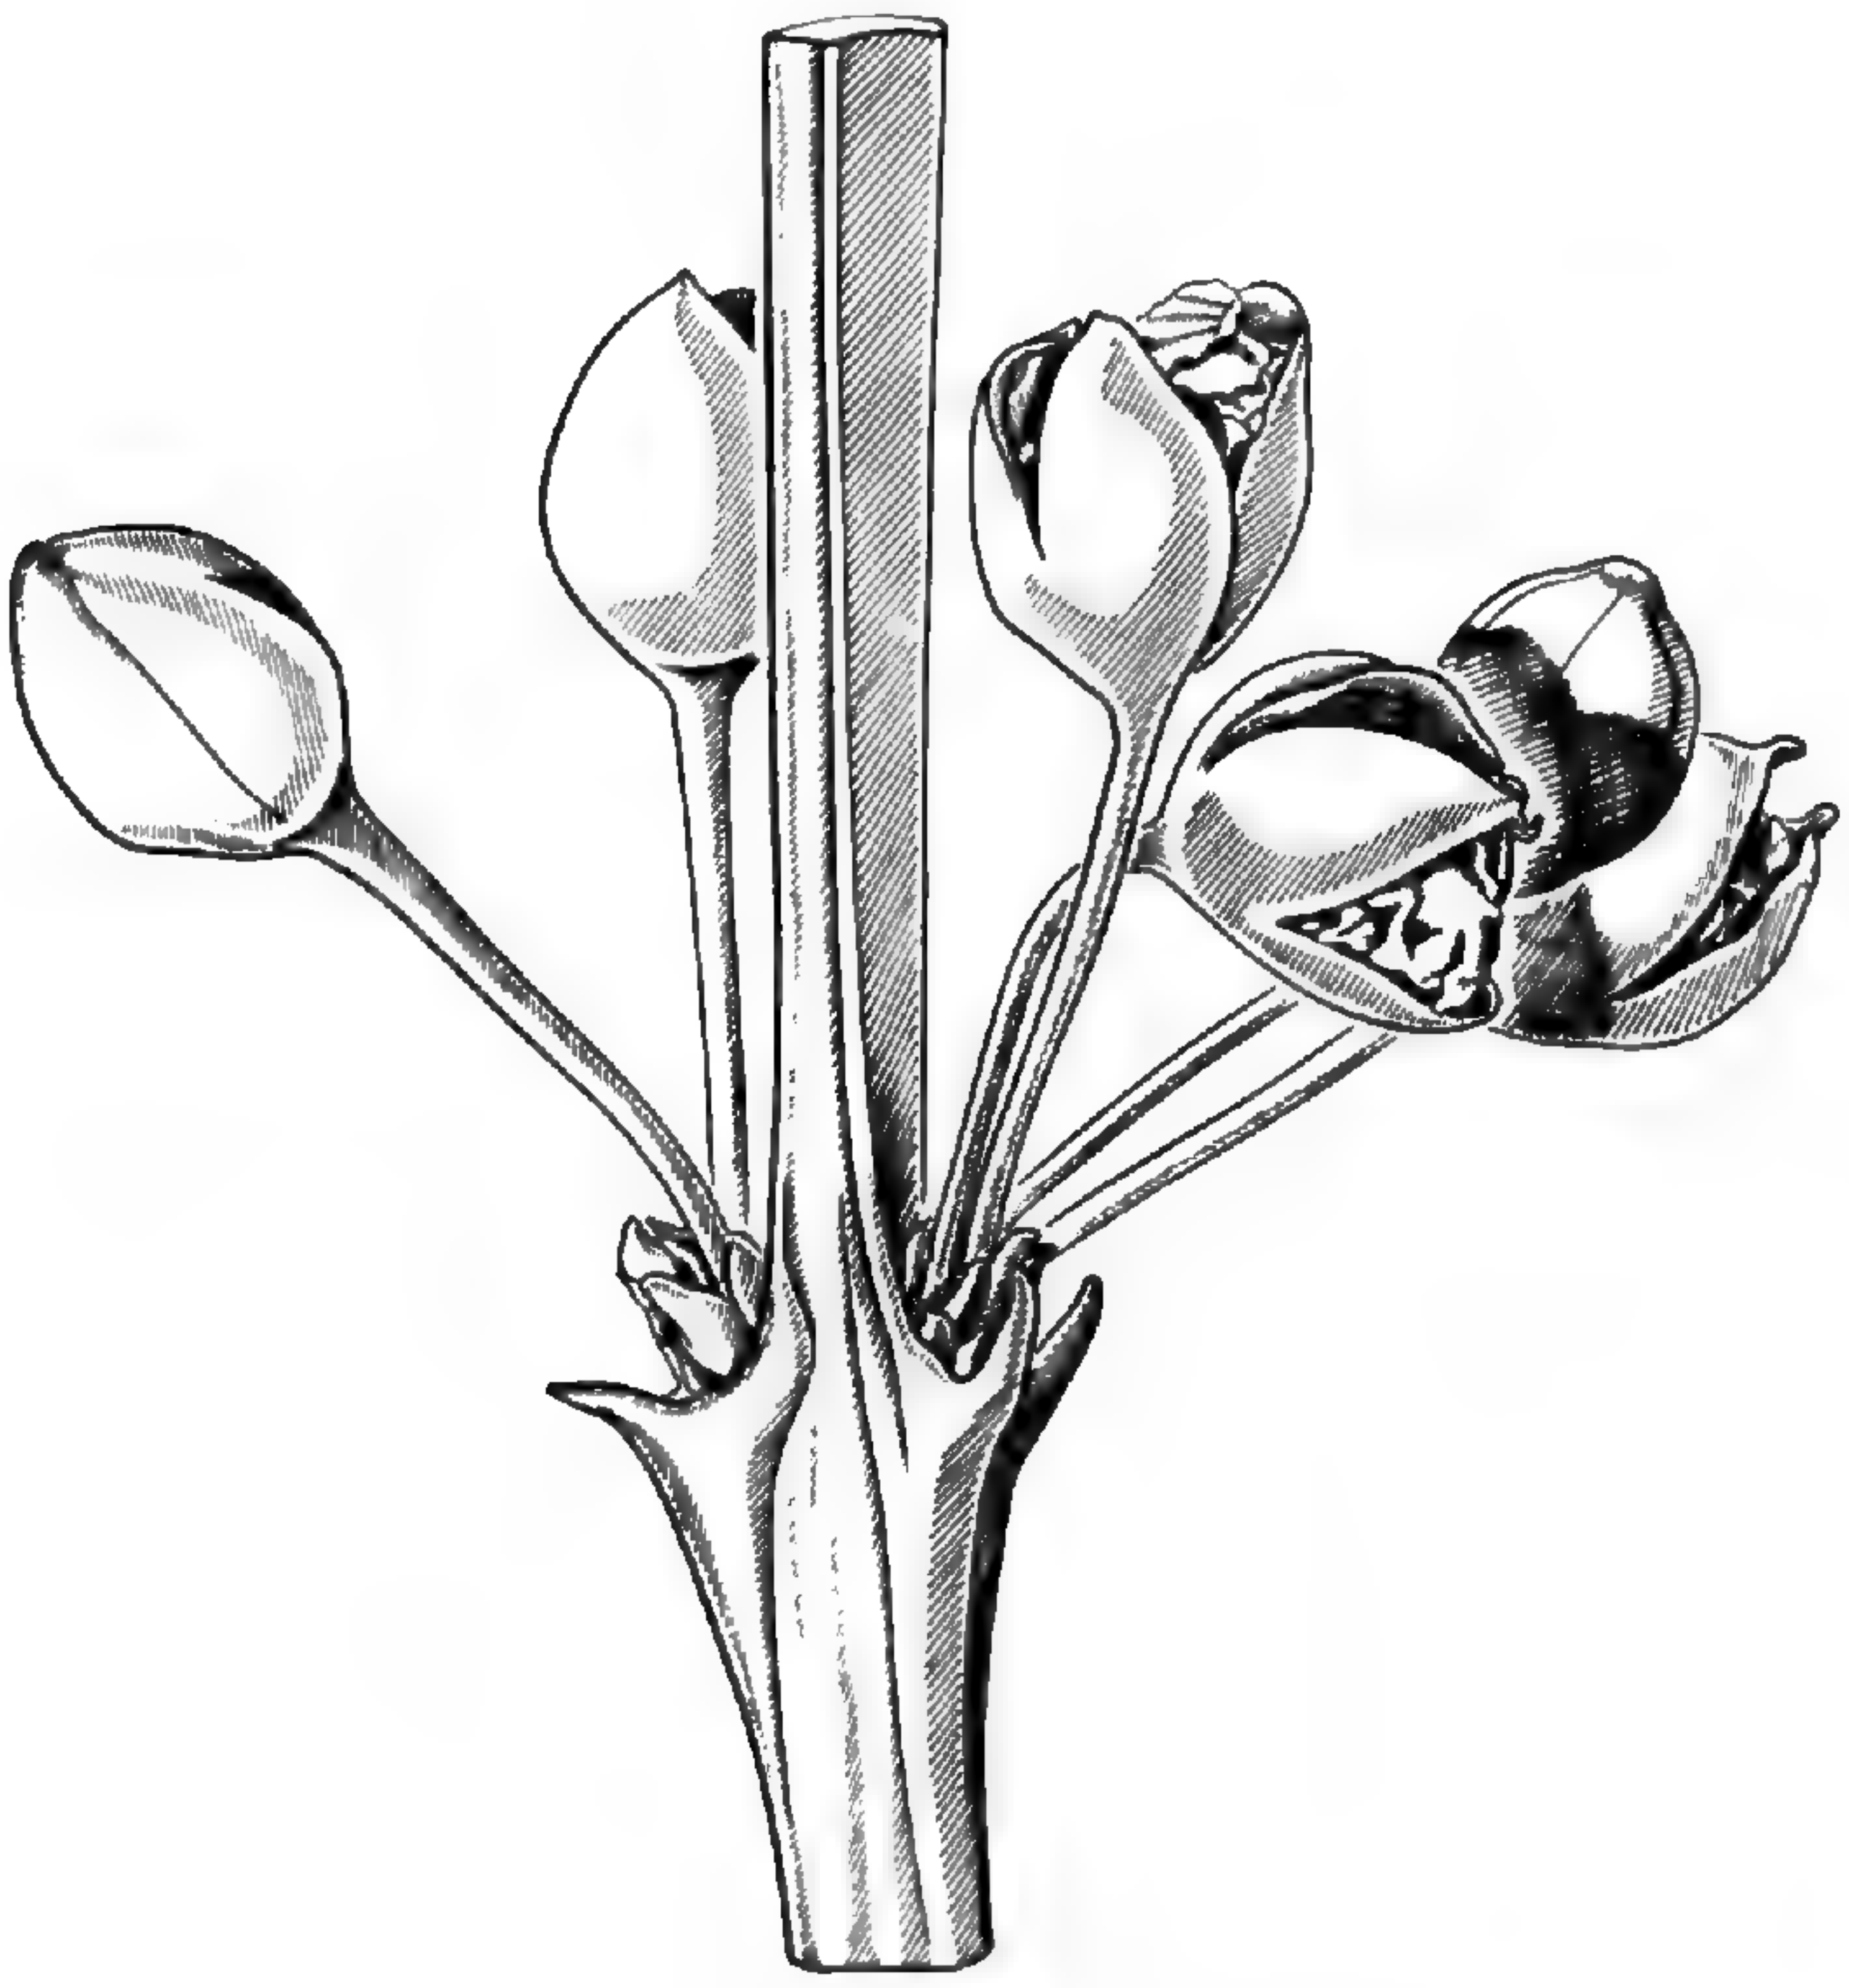

FIGURE 24. *Lythraceae.* Ginoria rohrii; *macroblast with two brachyblasts. (June, 1907,* Eichinger s.n. *(M).)*

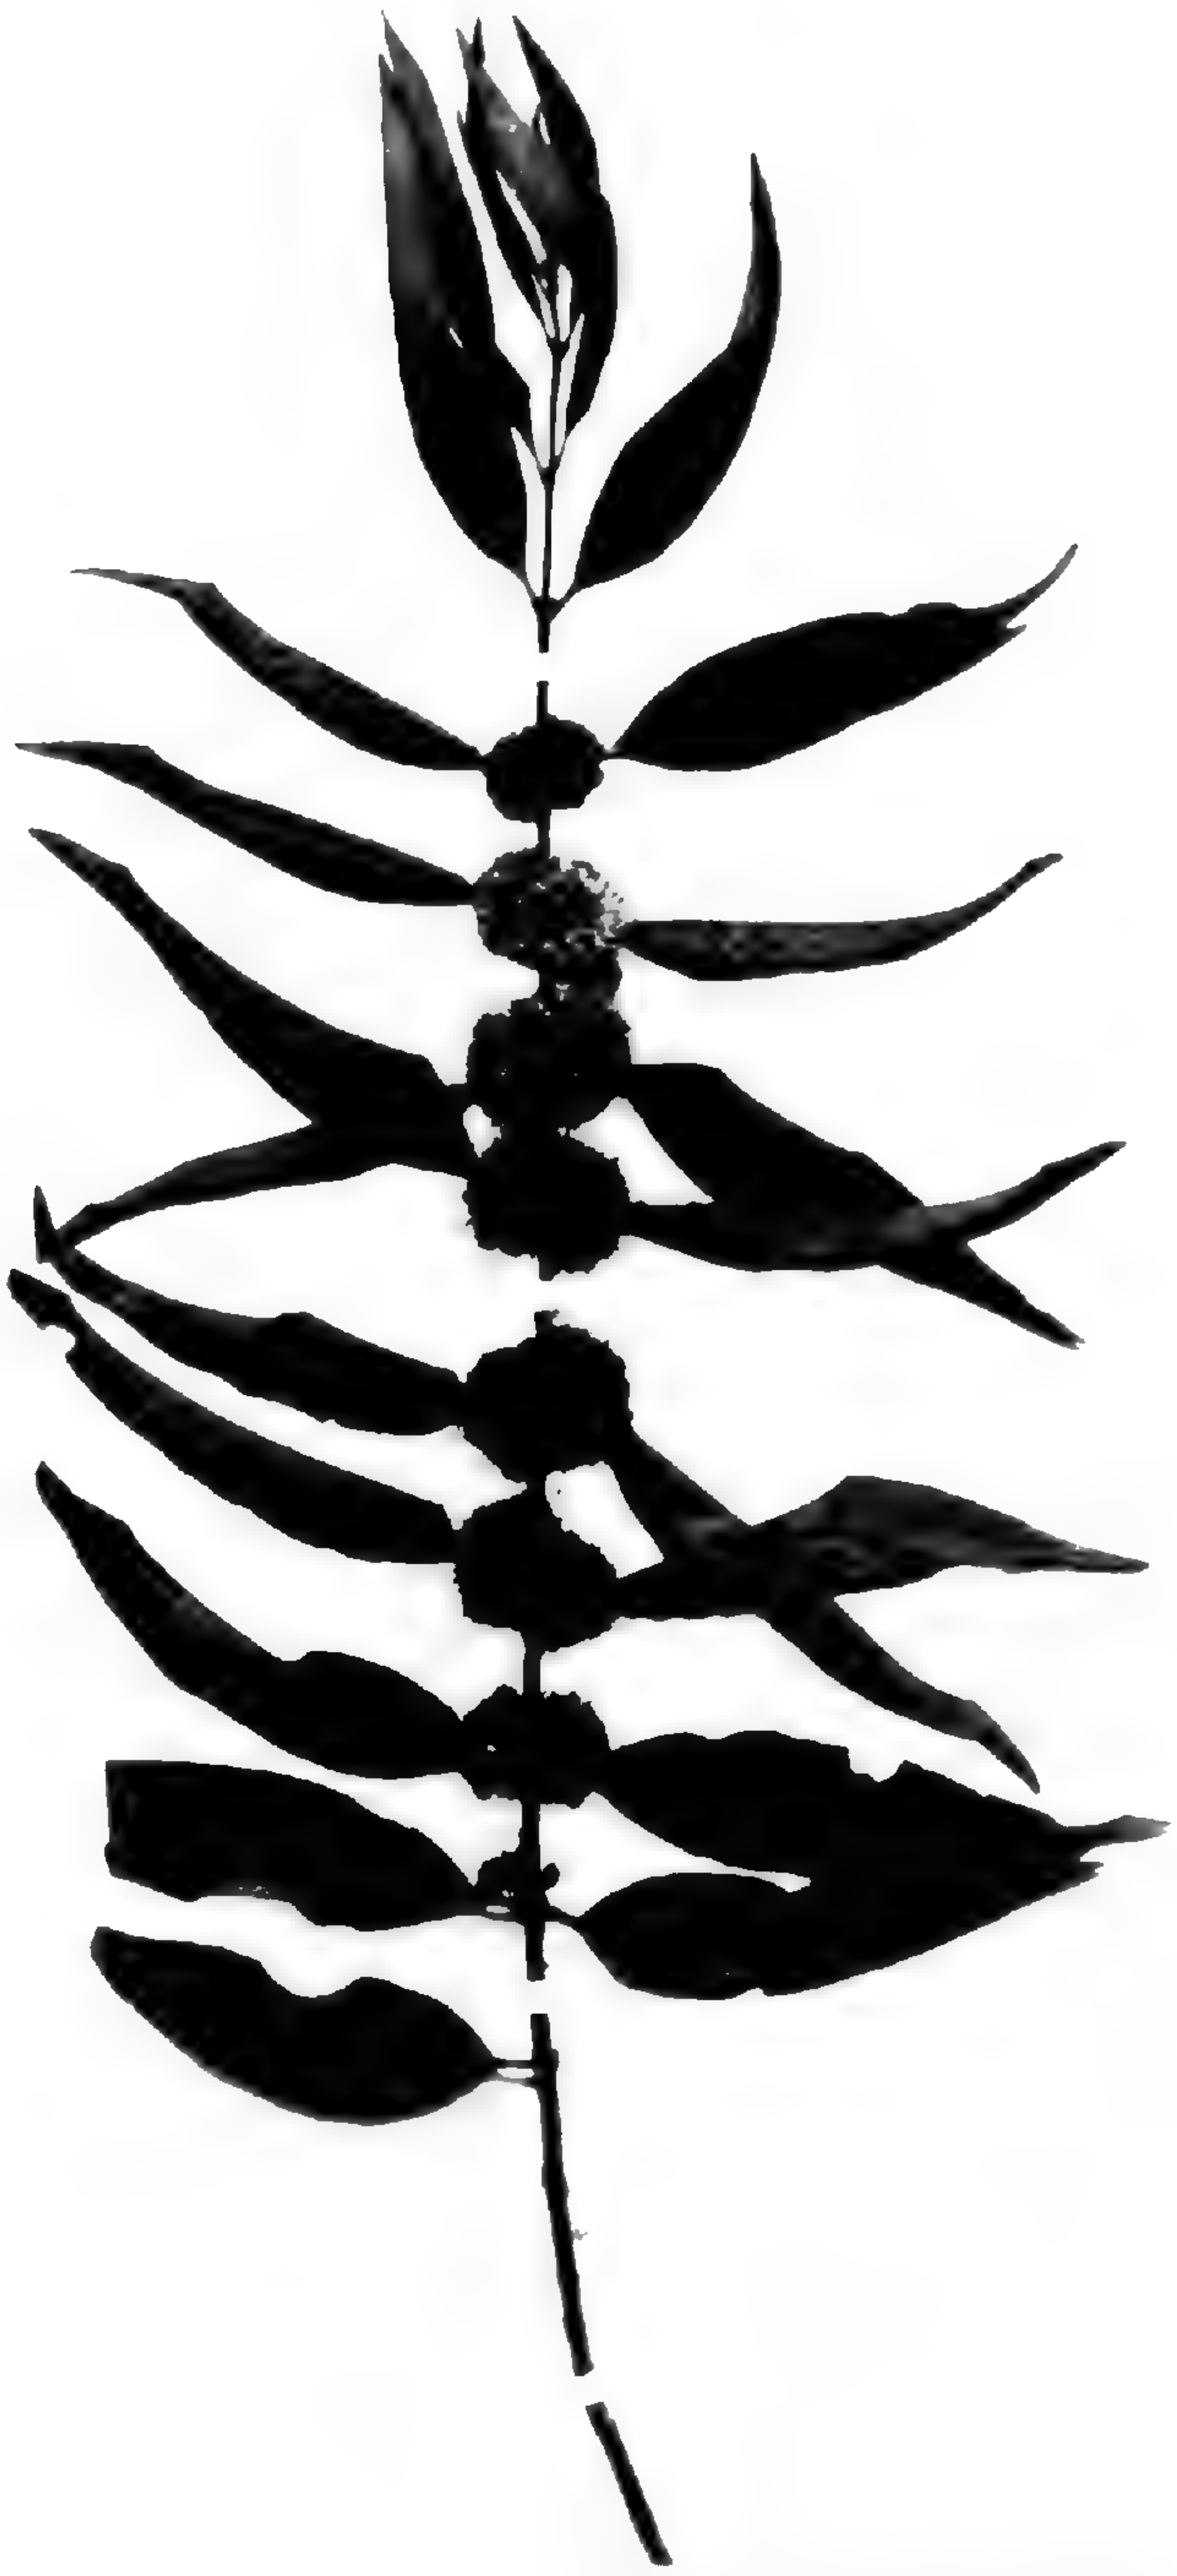

FIGURE 25. *Lythraceae.* Adenaria floribunda; *flowering branch. (Bolivia: Vic. Sorata,* M. Bang 1311 *(M).)*

there are also many groups with copiously branched thyrses. As an example, *Nesaea crassicaulis* (Guill. & Perr.) Koehne (Fig. 26 I) may be mentioned. Its partial florescences are loosely branched with only the hypopodia remaining relatively short, whereas in others, for example, *N. pedicellata* Hiern, even the hypopodia are prolonged and form long peduncles. In *N. aspera* (Guill. & Perr.) Koehne all internodes remain short, and the partial florescences form many-flowered glomerules (see also *N. sarcophylla* Koehne in Koehne, 1903: 227, fig. 43E).

Frequently the partial florescences are reduced to uniflory, thus converting the thyrse into a botrys or spike. This applies to some species of *Nesaea* (e.g., *N. linifolia* Hiern (Fig. 28 III) and *N. baumii* Koehne), most species of *Lythrum,* and all species of *Pleurophora, Cuphea, Heimia, Peplis,* and *Diplusodon.* In *Rotala,* only one species, *R. serpiculoides* Hiern, is reported to have 3–12 flowered dichasia (Koehne, 1883: 124), while in *Ammannia* reduction of the cymes to uniflorous elements occurs facultatively in many species.

A remarkable arrangement of flowers within the botrytic florescences can be observed in *Rotala wallichii* Koehne. It was reported by Koehne (1883: 118) for the verticillate species of the genus that in each whorl the number of flowers equals the number of leaves, i.e., the axil of each leaf bears a single flower. In *R. wallichii* (Fig. 26 II), however, the proximal verticils of a florescence comprising six or seven leaves bear only two or three flowers. The number of flowers increases distally, until each leaf axil of a verticil bears a flower. The disposition of the flowers in the lower whorls can be quite different, without any obvious rule. During the development of a shoot the number of leaves in the consec-

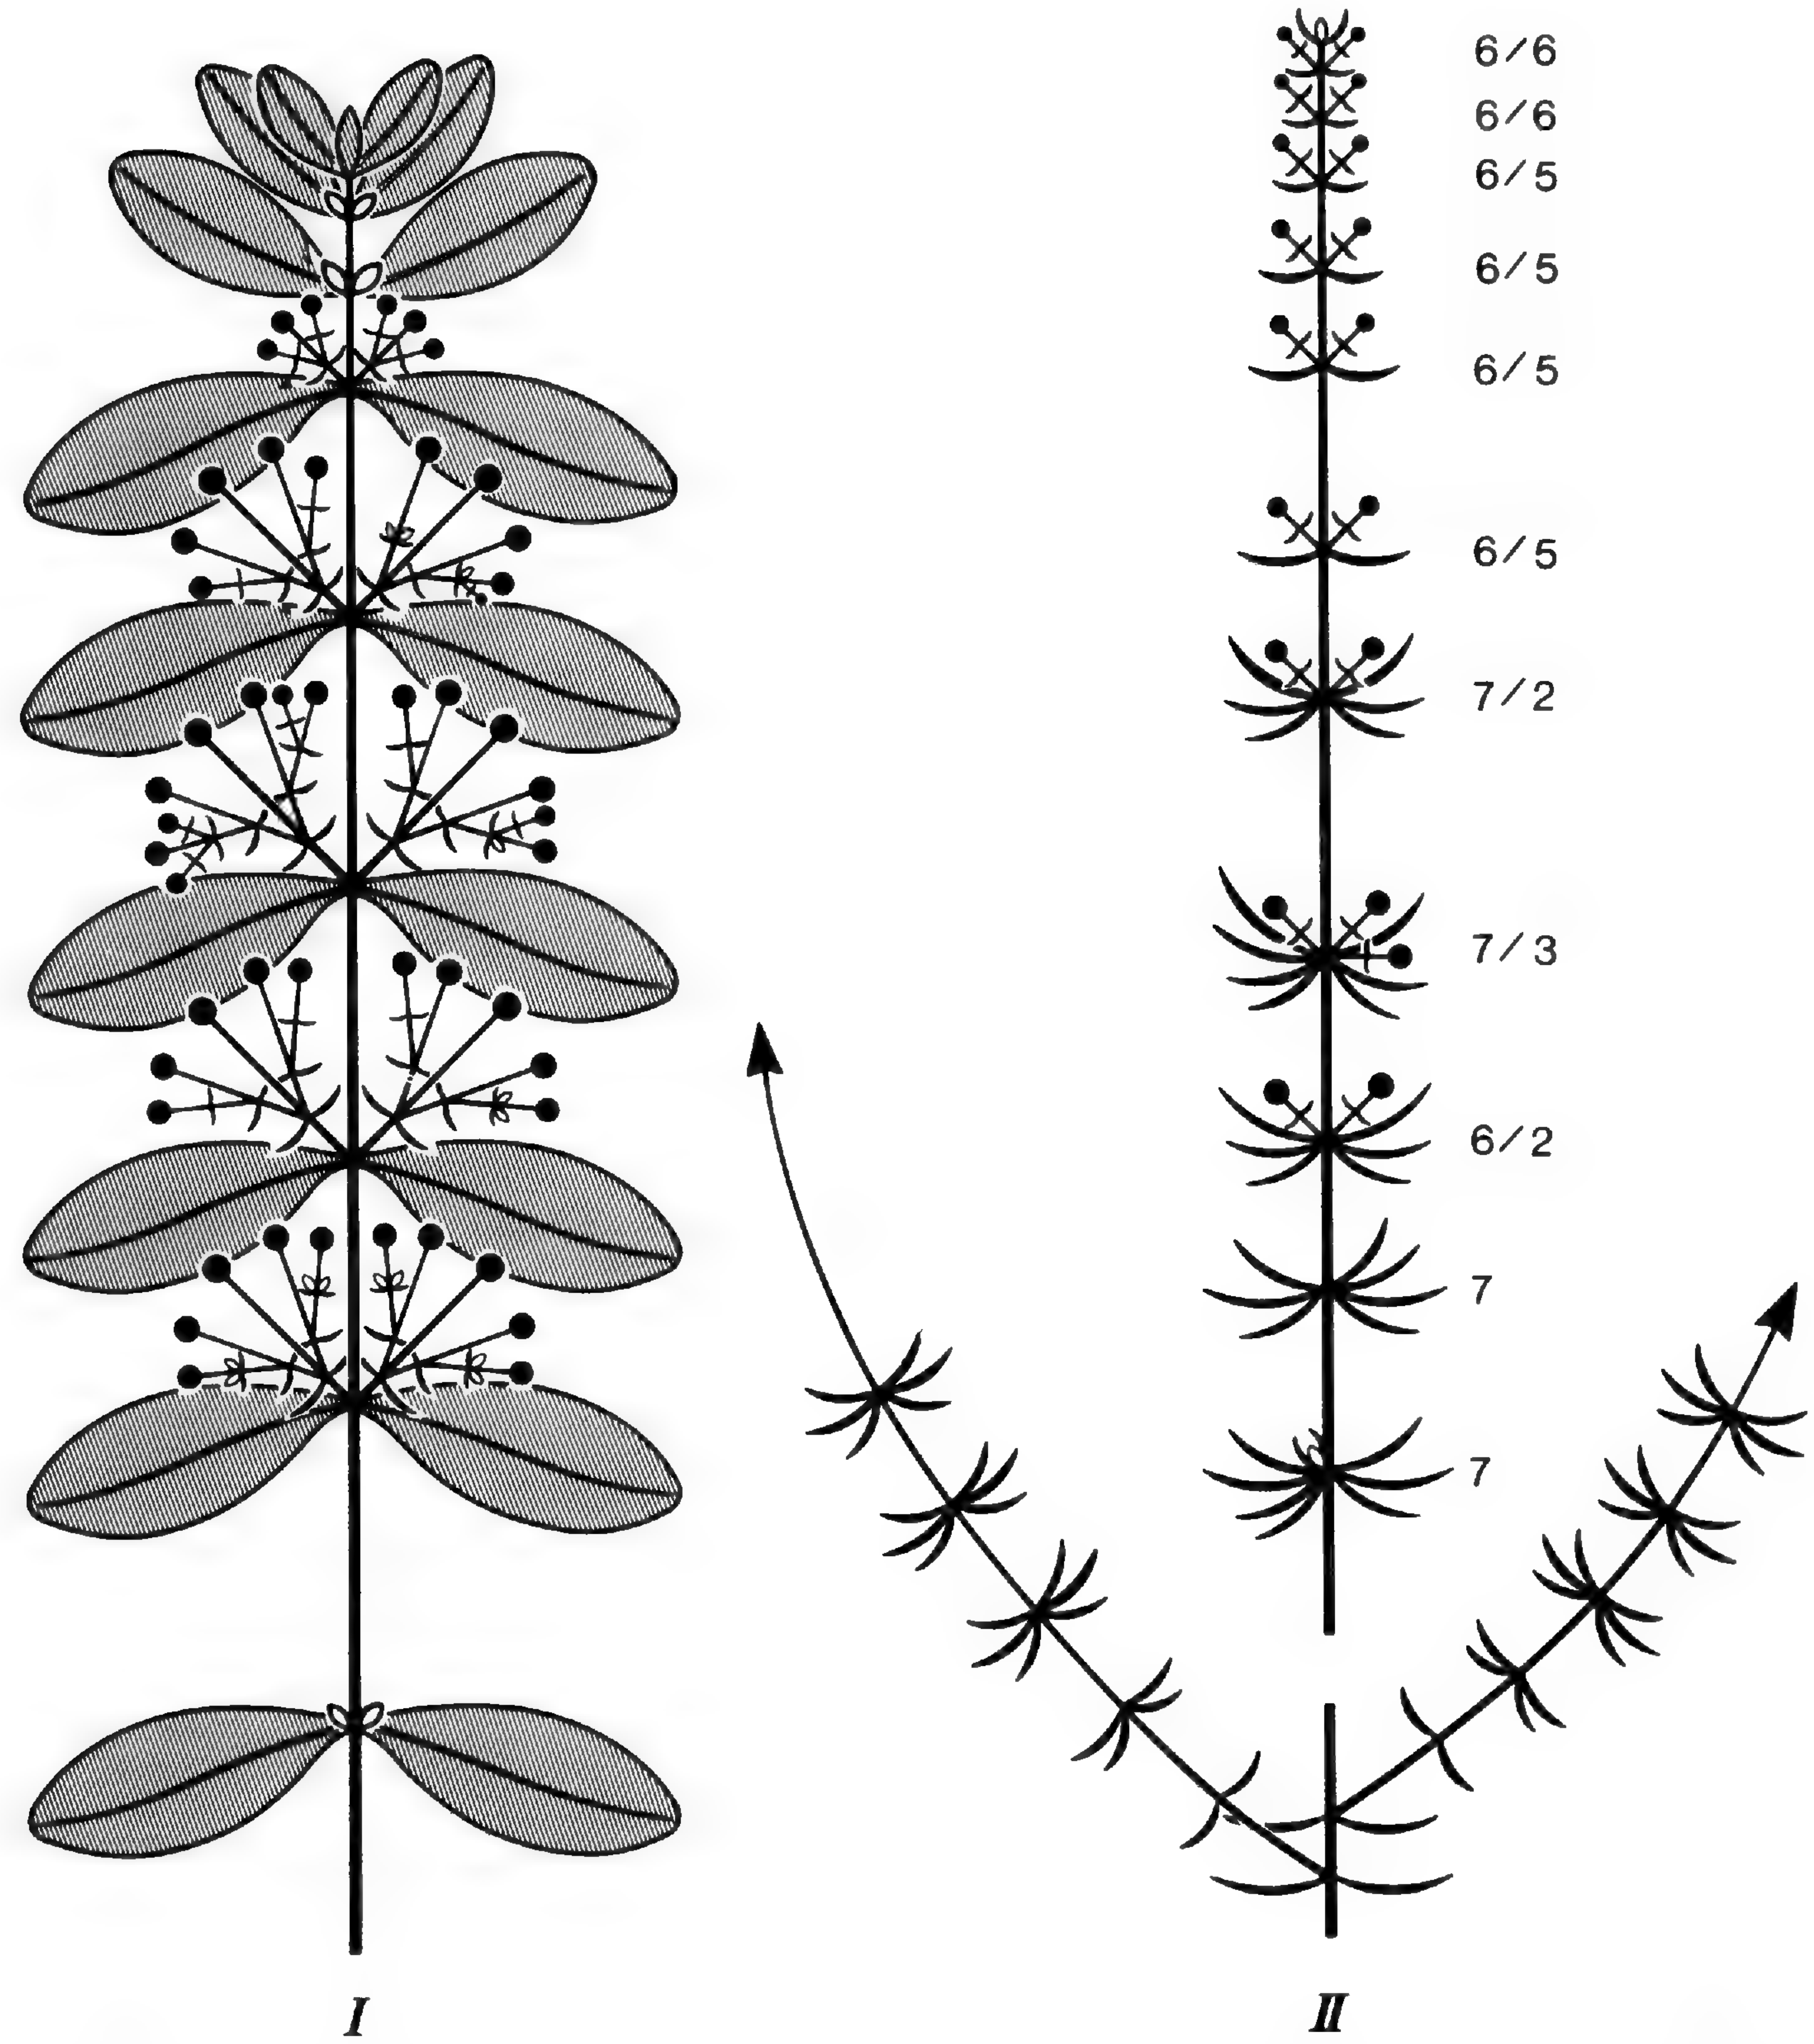

FIGURE 26. *Lythraceae.—I.* Nesaea crassicaulis; *diagram of a flowering shoot.—II.* Rotala wallichii; *flowering branch. (For each verticil of the main axis the number of leaves and of axillary flowers is added.)*

utive verticils increases gradually from two to four and six, then perhaps up to seven and decreasing to six again.

Among the taxa with copiously branched cymose partial florescences, the species of *Nesaea* sect. *Nesaea* (= sect. *Typonesaea* Koehne) subsect. *Tolypeuma* (E. Meyer) Koehne are remarkable. By shortening of the internodes of all consecutive ramifications the cymes are contracted to small headlike aggregations of flowers enveloped by an involucrum that is formed by the large cordate-lanceolate prophylls. The corollae of the flowers rise slightly above the border of these prophylls, which often are somewhat whitish and violet-nerved basally. The hypopodia of the capitulate partial florescences are prolonged. Since the main axis of the thyrsic florescences—the main florescence and the co-florescences—is anauxotelic, the flores-

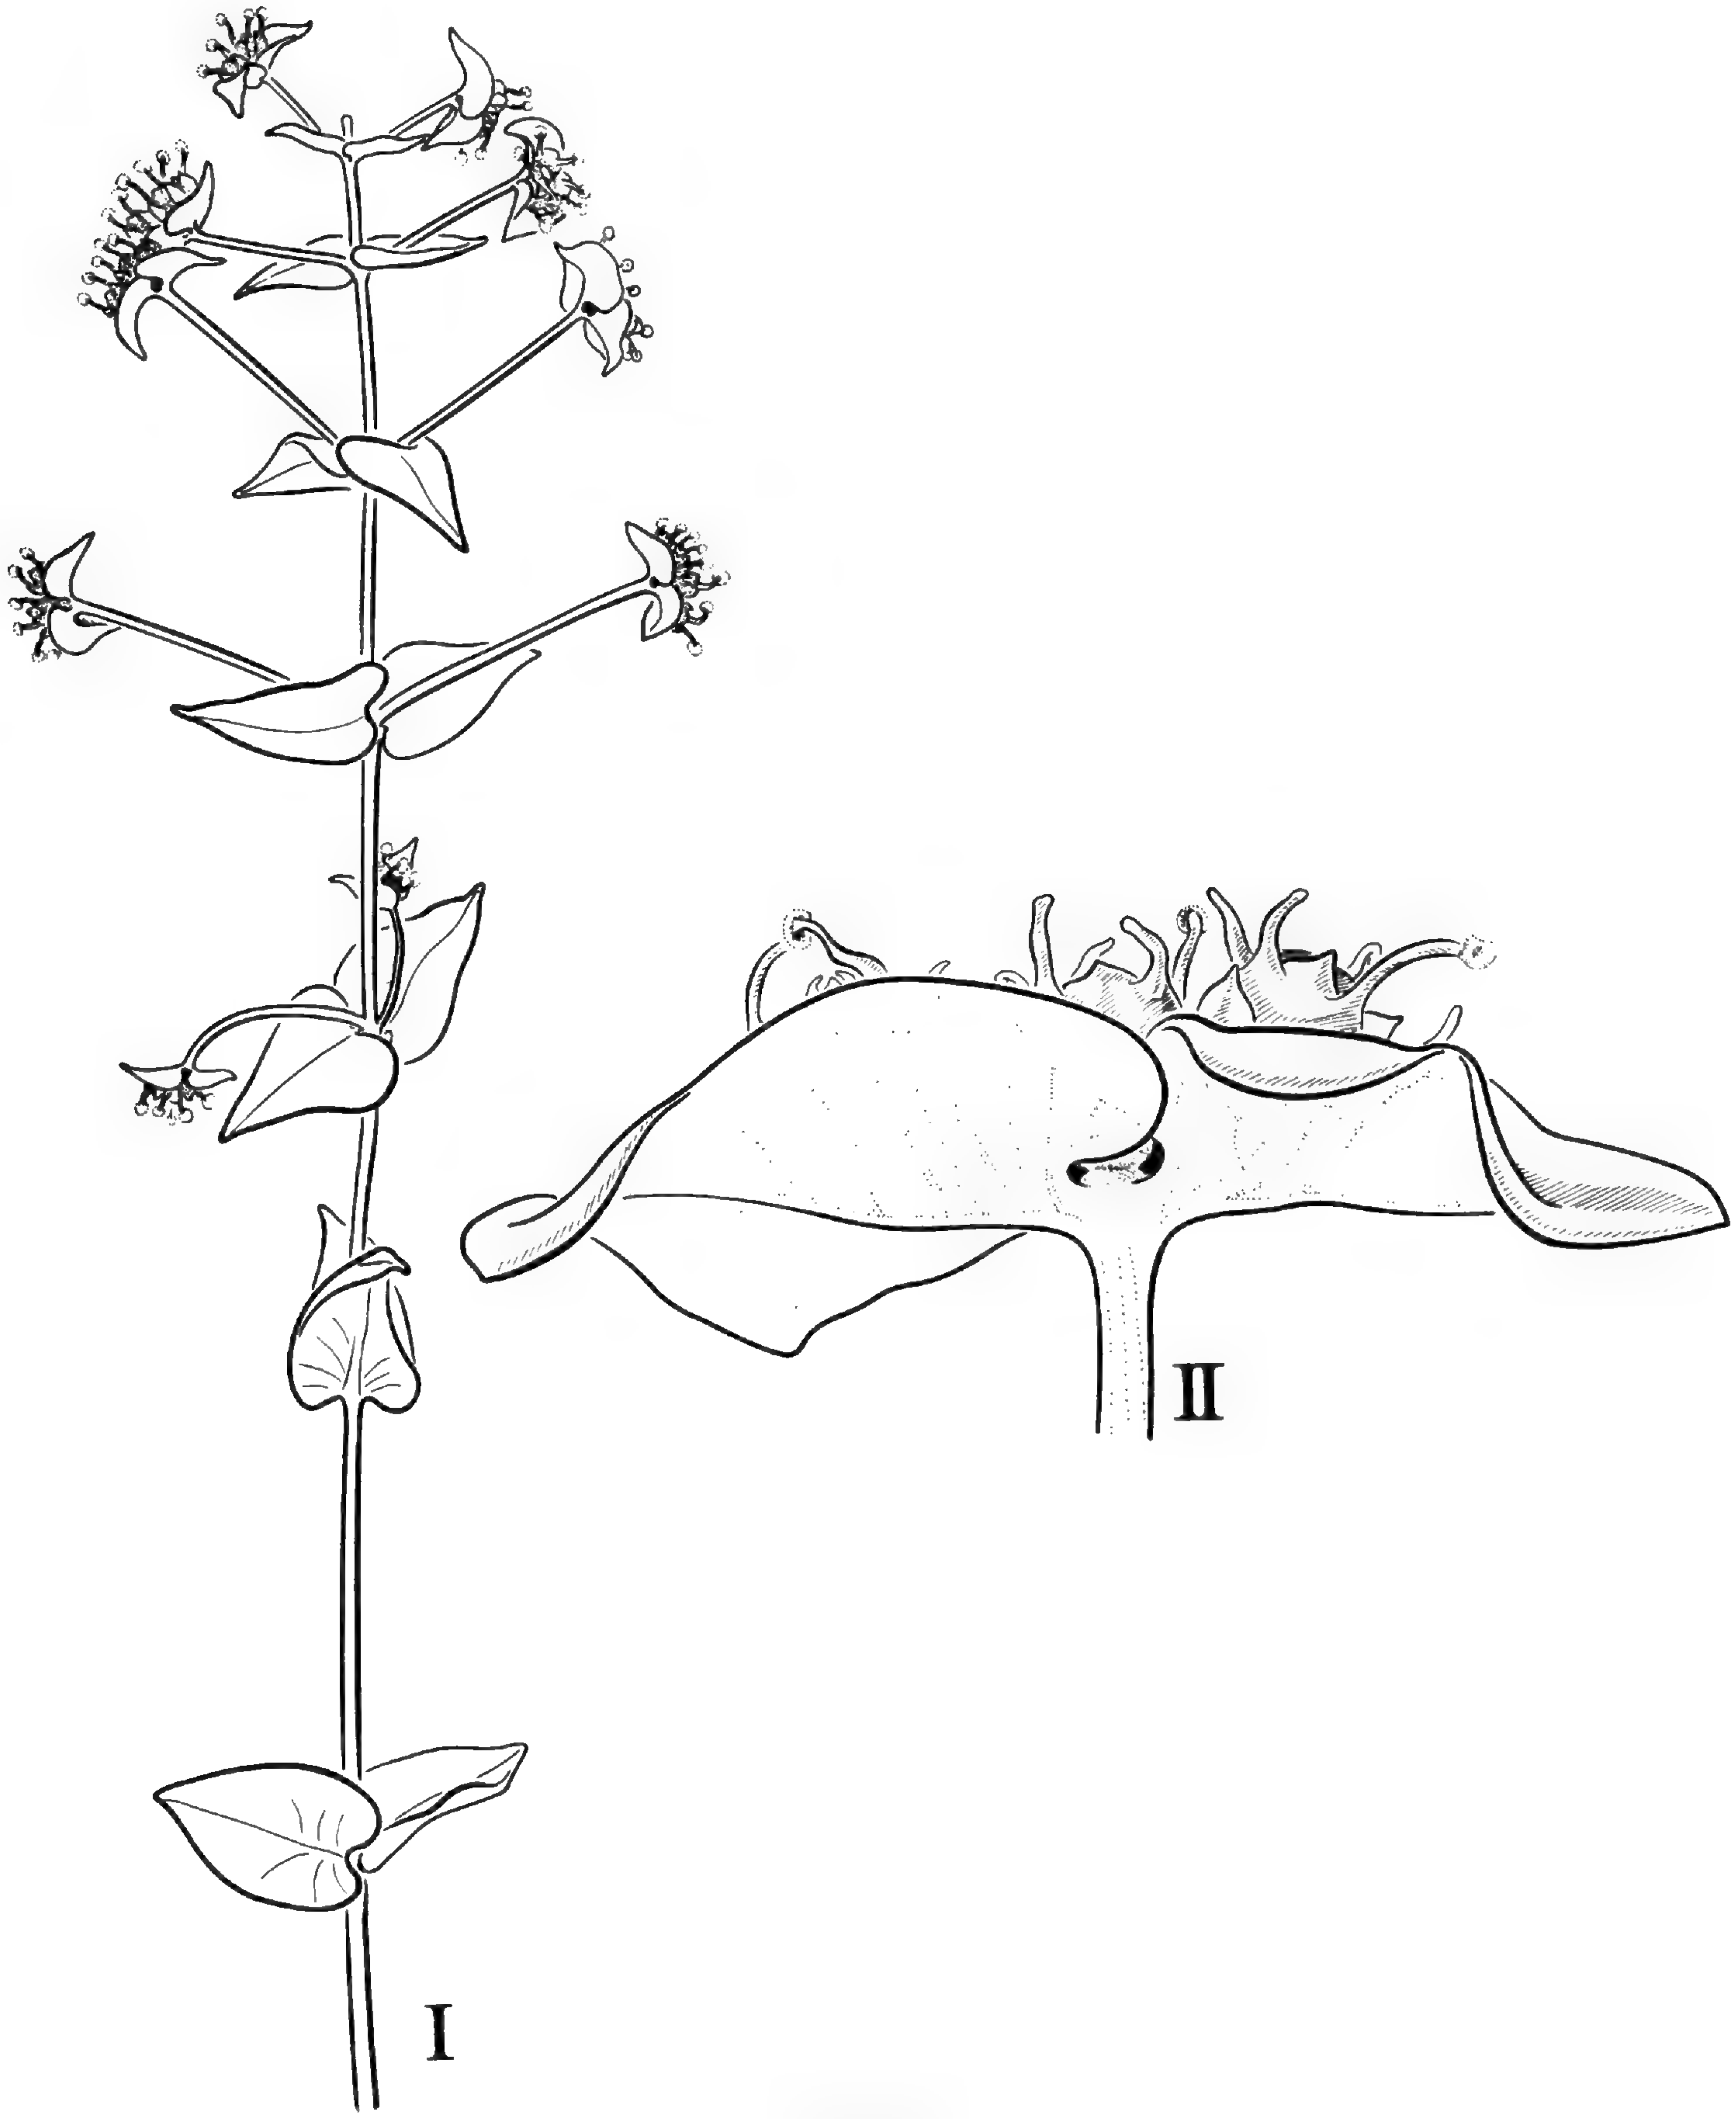

FIGURE 27. *Lythraceae.* Nesaea erecta.—*I. Flowering plant.—II. Cymose partial florescence. (Rhodesia: Mapanza,* E. A. Robinson 2839 *(M).)*

cences of these species, i.e., *Nesaea erecta* Guill. & Perr. (Fig. 27) or *N. cordata* Hiern, appear as botrytic systems composed of capitula.

In contrast to these species, the inflorescence of *Nesaea linearis* Hiern (sect. *Typonesaea* subsect. *Syntolypaea* Koehne) is described to form a terminal capitulum composed of "dichasia singula confertissima, sessilia, bracteolis superne dilatatis . . ." (Koehne, 1903: 223, 230, fig. 45C).

Likewise the lateral capitula of *Nesaea* *radicans* Guill. & Perr. (also subsect. *Tolypeuma*), which are of similar appearance to those in *N. erecta* and *N. cordata*, are described to have four or six enlarged "prophylls," each of them subtending a small "dichasium" (Koehne, 1903: 8, 231). Indeed, these capitula proved to have a thyrselike ramification and to be provided with a terminal flower as Koehne had affirmed already. He did not investigate *N. linearis* in this respect. At least for *N. radicans*, however, it seems to be evident that the inflorescences are monotelic, as Koehne (1903: 8) affirmed with the statement that the inflorescences of *N. radicans* seem to form a transition to those of *Woodfordia*, *Lagerstroemia*, and *Lawsonia*.

A remarkable condensation of florescences is typical for *Pleurophora polyandra* Hook. & Arn. also; here, however, the florescences are spikes (Fig. 28 I, II).

As the treatment of inflorescences in the Lythraceae has shown already, the disposition for proliferation of inflorescences is widespread within this family. Proliferation takes place especially in frondose florescences, for example in *Heimia*, *Nesaea crassicaulis* (Fig. 26 I), *N. sagittifolia* Koehne, or *Adenaria floribunda* (Fig. 25).

Another factor responsible for the high degree of growth-form diversity of inflorescences, especially in herbaceous and suffruticose taxa, is the variation of the proportions between the different zones of the flowering plant, i.e., in polytelic taxa the main florescence, the enrichment zone, the inhibition zone, and, in perennials, the innovation zone.

Thus, Troll (1970: 92) reported that in *Diplusodon thymifolius* DC. the main florescence remains very small in comparison with the paracladial zone. The same seems to apply to *D. virgatus* Pohl, whereas in other species, e.g., *D. villosissimus* Pohl and *D. villosus* Pohl, we found the main florescence to be predominant, although the paracladial zone can be well developed too. The distal paracladia of these species had no hypotagma.

Of course, to a certain degree such differences as the unfolding of a smaller or greater number of paracladia depend on the developmental stage of a plant and on environmental circumstances. The latter especially applies to annuals. Under severe environmental stresses such plants can be highly reduced and develop reduced inflorescences only, as Troll (1964: 363–364) described for *Ammannia coccinea* Rottb. The original plant depicted by Troll is presented here in a photograph (Fig. 28 IV). Probably the plant investigated and figured by Troll is not *Ammannia coccinea* but *A. latifolia* L.; the same then applies to Figure 28 IV. The hypotagma is reduced to two nodes. Only the uppermost of them bears paracladia, while the paracladia in the axils of the cotyledons remain undeveloped. The largest part of the plant is formed by the frondose proliferating florescence with many triadic partial florescences. In reduced plants of *Pleurophora polyandra* the inflorescence frequently only consists of a short headlike spike that is preceded by the cotyledons and two pairs of foliaceous leaves with paracladia absent from their axils (Fig. 28 I). In other individuals, more or less vigorous paracladia ending in a florescence can develop from the axils of the cotyledons and/or from the axils of the following leaf pairs (Fig. 28 II). In *P. pusilla* Hook. & Arn. the reduction of ramification seems to be a constituted character.

By dense sowing of *Lythrum hyssopifolia* L., plants without any paracladia were obtained by Troll (posthumous notices), whereas in normal plants the paracladial zone is well developed.

The frequent occurrence of accessory buds that develop as single flowers or vegetative or flower-bearing branches has been mentioned already. With the exception of *Cuphea* (Eichler, 1878b: 479), there is scarcely a genus of Lythraceae in which they are completely missing. Since Koehne (1873: 112) has given a survey of the various forms and their distribution within the family, we can confine ourselves to the treatment of the genus *Lythrum*, in which the occurrence of accessory flowers is very important for the appearance of the inflorescences.

In *Lythrum* the florescences of subgen. *Lythrum* (= *Salicaria* Koehne) and of sect. *Mesolythrum* Koehne of subgen. *Hyssopifolia* are spikes or botrya.

A flowering individual of *Lythrum salicaria* L. (Fig. 29 II, III) shows a clear zonation: the frondulose main florescence, a paracladial zone (enrichment zone) in which the paracladia are still unfolding, and an inhibition zone below the paracladial zone. Since *Lythrum salicaria* is a perennial, the inhibition zone is preceded by an innovation zone at the base of the plant. According to Troll (posthumous notices), *L. salicaria* is a subshrub rather than a perennial herb since the primary axis as well as the primary root shows intense lignification, as in *Hypericum perforatum*. In young plants (Fig. 29 I) a favored development of the axillary buds of the cotyledons (cotyledonary shoots) and of the next basal leaf pair can be seen. The cotyledonary shoots can develop branches from the axils of their prophylls at early stages, and a phylloscopic accessory bud can arise in the axils of the cotyledons. In vigorous plants the paracladial zone can be considerably expanded, and the paracladia can develop second-order paracladia. In the basal part of the flowering zone the phyllotaxis changes from decussate to alternate (Wydler, 1860: 238; for the phyllotaxis of *L. virgatum* and *L. hyssopifolia* see Wydler, 1872: 254). The florescences are thyrses, however exceedingly modified by the formation of phylloscopic accessory cymes or flowers (Roeper, 1826: 109).

Eichler (1878b: 479) observed that below the cymose partial florescence there are mostly two accessory three-flowered cymes (Fig. 30 IIa), the lower of which is often rudimentary. There is an additional accessory flower below each of the lateral (secondary) flowers of the primary partial florescence. These additional flowers bear prophylls as do the regular lateral (secondary) flowers of the cyme. Thus a transversal series of five flowers results, below which there is a three-flowered cyme still provided with prophylls of first order, and below this another one of rudimentary flowers without prophylls. *Lythrum purshianum* Steudel is reported to be similar in this respect (Fig. 30 IIb).

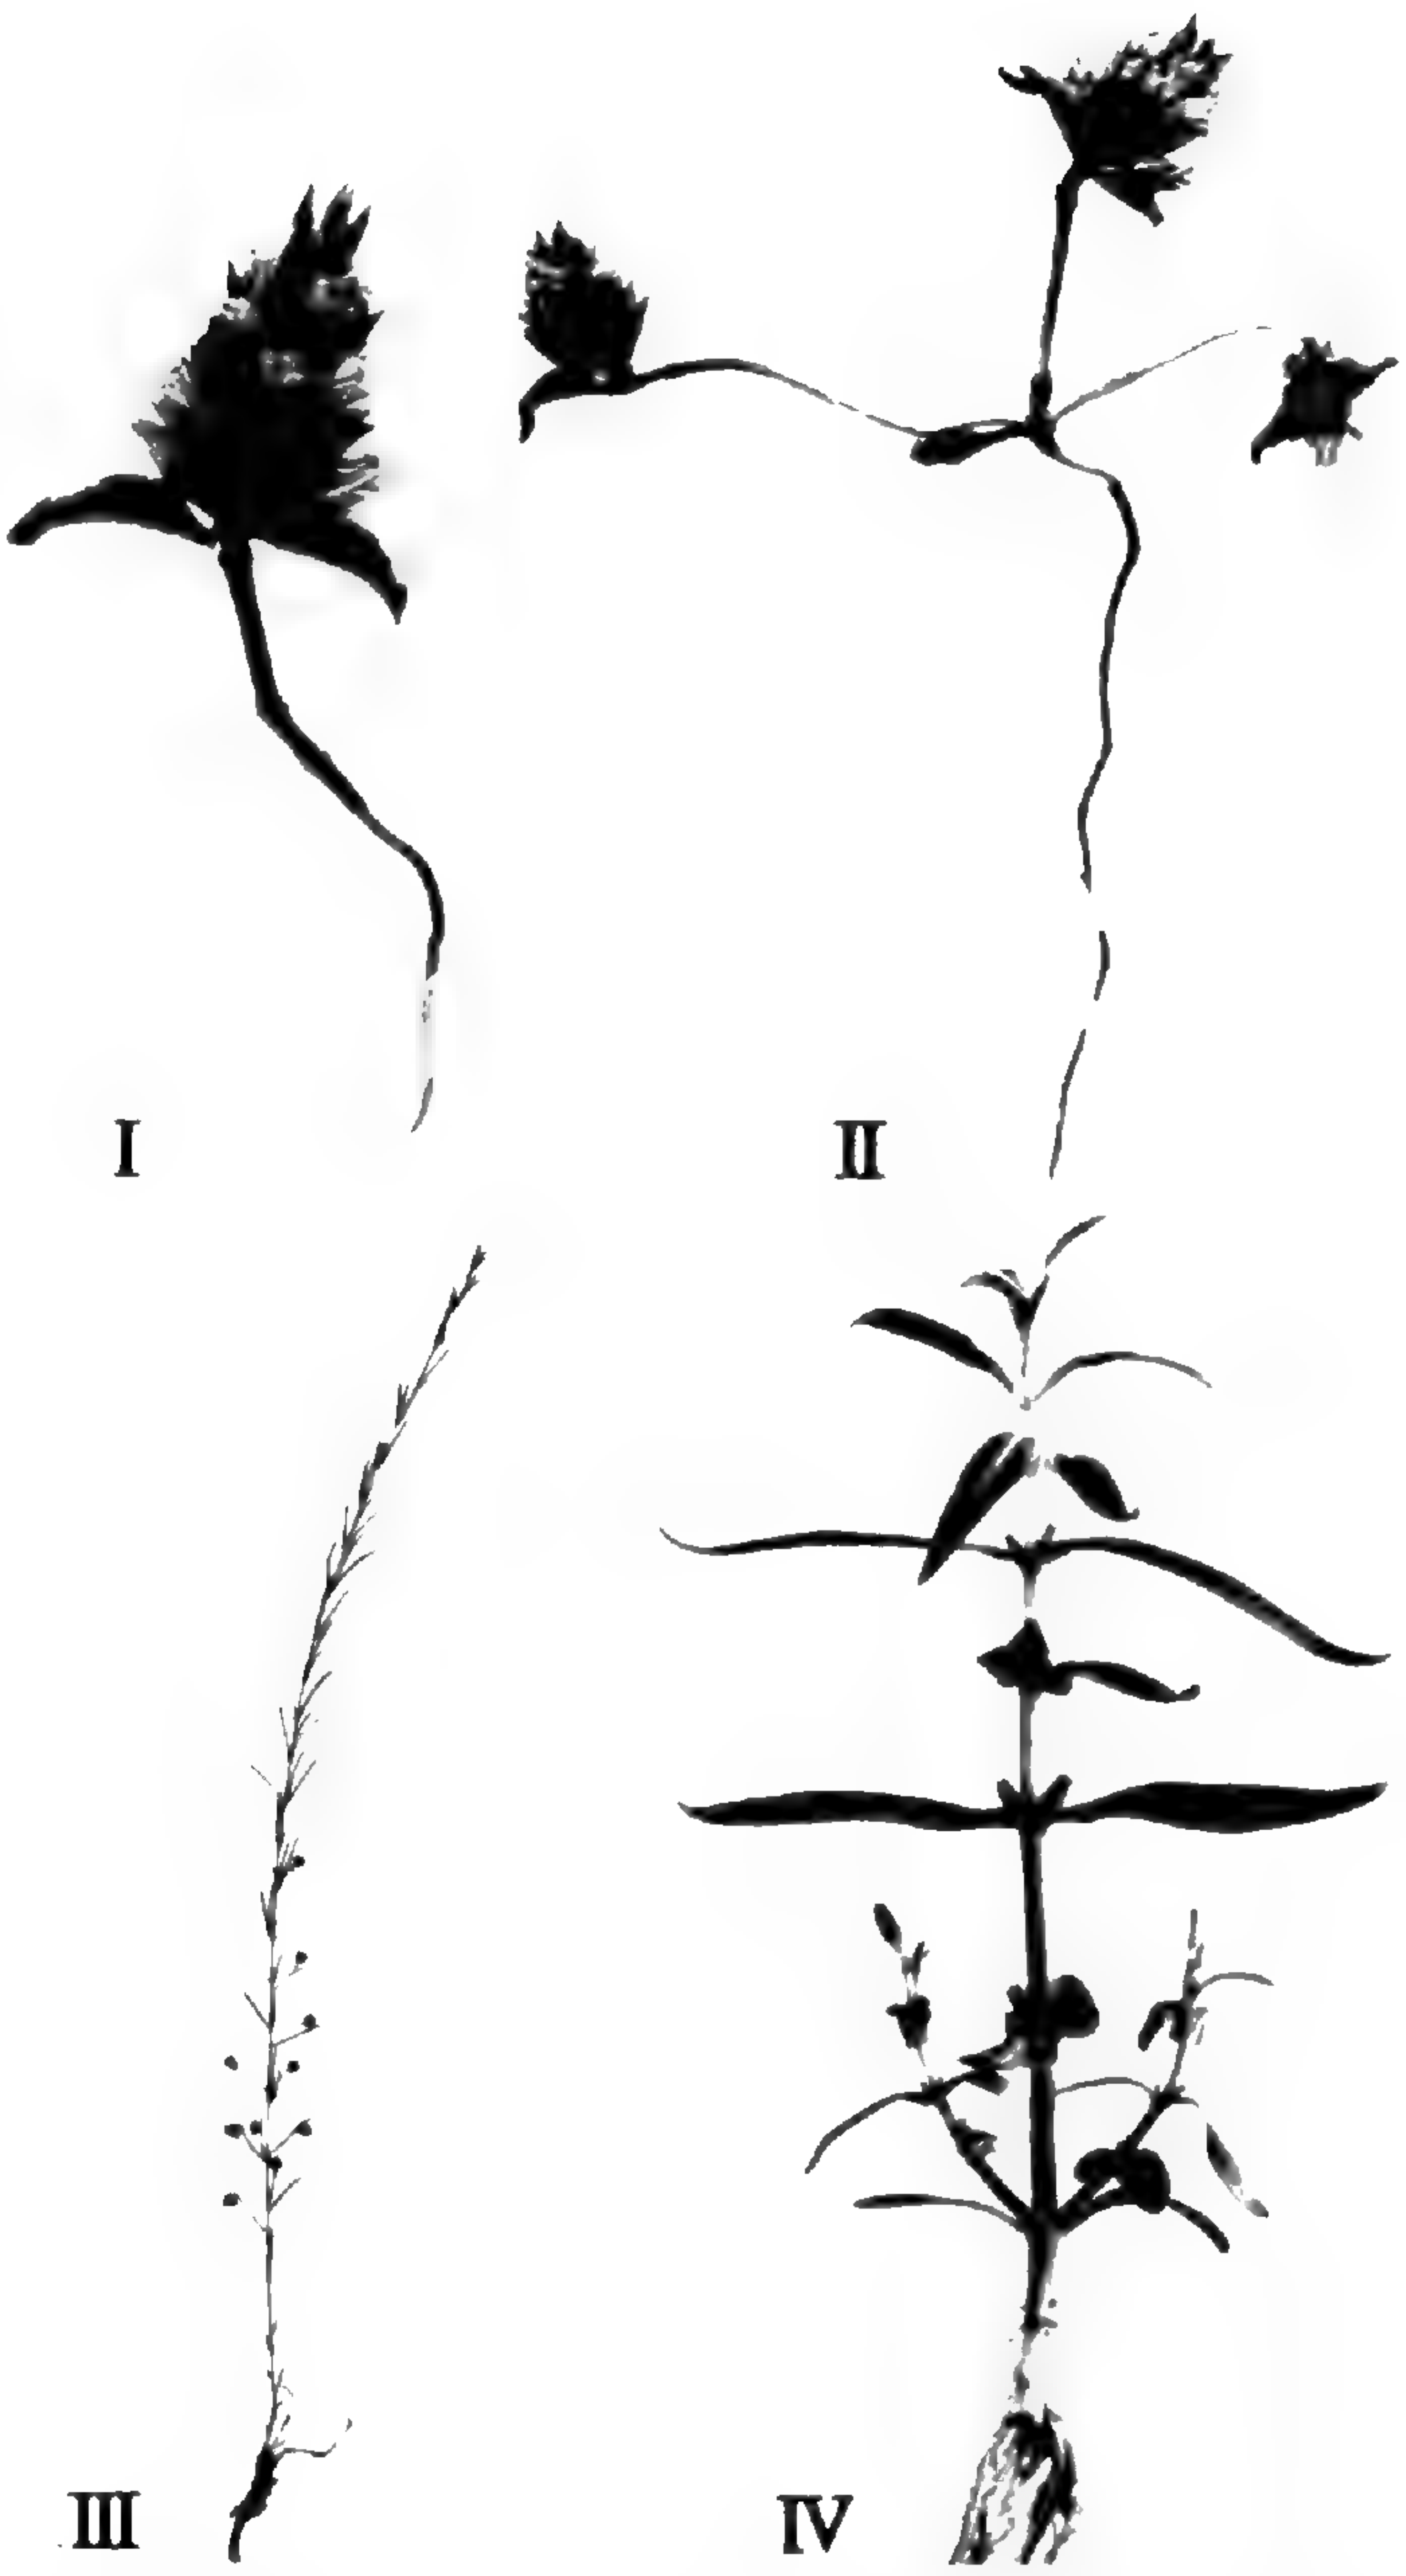

FIGURE 28. *Lythraceae.—I, II.* Pleurophora polyandra; *reduced form (I) and plant with well-developed basal paracladia (II).—III.* Nesaea linifolia; *flowering individual.—IV.* Ammannia coccinea; *reduced individual. (Photographs III and IV from Troll.)*

Troll (posthumous notices), however, found triadic flower groups in place of the singular accessory flowers that accompany the secondary flowers of the regular partial florescence (Fig. 30 Ia). He also noted that there may be one (as_1) or two (as_1, as_2) accessory cymes. In the latter case the as_1 bears single accessory flowers in the axils of its prophylls, and the as_2 likewise is provided with prophylls (Fig. 30 Ic).

In all partial florescences, anthesis of the primary flower takes place first, followed by the secondary flowers, then the primary flow-

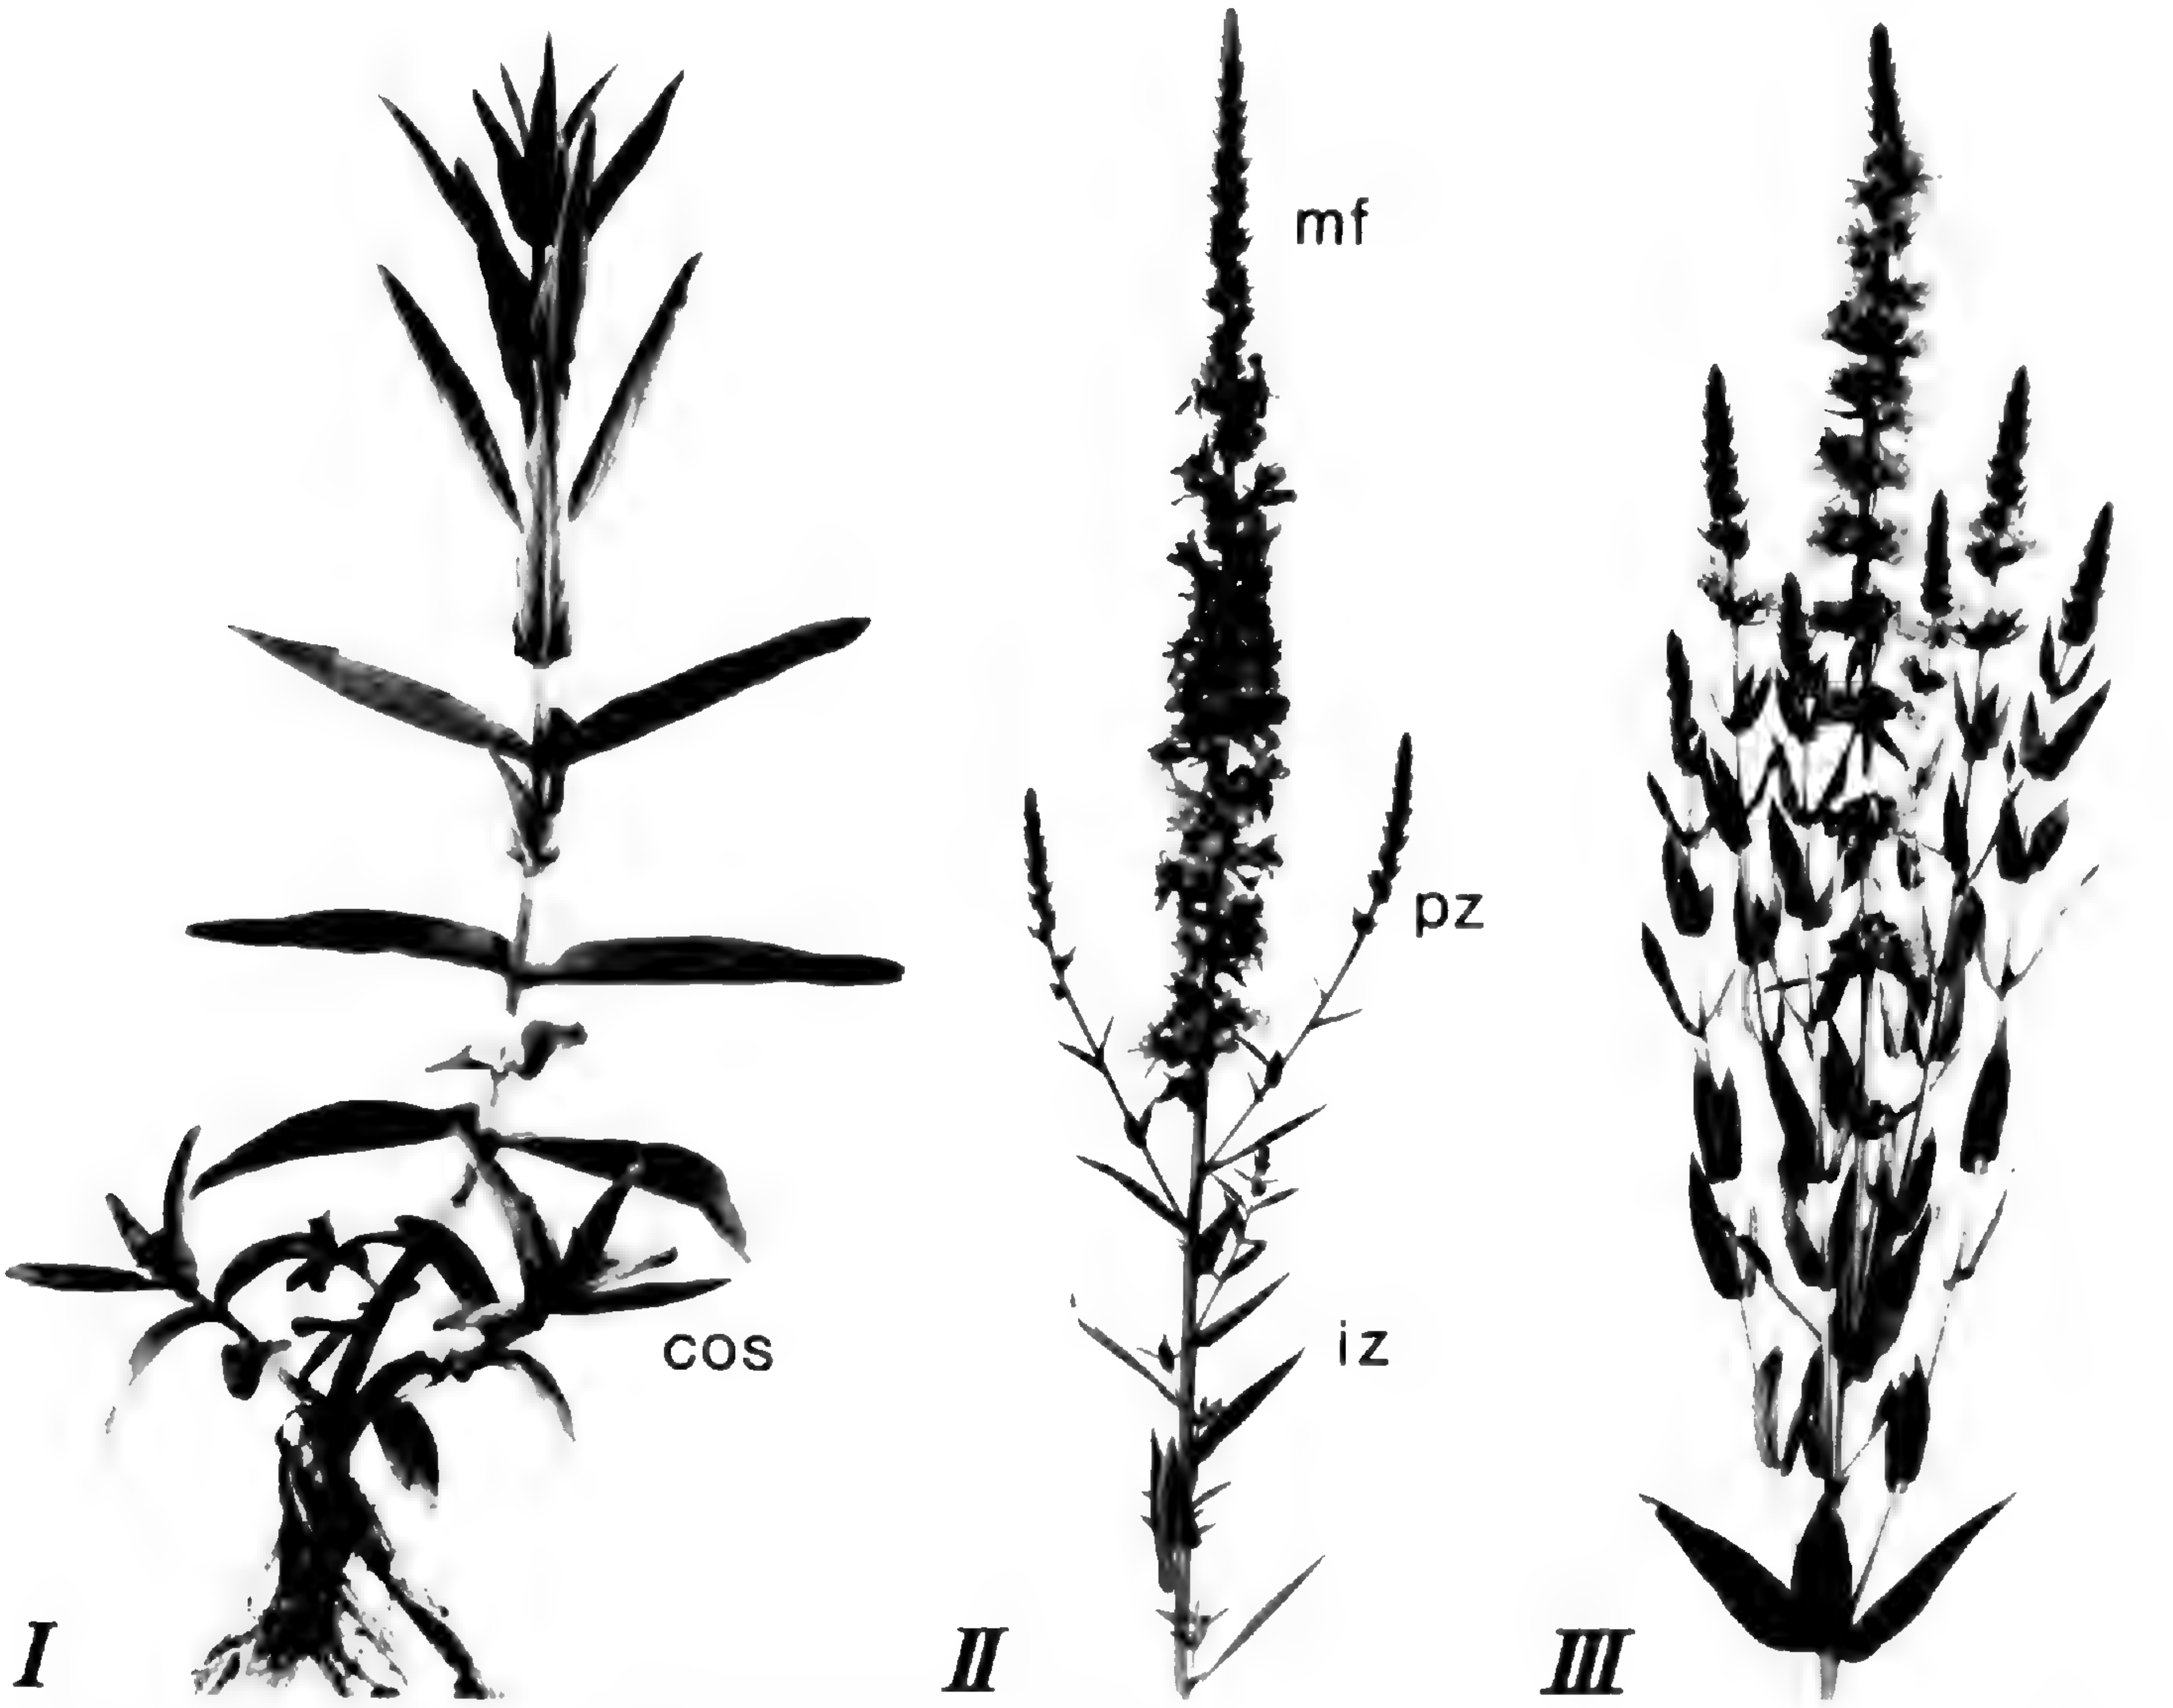

FIGURE 29. *Lythraceae.* Lythrum salicaria *L.—I. Young plant with favored development of the cotyledonary shoots (cos) and a second pair of basal branches.—II. (Photographs from Troll.)*

ers of the as_1, and so forth. As a consequence, the efflorescence of the whole florescence is progressing from base to top repeatedly "as in *Verbascum*" (Wydler, 1843: 184, 1851a: 370–371). According to Wydler (1860: 240), who referred to Koch, it is not rare to have a vegetative accessory bud below the single flowers of the spicate florescence.

Koehne (1903: 6) reported that in *Lythrum tribracteatum* Salzm. and some other species the accessory branch forms a short, dense botrytic florescence.

By *recaulescent* shifting, the place of attachment of the subtending leaves (pherophylls) can be relocated onto the pedicels of the flowers, which in reality originate from the axils of the pherophylls. Thus these can be situated just below the flower. Examples can be found in *Rotala* and *Decodon*.

In most species of *Cuphea*, the attachment of the flowers within the botrytic florescences is modified by the coalescence of their pedicels with the main axis up to the next node (Hochstetter, 1850: 182; Wydler, 1851a: 371, 1861; Eichler, 1878b: 478 ff.). This sort of concrescence is well known as *concaulescence*. In *C. nitidula* Kunth, *C. appendiculata* Benth., and some other species (cf. Koehne, 1883: 119), the flowers are mostly still in normal axillary position. In the case that both axils of the decussate leaves are fertile ("*Cupheae oppositiflorae*"), the pedicels of both flowers are attached to the main axis up to the next node (Fig. 31). Thus the flowers and prophylls attached between the insertion of the leaves (or somewhat below) really originate from the leaf axils of the preceding node. In "*C. oppositiflorae*" even the

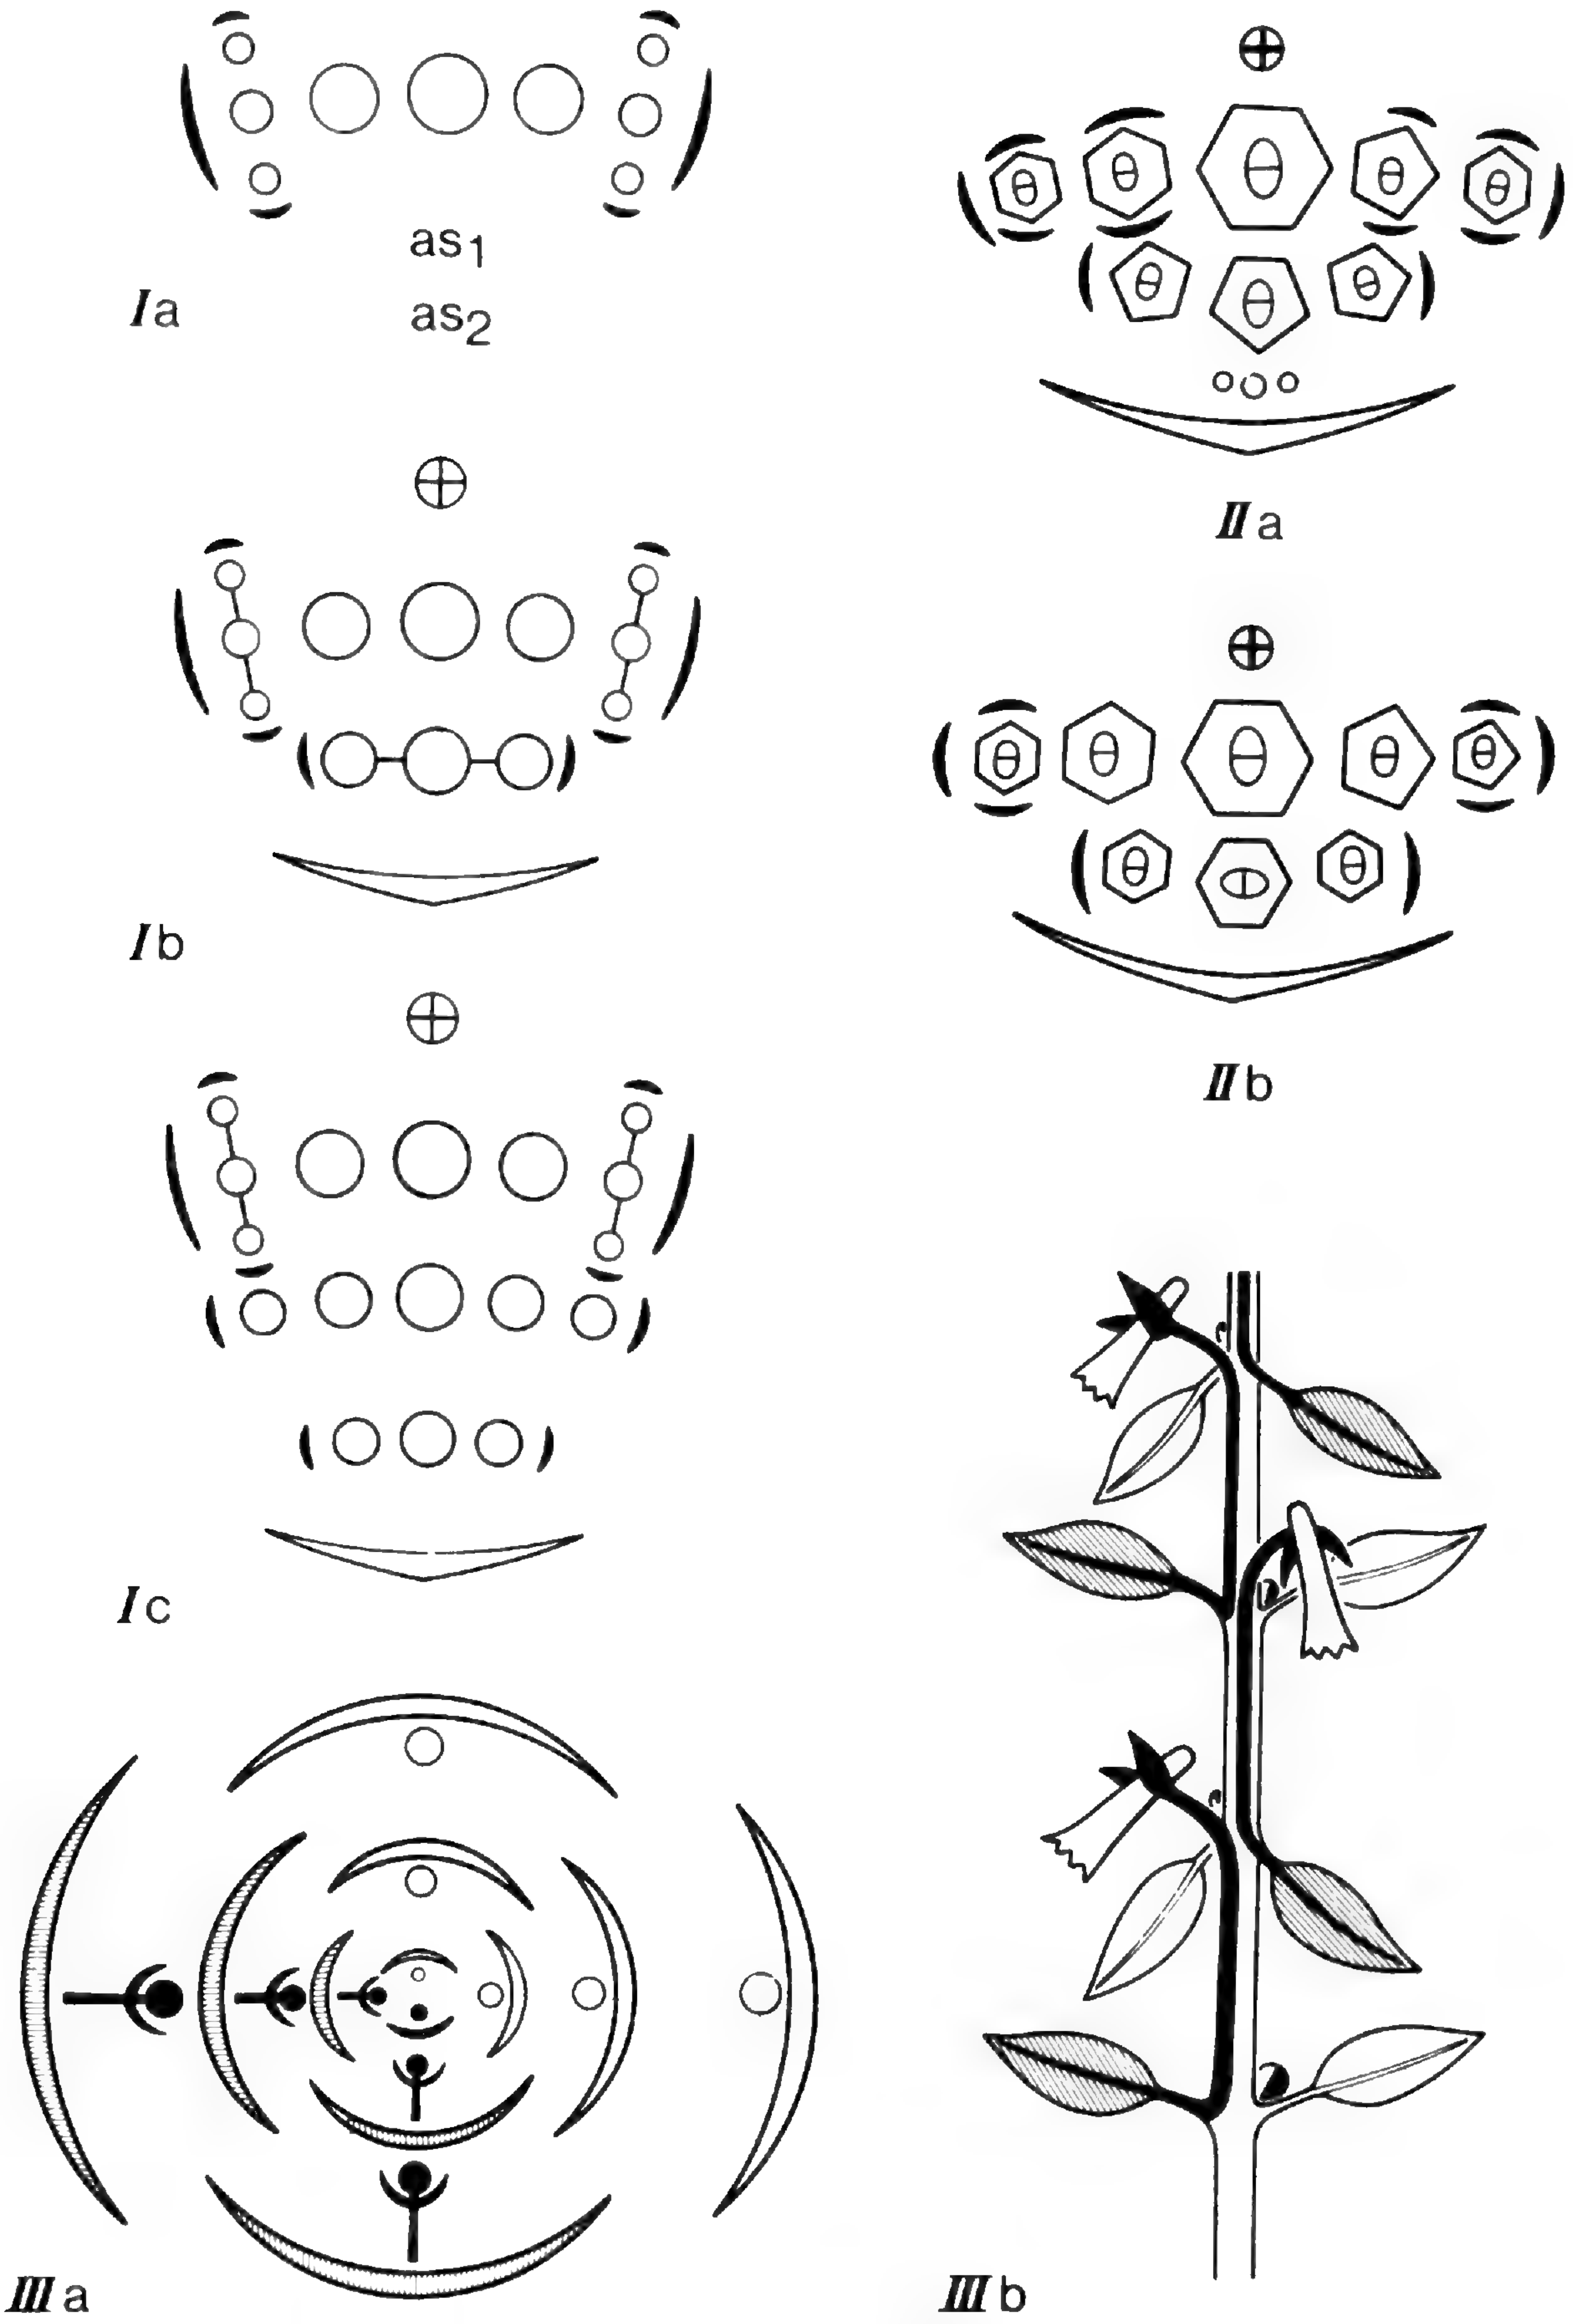

FIGURE 30. *Lythraceae.—I, II. Partial florescences and accessory flowering branches (as₁, as₂) of* Lythrum salicaria *in diagrams according to Troll (Ia–c) and Eichler, and of* L. purshianum *according to Eichler (IIb).—III. Horizontal (IIIa) and vertical (IIIb) projections of ramification in alternatiflorous* Cuphea latifolia *after Eichler (slightly modified).*

initially vegetative branches show a slight concaulescence (Koehne, 1873: 111). In the case that only one leaf axil of a node is fertile (*C. alterniflorae*), there is only one flower attached at the flanks of the next node. The bud situated in the second axil of the opposite leaves remains within the axil. Since the fertile axil of the third node always is placed above

FIGURE 31. *Lythraceae.—Top, left.* Cuphea latifolia; *plant at the beginning of flowering.—Top, right.* C. procumbens; *florescence.—Bottom.* C. micropetala; *florescence (left), and detail (right). (Photographs from Troll.)*

FIGURE 32. *Combretaceae.* Combretum coccineum; *flowering branches in anthesis (I) and before anthesis (II). (Photographs from Troll.)*

the fertile axil of the first, and the fourth always is superposed to the fertile axil of the second node (Fig. 30 IIIb), the result is two vertical rows of flowers diverging by 90° (just as two vertical rows of axillary buds, Fig. 30 IIIa).

The ligneous genus *Rhynchocalyx* Oliv., formerly included in Lythraceae and now regarded to represent a separate family, has monotelic inflorescences. In *R. lawsonioides* Oliv., the inflorescence forms a bracteose thyrso-paniculate system at the end of leafy shoots. At the bases of the paracladia uniflorous or triflorous accessory branches can be found.

The monotypic genus *Alzatea*, which is now regarded to form a separate family, has diplothyrsoidal inflorescences, probably of monotelic character. On the latter point some uncertainty remains because of the fragmentary state of the examined herbarium material of *A. verticillata* Ruiz & Pavón. The lowermost thyrsoidal paracladia are accompanied by accessory branches that form thyrsoids too.

In the monotelic character of their conical dithyrsoidal inflorescences, *Rhynchocalyx* and *Alzatea* at least do not join the progressed members of the Lythraceae.

COMBRETACEAE

The inflorescences of Combretaceae are polytelic throughout. Although there are prophylls present in *Laguncularia*, *Lumnitzera*, and *Macropteranthes*, the florescences are nearly always spikes or rarely botrya.

The central type of inflorescence architecture within the family may be represented by *Combretum coccineum* (Sonn.) Lam. (Fig. 32 I). The leafy shoots terminate in a synflorescence composed of a botrytic main florescence at the top of the whole ramification system, preceded by several pairs of paracladia. Phyllotaxis is often not strictly decussate

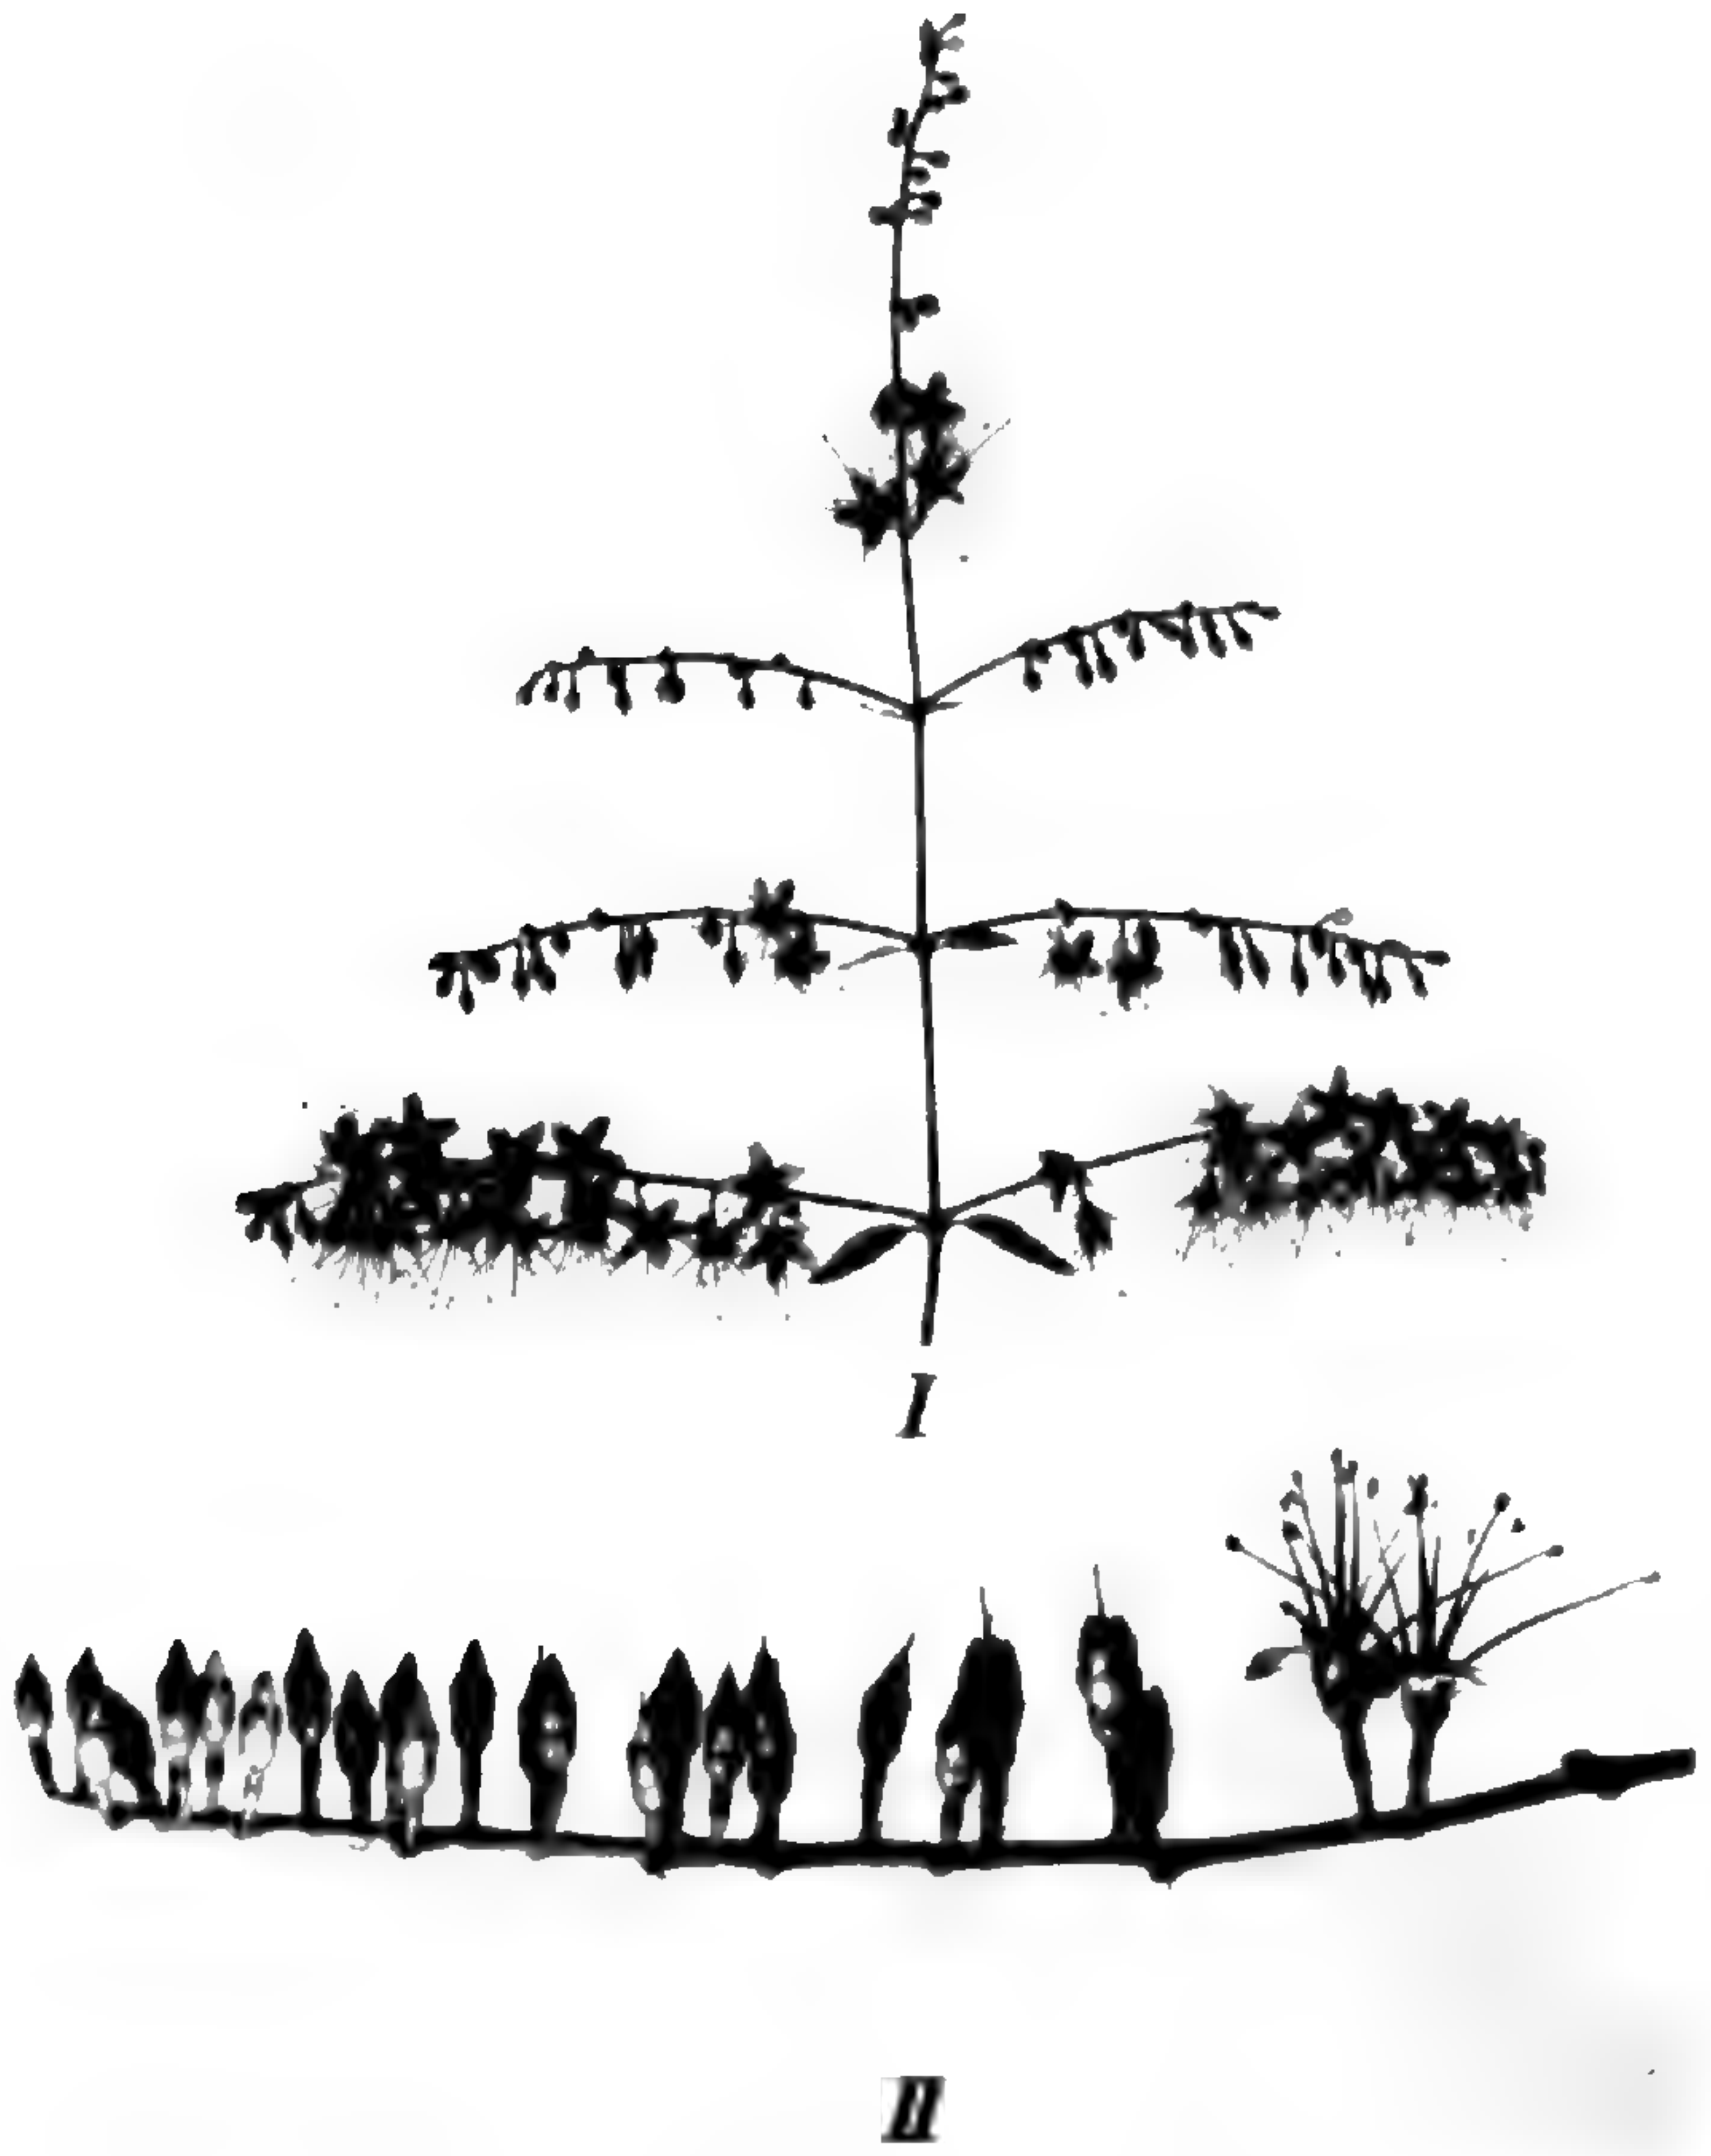

FIGURE 33. *Combretaceae*. Combretum coccineum.—*I. Mode of efforation.—II. Detail. (Photographs from Troll.)*

within the family. Besides *Terminalia*, seven genera are reported to have alternate leaves, though in many cases they are subdecussate. In many climbers only the distal branches show decussate leaves. In *Terminalia*, *Bucida*, *Buchenavia*, *Ramatuela*, *Anogeissus*, *Finetia*, *Conocarpus*, and *Lumnitzera*, the leaves are spiral. The four distal pairs of paracladia are confined to their (co-)florescences, whereas the two proximal pairs bear two or four pairs of second-order paracladia, which are likewise limited to their (co-)florescences. In descriptive terms the ramification can be classified as a heterothetic triplobotryum. The foliation in the proximal part of the main axis is frondose but quickly changes over to bracteose; the flower-bearing twigs only develop small bracts. As shown by Figure 33 I, II, the efflorescence progresses from base to top in the sequence of the paracladia (I) as well as in the paracladia themselves (II); in this course the main florescence gains a slight lead in comparison with the preceding paracladia. Figure 33 II also shows that all flowers of the florescences, even those of plagiotropic orientation, are turned upwards, a typical feature of many species, which has led to the popular name "cepillo de mono" (monkey's brush). This name especially applies to *C. fruticosum* (Loefl.) Stuntz (*C. secundum* Jacq., Fig. 34), in which the paracladia are poorly developed in favor of the vigorous development of the dense-flowered main florescence. In Figure 32 II, each of the first-order paracladia is accompanied by an accessory branch bearing a botrytic florescence. This is typical of many Combretaceae.

Synflorescences similar to those described here for *Combretum coccineum* can be found in various taxa of the family, such as *Laguncularia racemosa* (L.) Gaertner, *Thiloa glaucocarpa* (Martius) Eichler, *Calycopteris floribunda* (Roxb.) Lam., *Meiostemon tetrandrus* (Exell) Exell & Stace (cf. table I in Exell & Stace, 1966), *Campylogyne* Welw. ex Hemsley (the florescences with showy bracts), species of *Buchenavia* and *Terminalia* (*T. tomentosa* Bedd.; *T. paniculata* Roth, see also Sell, 1982, fig. 10a; *T. citrina* (Gaertner) Roxb. ex Fleming; *T. chebula* Retz., cf. Brandis, 1893, fig. 55), and in *Quisqualis*. In *Q. indica* L., the inflorescence can consist of a spicate main florescence terminating leafy twigs, contrasting with them by its bracteous foliation. The main florescence, however, can be accompanied by one or two pairs of paracladia originating from the axils of the foliaceous leaf pairs preceding the main florescence. These paracladia usually bear one or two more or less foliaceous leaf pairs at their bases. Likewise, the lowermost leaf pair of the main florescence may be somewhat foliaceous. *Cacoucia coccinea* Aublet (*Combretum cacoucia* (Ball.) Exell) seems to be characterized by developing only a long voluminous main florescence (Fig. 35). The same applies to some other species formerly included in this genus (*Cacoucia splendens* Hemsl. = *Combretum bracteatum* (Laws. pro parte) Engl. & Diels, *Cacoucia paniculata* Laws.).

Lumnitzera coccinea and *L. racemosa* differ considerably in the position of their spicate florescences (see also Brandis, 1893). In *L.*

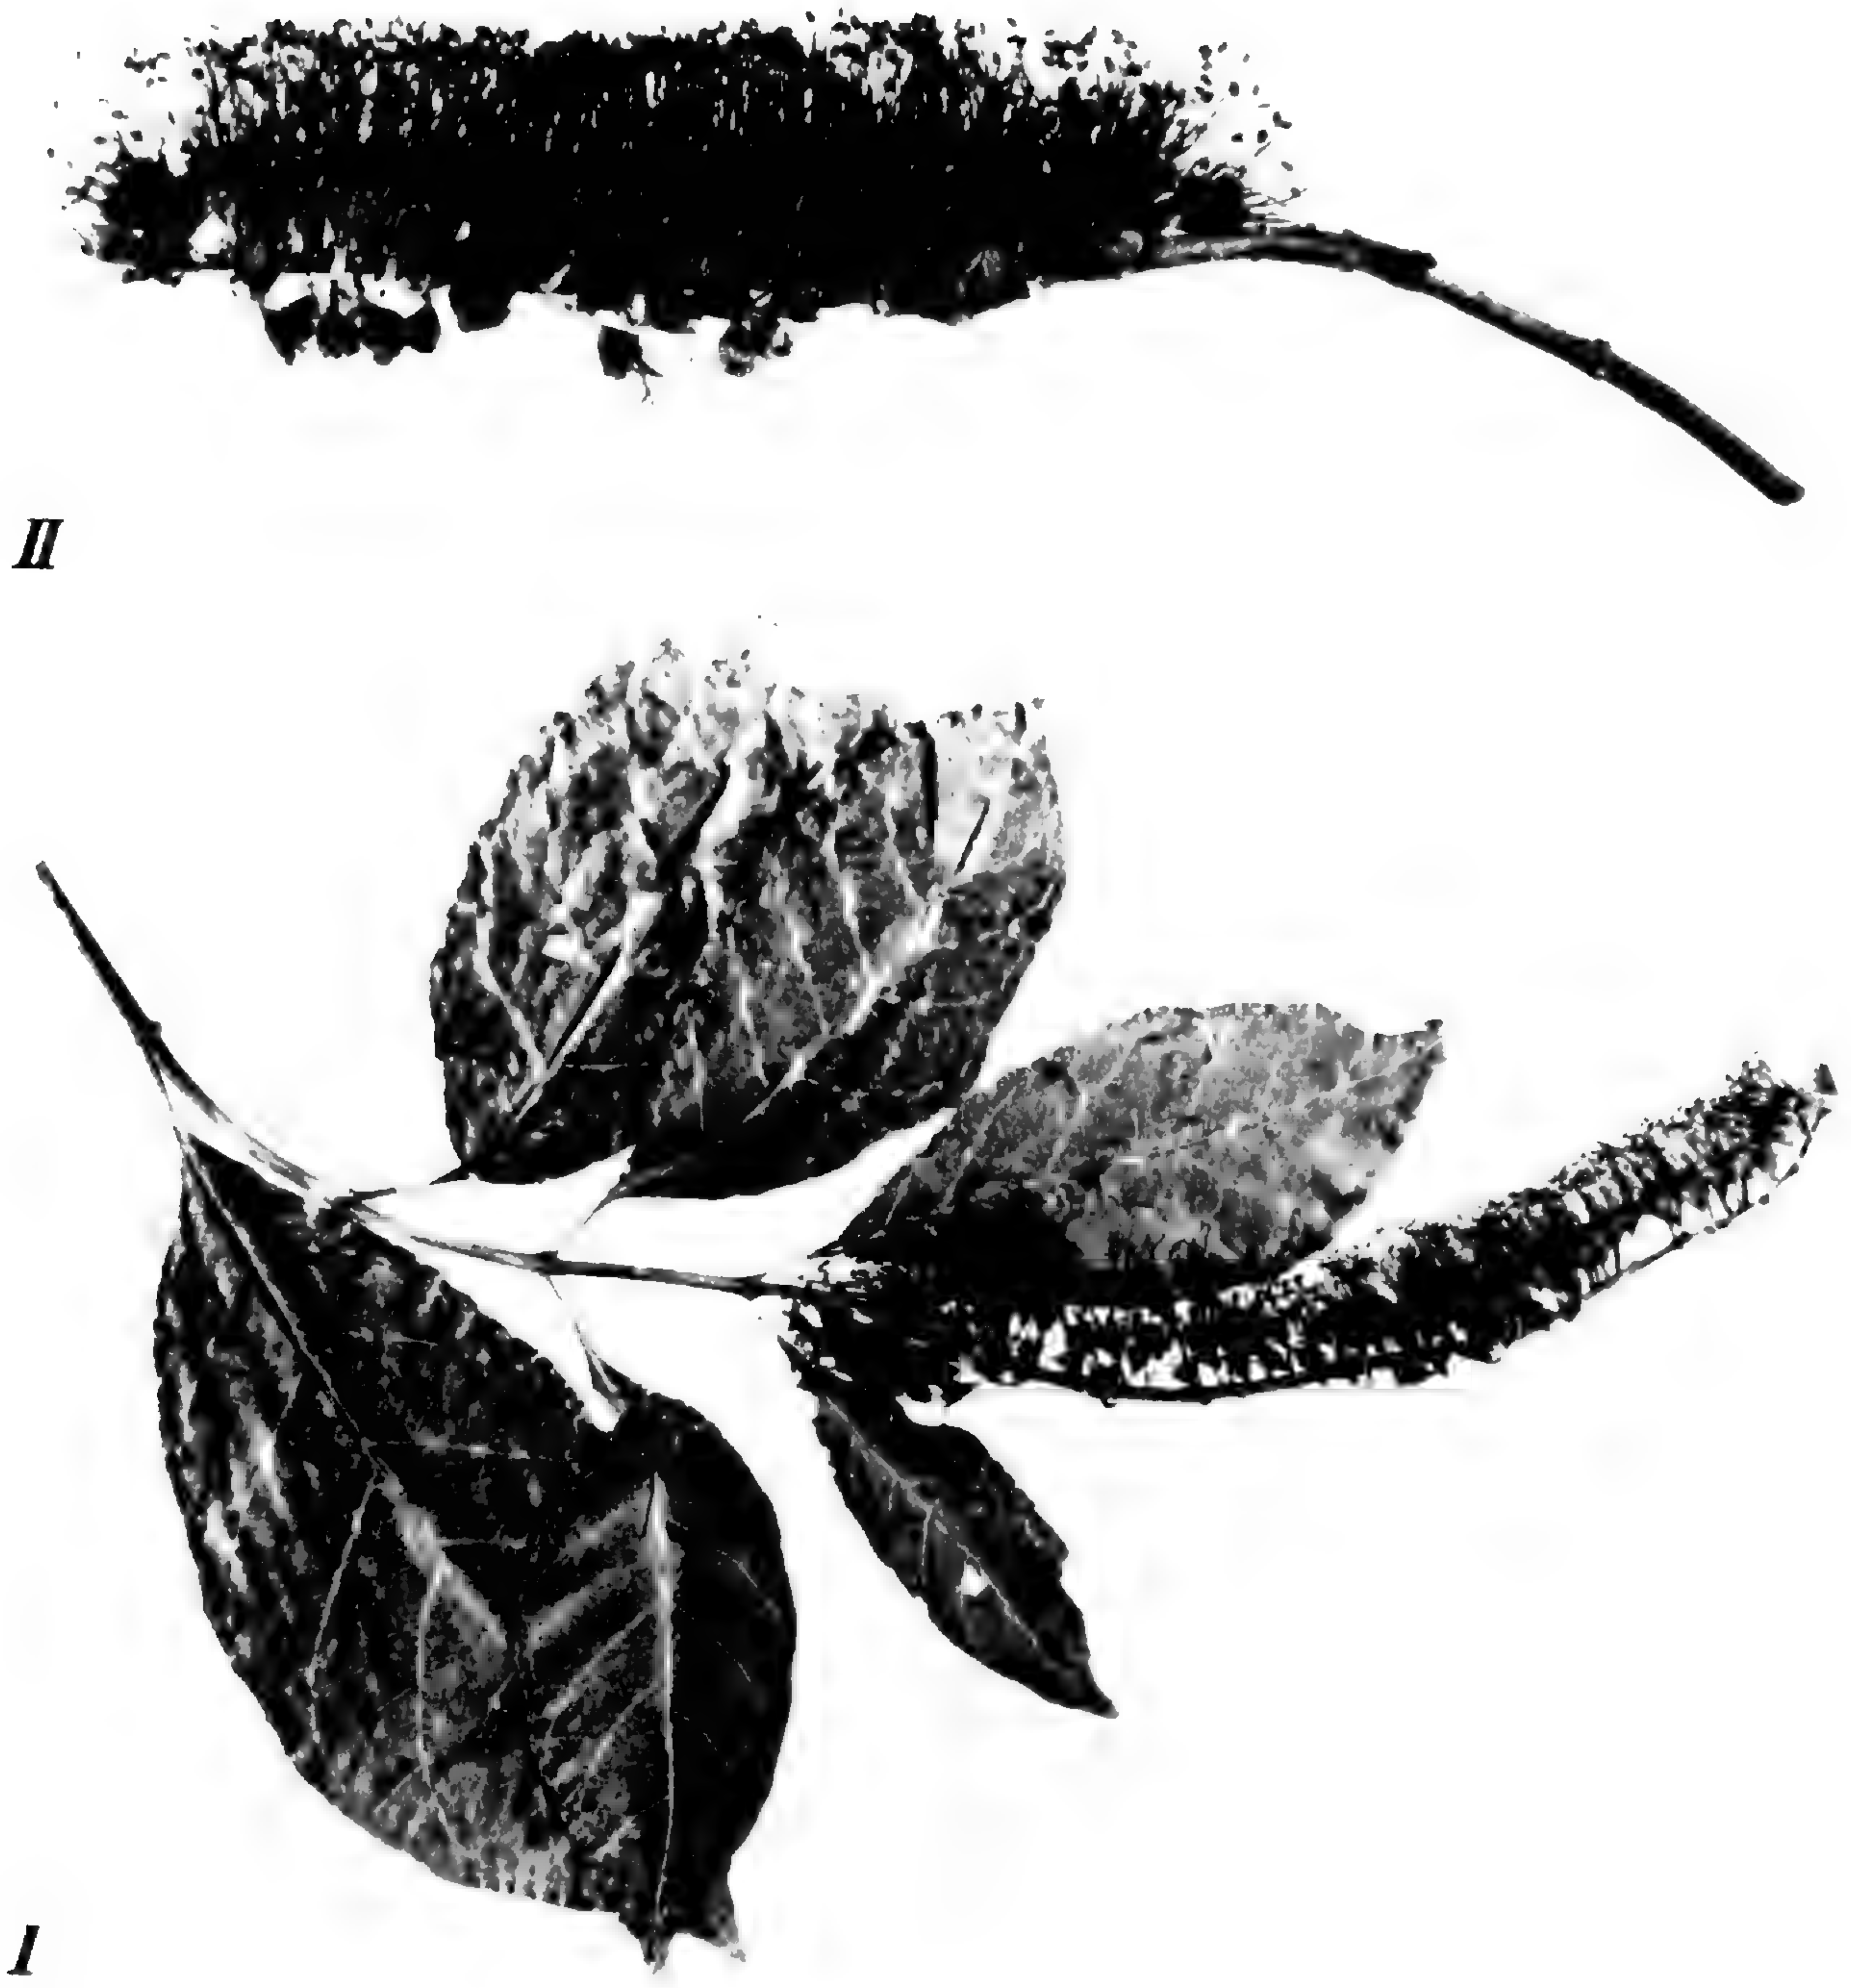

FIGURE 34. *Combretaceae.* Combretum fruticosum (= C. secundum); *flowering branch (I) and botrytic florescence (II). (El Salvador:* Weberling 164, 175.)

littorea (Jack) Voigt, normally a bracteose spicate main florescence terminates a leafy shoot, and paracladia are missing. In *L. racemosa* Willd., however, the synflorescence consists of paracladia only, which form 10–20-flowered, long-peduncled spikes originating in the axils of foliaceous leaves of a leafy shoot with indeterminate growth. In *L. coccinea*, however, the foliaceous shoots that end in a spicate main florescence are not very large and represent branches of a shoot with indeterminate vegetative growth, too.

Within *Terminalia*, a great number, perhaps the majority, of the species are characterized by leafy proliferating inflorescences. In some of these species the flowering branches grow with well-developed internodes, and after the production of several spicate paracladia which originate in the axils of foliaceous leaves, these branches return to vegetative growth. *Terminalia oblonga* (Ruiz & Pavón) Steudel serves as an example (see also *T. brownii* Fresen., Sell, 1982, fig. 10d). In other species the internodes of the main axis remain short within the flowering zone. Thus the leaves are "crowded at the ends of the

FIGURE 35. *Combretaceae.* Cacoucia coccinea *(from Aublet, J. B., Hist. Pl. Guiane Franç. III, pl. 179, 1775).*

branches," and the synflorescence has a rosettelike shape. This applies to *T. catappa* L. (Fig. 36; for the crown form and branching pattern of *T. catappa* and *T. latifolia* see Fisher & Hibbs, 1982), *T. bellirica* (Gaertner) Roxb., *T. zollingeri* Exell, *T. sumatrana* Miq., *T. trivialis* Slooten, and many other species, also to *Bucida* L. In *T. gigantea* Slooten, which shows a similar architecture, the spicate paracladia are very long, with many loosely arranged flowers. In *T. australis* Camb., on the other hand, the paracladia bear a smaller number of densely aggregated flowers that form a long-peduncled head. The flowering branches of this species are brachyblastlike proliferating twigs with well-developed internodes. They develop from axillary buds of an older shoot but also arise from its terminal bud and later continue its growth. In *T. triflora* (Griseb.) Lillo, the brachyblasts, which bear several bud scales at their bases, remain very short, at least during the anthesis of their four to six paracladia, which likewise form few-flowered, long-peduncled heads.

Formation of flowers is limited to brachyblasts in many species of other genera. Thus in the species of *Pteleopsis* Engl., the flowering branches are brachyblasts originating from older macroblasts. They bear a few bud scales at their bases, some pairs of foliaceous leaves, and an umbel-shaped to botrytic main florescence, which in its proximal part can bear small foliaceous pherophylls. We could, however, also observe heterothetic diplobotrytic inflorescences with somewhat umbellate florescences in some specimens of *P. myrtifolia* (Lawson) Engl. & Diels.

In *Combretum salicifolium* E. Meyer, and in *C. apiculatum* Sonder (Fig. 37 I) brachyblastlike branches situated on macroblasts of the previous year bear simple paracladia in the axils of the two or three lowermost pairs of foliaceous leaves; these brachyblasts proliferate at the end of the anthesis of the paracladia (see also Brandis, 1893, fig. 59). *Combretum bracteosum* (Hochst.) Brandis is similar.

The florescences of *Combretum salicifolium* are contracted to 15–20-flowered headlike aggregations (see Brandis, 1893: 122, fig. 59A). The same applies to *C. erythrophyllum* (Burch.) Sonder (Fig. 37 II), in which the proliferating brachyblasts bear several pairs of long-peduncled globose umbels arising from the axils of foliaceous leaves. Capituliform florescences are also reported, for example in *C. punctatum* Bl. (van Slooten, 1922), whereas in *C. apiculatum* Sonder the axillary florescences are spicate (Fig. 37 I).

Capitulate and very densely flowered, long-peduncled florescences can also be found in *Guiera senegalensis* Lam. and in species of *Buchenavia*, *Finetia*, and *Anogeissus*. In *Buchenavia capitata* (Vahl) Eichl. and *B. ochroprumna* Eichl., the paracladia bearing globose, ca. 20-flowered heads were observed on terminal rosette-shaped proliferating brachyblasts. They were inserted here at the base of the brachyblasts, thus preceding the leaf rosette. In contrast to these species, the floral zone of the brachyblasts in *B. kleinii* Exell succeeds the leaf rosette, and the inflorescences are ovoid. In some other species the paracladia bear loosely flowered spikes and are inserted at the top of the brachyblasts

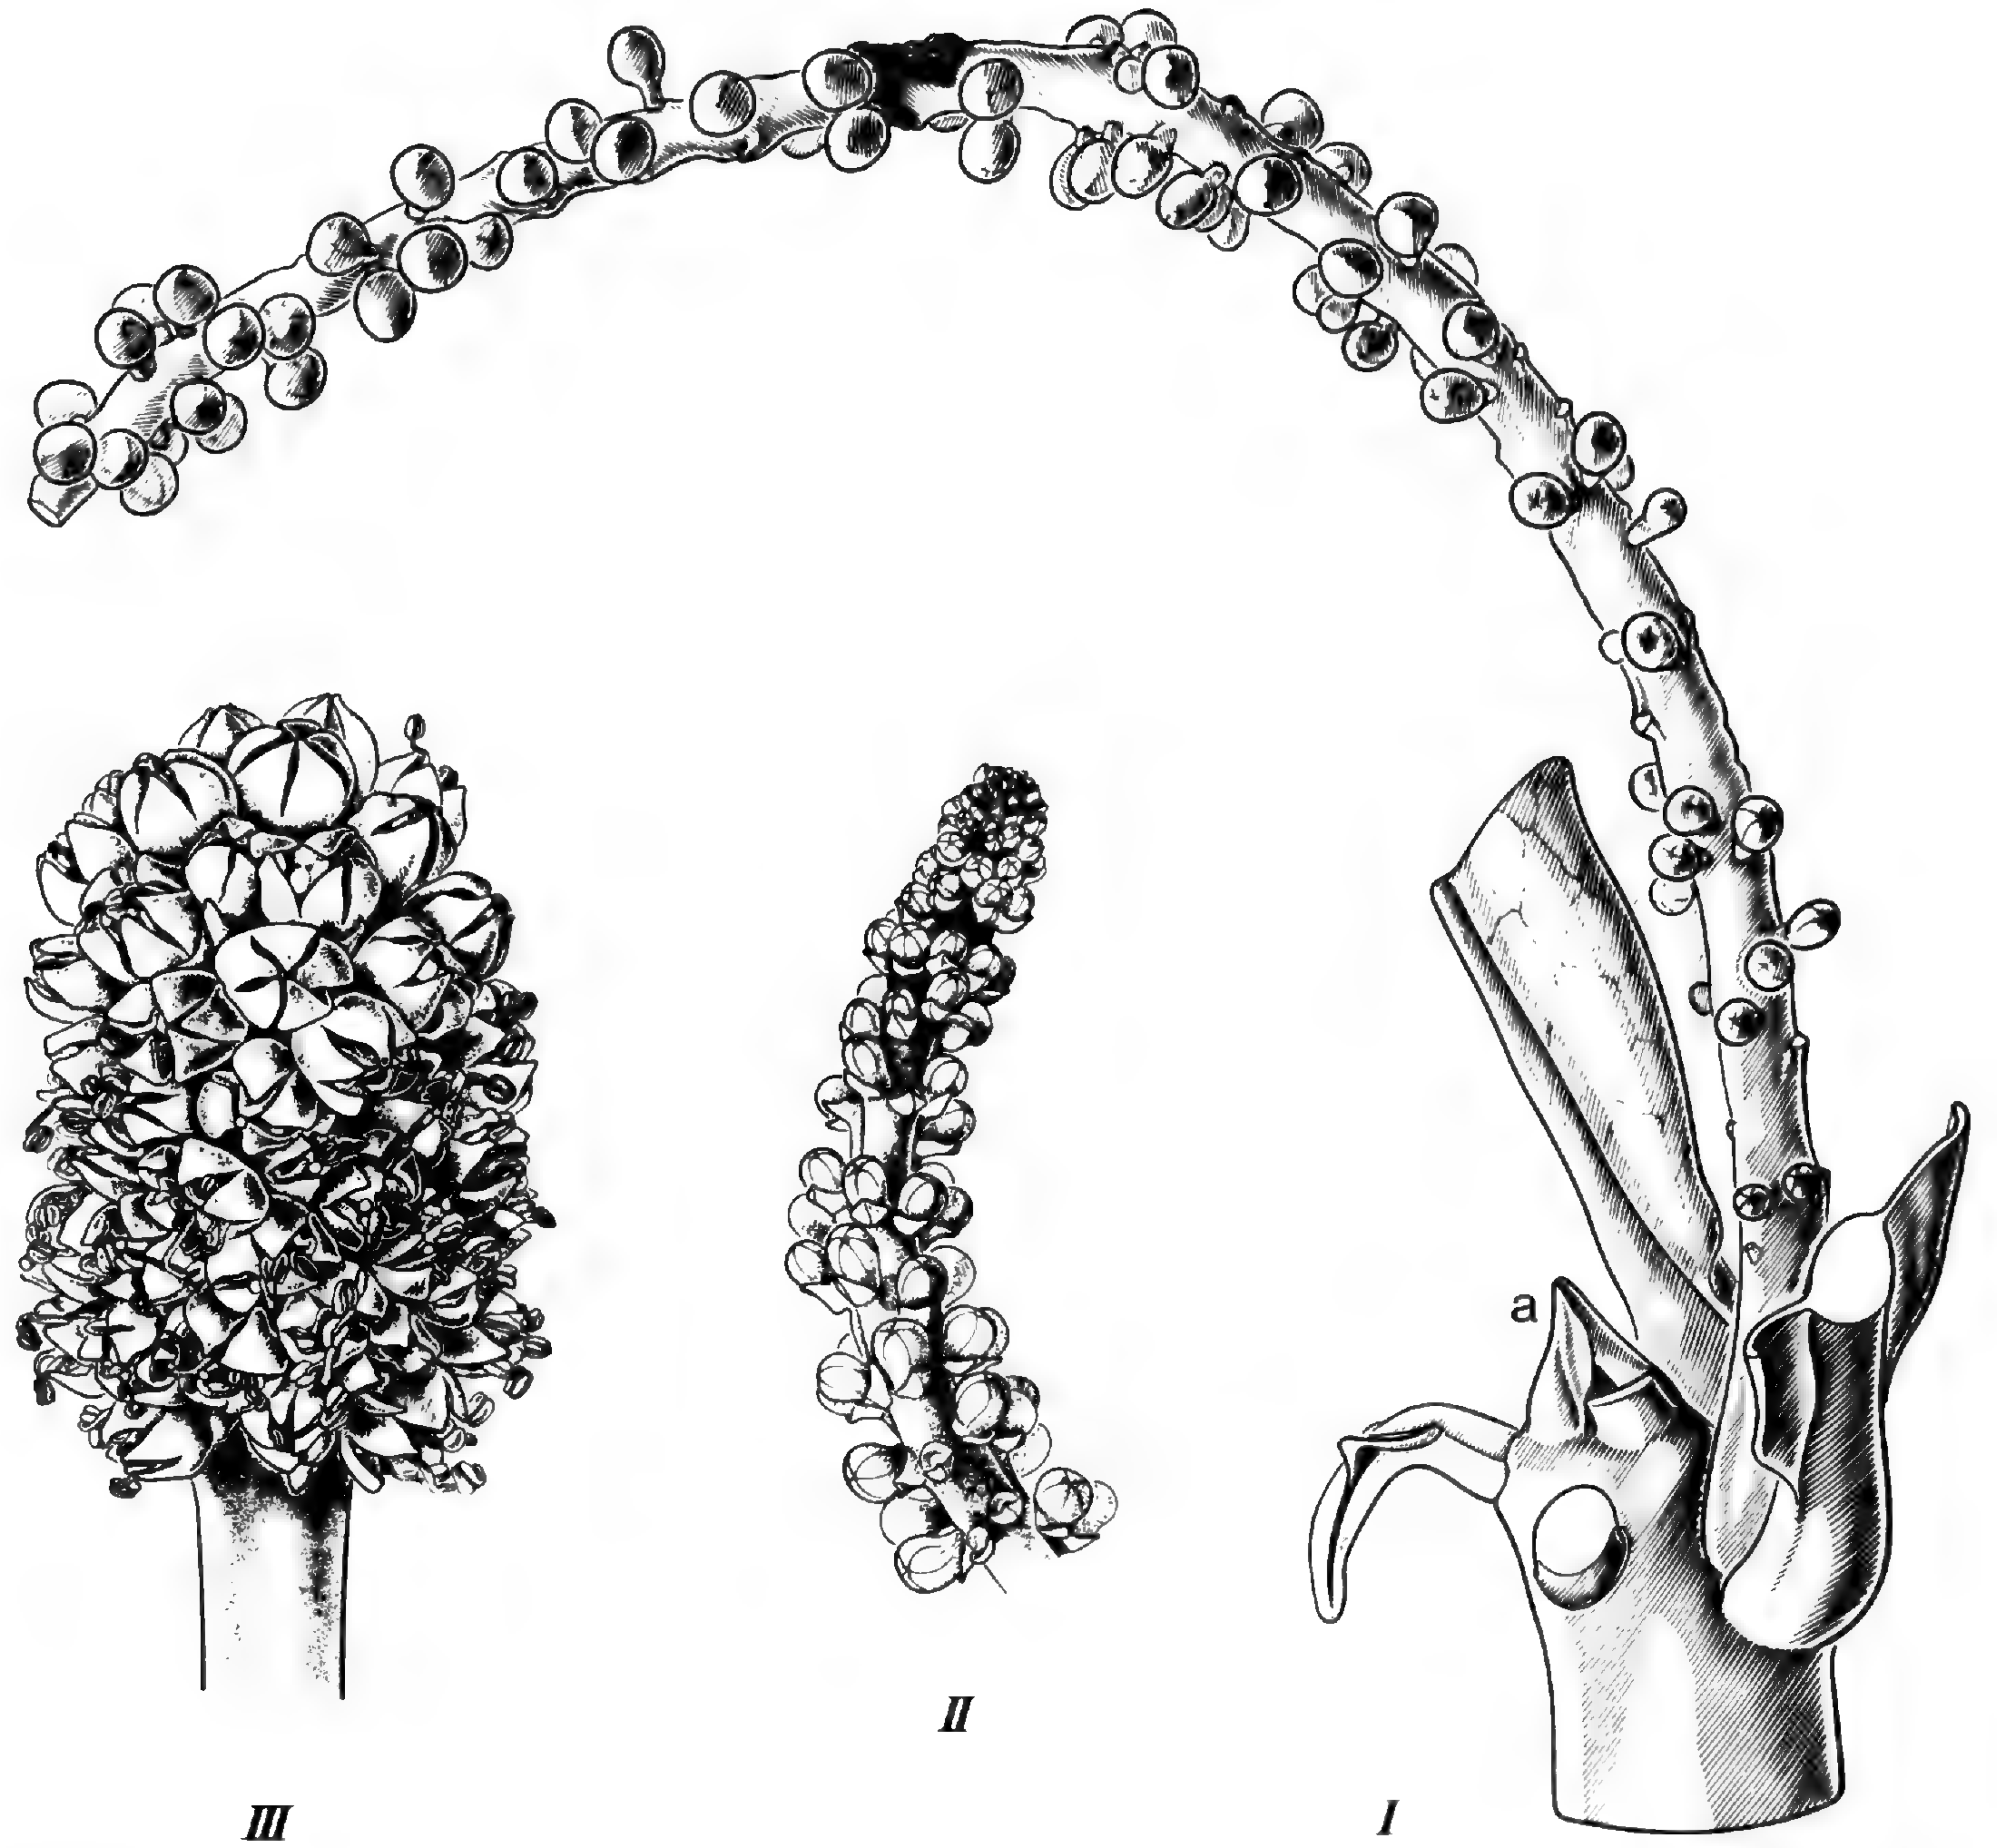

FIGURE 36. *Combretaceae. I, II.* Terminalia catappa.—*I. Proliferating inflorescence with one spikelike paracladium, the leaves partly removed; apex (a) of the main axis.—II. Distal part of a paracladium.—III.* Conocarpus erecta; *capitulate paracladium.*

more or less following the leafy zone (*B. macrophylla* Eichl., *B. suaveolens* Eichl.) or at the base of the brachyblasts, preceding the rosette (*B. oxycarpa* (Martius) Eichl.).

In *Anogeissus acuminata* (Roxb. ex DC.) Wall. ex Bedd. and *A. latifolia* (Roxb. ex DC.) Wall. ex Bedd., the synflorescences consist of a globose main florescence and an enrichment zone comprising several paracladia, each originating in the axil of a foliaceous leaf and bearing a globose co-florescence on a long peduncle. The paracladia can be accompanied by similar-shaped accessory branches.

In *Conocarpus erecta* L. (Fig. 38) the inflorescence terminating a leafy shoot is composed of one terminal and many lateral, short-peduncled, ovoid capitula, which together form a heterothetic botrytic or diplobotrytic system. The basal leaves within this system are foliaceous, diminishing distally, and ultimately convert to small bracts. At least in the distal part of the inflorescence the paracladia are accompanied by accessory branches forming particular peduncled capitula.

In general the tendency to form condensed inflorescences is not very strong within the Combretaceae. Exell (1962), however, saw some evolutionary consequences resulting from a conflict between pollination strategies and the development of winged fruits of "massed flowers" that might cause "space

FIGURE 37. *Combretaceae. Brachyblasts.—I.* Combretum apiculatum. *(SW Africa, Windhoek,* R. Seydel 3666 *(M).)—II.* C. erythrophyllum. *(South Africa, Cape Prov.: King Williams Town,* D. M. Comens 1715 *(M).)*

problems." The problem, however, seems to be more complex and needs empirical treatment with regard to flower biology as well as to carpology and chorology.

PENAEACEAE

The inflorescences of Penaeaceae were carefully investigated in the monographic work of Dahlgren (1967a–c, 1968, 1971). The basic type of ramification is a thyrsoid (a thyrse with a terminal flower) as in *Sonderothamnus petraeus* (Barker) Dahlgren (Fig. 39 II) and *S. speciosus* (Sonder) Dahlgren. In the majority of taxa the cymose (triadic) paracladia are reduced to their primary flower. The thyrsoid thus is converted to a stachyoid as presented by *Saltera sarcocolla* (L.) Bullock (Figs. 39 I, 41 II, 42 I).

A peculiarity of the *Saltera* inflorescence is that the terminal flower is preceded by two pairs of pale membranaceous bracts. The lower bracts are narrow but broaden distally to an emarginate end; the next pair is much narrower, nearly linear, but also broadens to a truncate or slightly emarginate end. Two or three of the preceding leaf pairs bear single flowers in their axils, each of them with a pair of linear-spathulate prophylls. Since these prophylls are similar in shape to the upper pair of bracteoles preceding the flower that terminates the whole inflorescence, one could wonder if this flower is terminal or lateral. Dahlgren (1968), however, reported that the inflorescence can be reduced so far that the terminal flower is the only one remaining (Fig. 43 II). This, together with the comparison with the structure of inflorescences in some related taxa, particularly that of *Stylapterus fruticulosus* (L. f.) A. Juss. (Figs. 40 II, 41 IV), confirms that there is a true terminal flower.

In some other taxa the terminal flower is sometimes facultatively lacking or missing in all specimens. Thus in *Glischrocolla formosa* (Thunb.) R. Dahlgren the "inflorescence apex generally bears a terminal flower, but this may drop in an early stage" (Dahlgren, 1967b).

The inflorescences of *Brachysiphon rupestris* Sonder and *B. mundii* Sonder still have a terminal flower, whereas *B. fucatus* (L.) Gilg and *B. acutus* (Thunb.) A. Juss. have indeterminate spikes. In such cases the "apex ends in some scalelike leaves" (*B. fucatus*) or "as a dry tip" (Dahlgren, 1968). In *B. fucatus* (Fig. 39 IV), however, all the paracladia end in a terminal flower, and this refers not only to paracladia that are provided with the pair of prophylls only (and therefore otherwise could be interpreted as partial florescences of a polytelic thyrse), but also to the lower paracladia with three or more leaf pairs. With some alterations the same applies to *Brachysiphon acutus*. Consequently we have to interpret these inflorescences as truncate monotelic systems.

In *Stylapterus* the inflorescence is "generally indeterminate, the apical tip being degenerated and dry, but in *S. fruticulosus* and *S. ericifolius* it often ends with a terminal flower" (Dahlgren, 1967a). The semidiagrammatic figures of "selected rich-flowered inflorescences" of both species (Fig. 40) show that there is a strong tendency to reduce the number of flowers in the paracladia to their terminal flower. Particularly in *S. fruticulosus* the result of this reduction is that the terminal flower of the whole ramification system as well as the terminal flower of the paracladia are preceded by two or three pairs of sterile leaves (see also Fig. 41 IV). This is in good concordance with the occurrence of two pairs of sterile bracts below the terminal flower of the *Saltera* inflorescence (Fig. 39 I). We also should note that the flowering system of *Stylapterus fruticulosus* has a secondary inhibition zone below the terminal flower in addition to the primary inhibition zone that commonly precedes the paracladial zone.

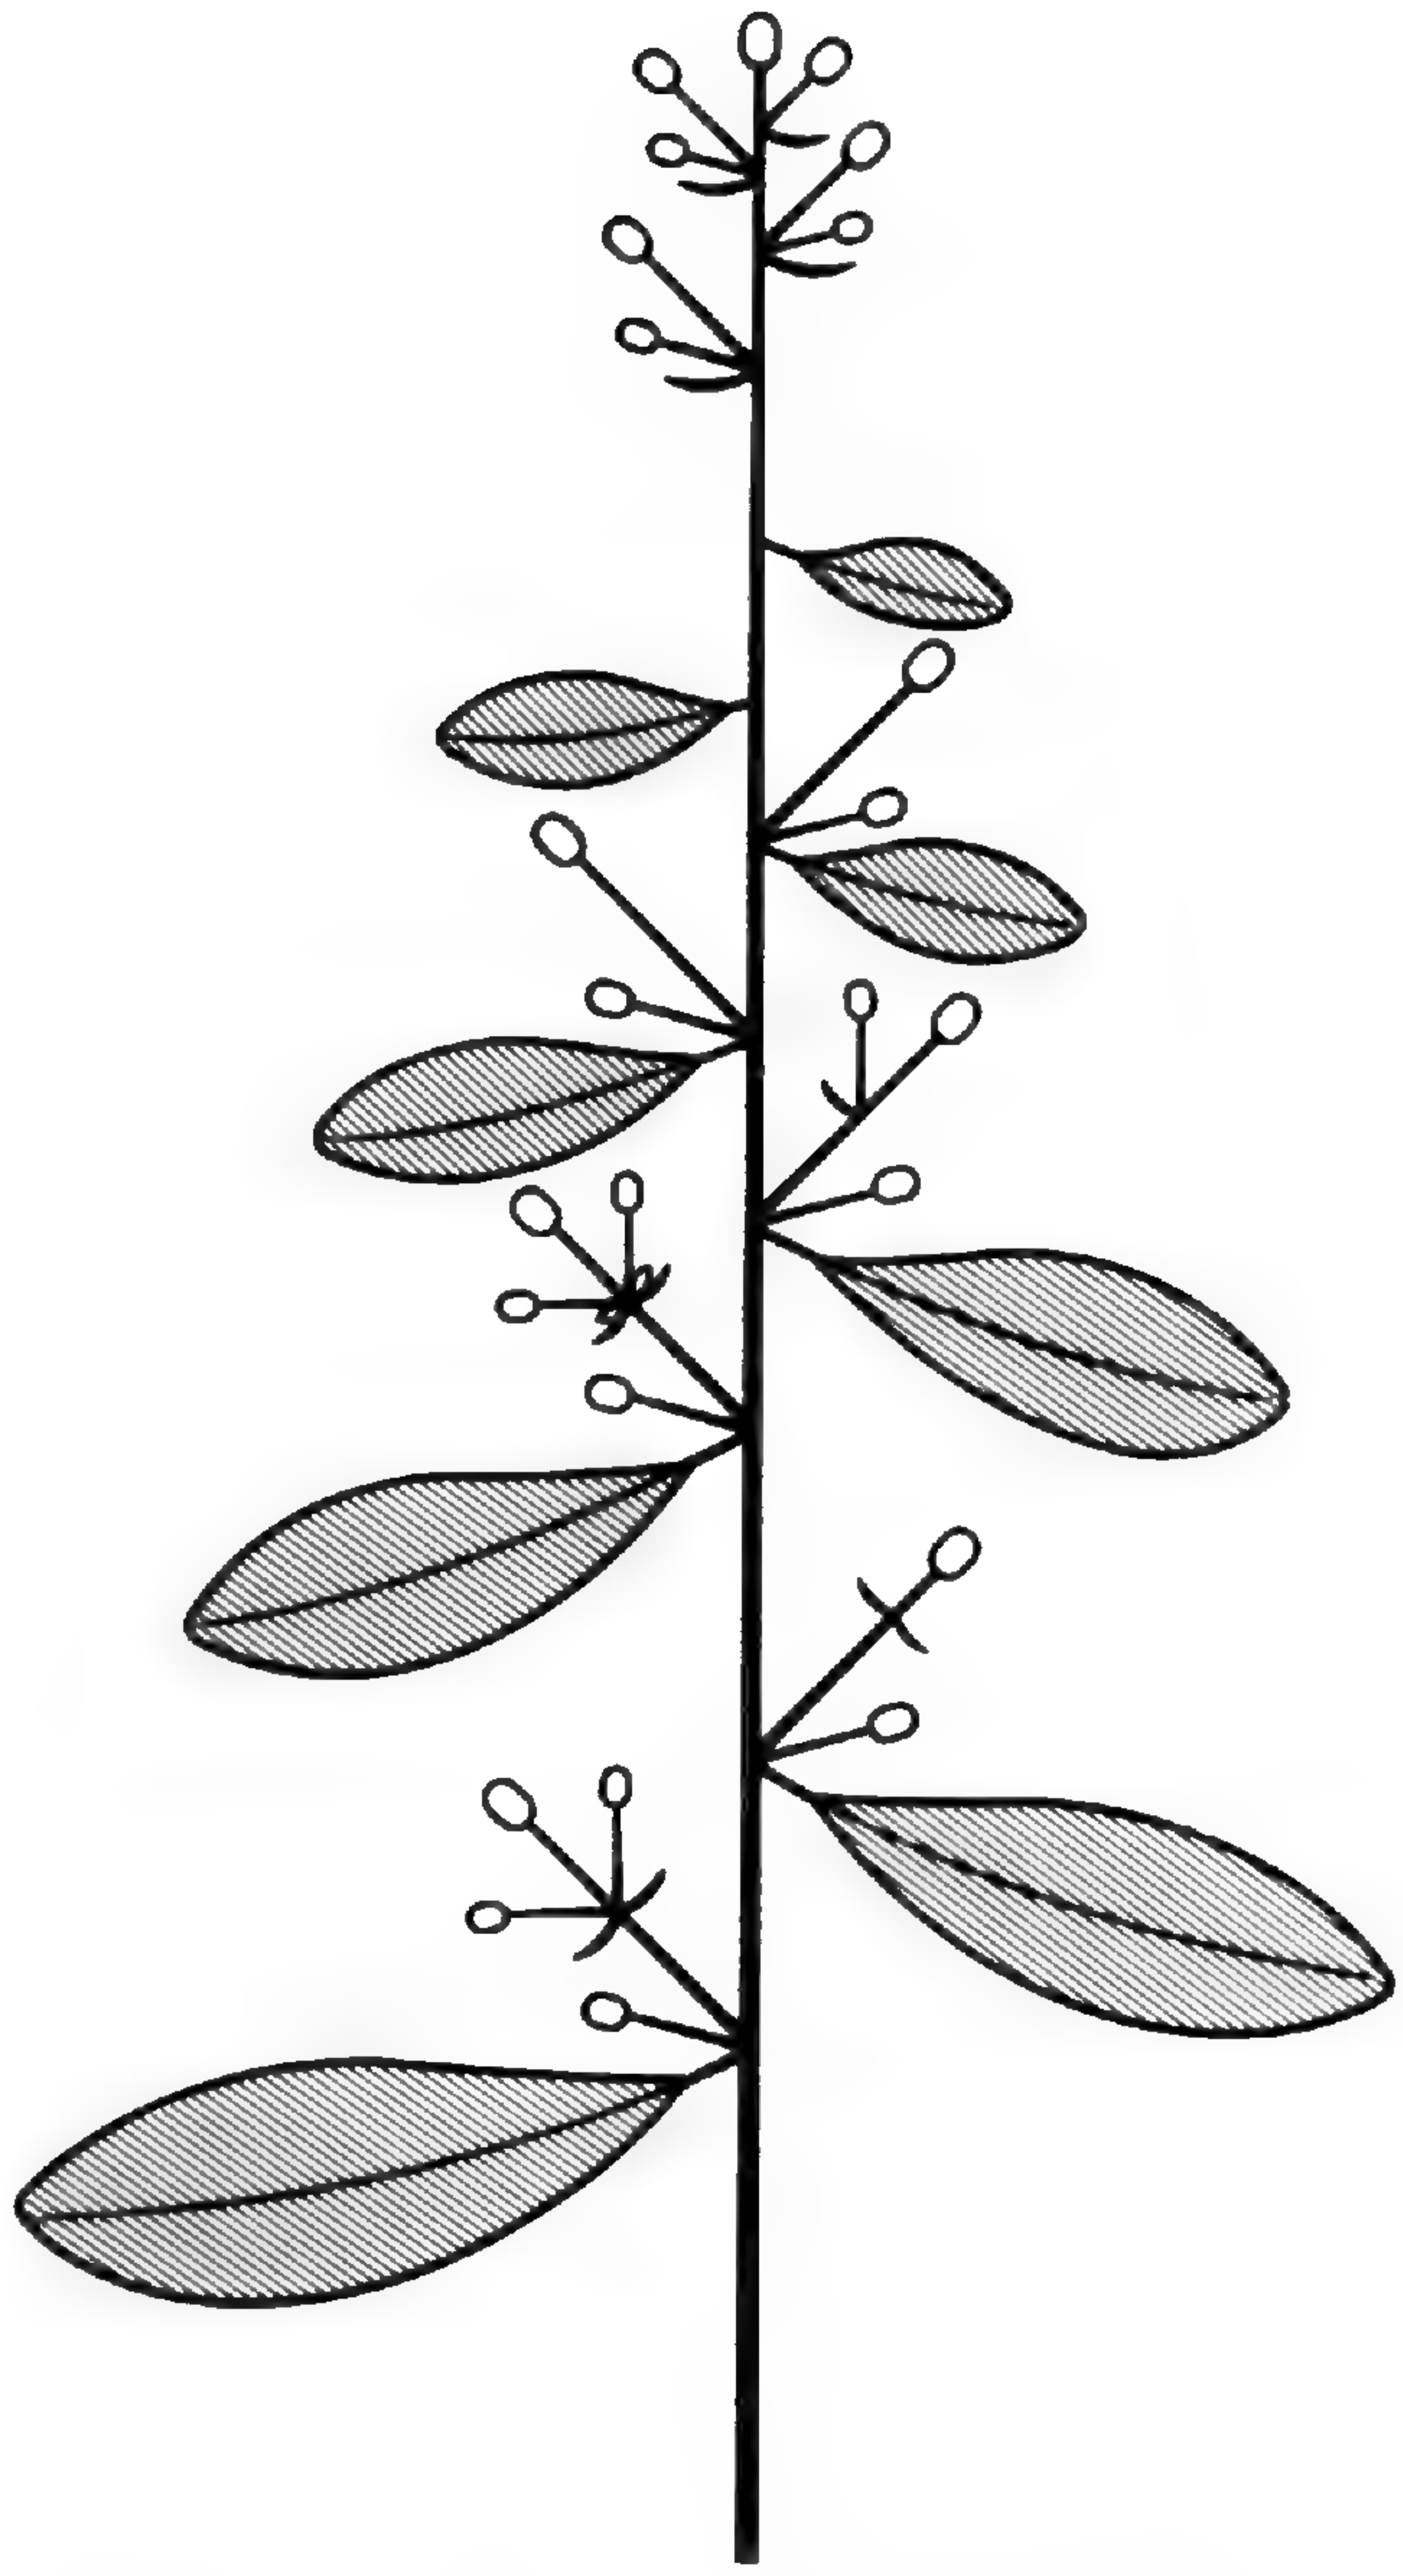

FIGURE 38. *Combretaceae.* Conocarpus erecta; *diagram of a flowering branch.*

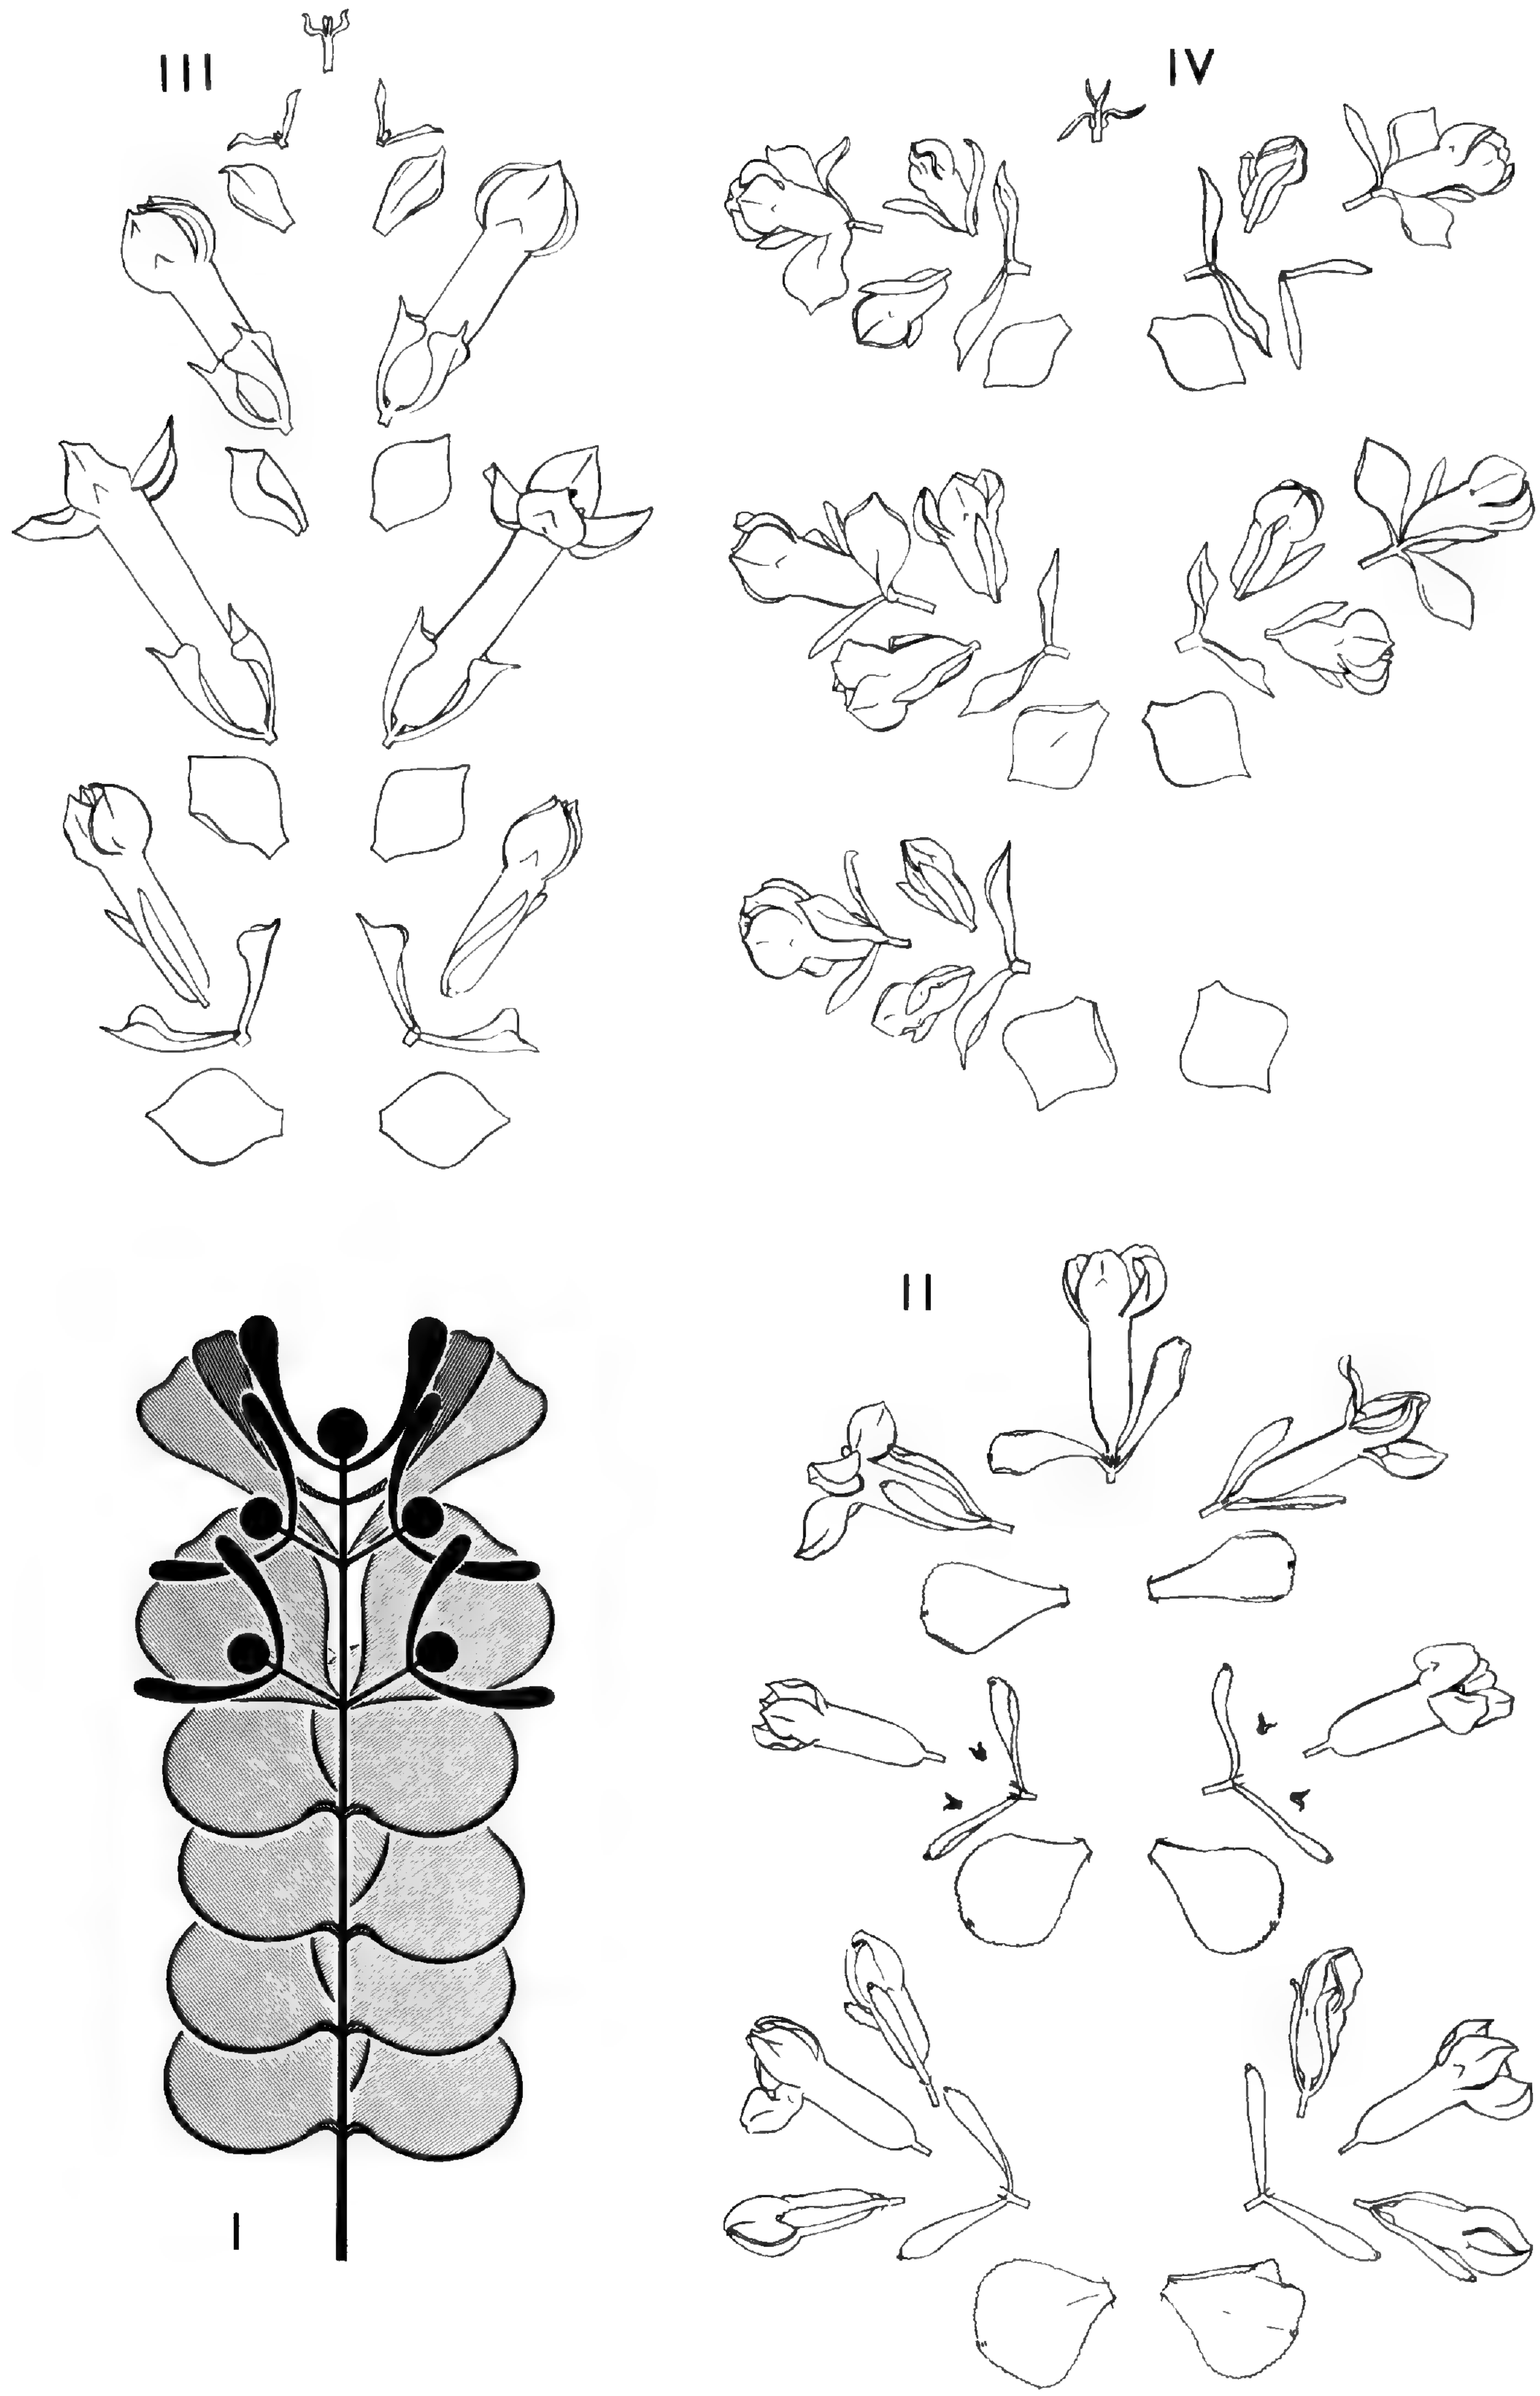
Dahlgren (1971) described the inflorescence of *Penaea acutifolia* A. Juss. as "generally with a terminal flower," whereas *P. mucronata* L. was reported as "with or without terminal flower," and *P. cneorum* Meerb. as "without or sometimes with a terminal flower, when well developed with 6–14 flowers." In our own investigations based on very restricted material only, we could only once find a terminal flower. An indeterminate (anauxotelic) inflorescence of *P. mucronata* is shown in Figure 42 II, a terminal flower in Figure 41 III. Dahlgren (1971: 8) stated that in general the "flowering sequence is acropetal, but when a terminal flower is present, this develops in head of the upper neighboring flowers." This feature is very typical for terminal flowers.

In all genera, innovation, i.e., the production of vegetative shoots continuing the ramification system and perhaps later producing



III

terminal inflorescences, takes place from the axils of foliage leaves somewhat below the flower-bearing zone.

Inasmuch as the spikelike inflorescences actually no longer develop a terminal flower, they could be interpreted as a botrytic polytelic main florescence. We hesitate, however, to classify them in this way, not only because terminal flowers are reported for some cases, but particularly because of the lack of paracladia terminating in co-florescences. If such paracladia could be found in well-developed inflorescences, this would prove that the strong evolutionary tendency from the formation of monotelic inflorescences to the development of polytelic systems that appears independently in various branches of the family has really arrived at the polytelic stage. Without this proof we prefer to classify the indeterminate inflorescences as truncate monotelic systems.

A special case within the family is the inflorescence of *Endonema*. In both species, *E. lateriflora* (L. f.) Gilg and *E. retzioides* Sonder (Fig. 43 I), two or more single flowers are situated in the axils of leafy pherophylls

---

on a young branch, which continues vegetative growth. Each of these lateral flowers bears two (*E. retzioides*) or three (*E. lateriflora*) pairs of bracts. Dahlgren (1967c) reported that suppressed buds are sometimes found in the axils of the lowest pair of "bracteoles." Thus the whole branchlet in Figure 43 I may be explained as a proliferating monotelic inflorescence with highly reduced paracladia.

MELASTOMATACEAE

Variety of inflorescences in Melastomataceae corresponds to the size of the family but shows less diversity than Myrtaceae.

The inflorescences are monotelic throughout. Cases of complete transition to polytelic structures were not found. Even truncation seems to be rare. A single case noted by Troll (posthumous manuscript) is that of *Medinilla magnifica* Lindley, in which the inflorescence sometimes ceases development before the ultimate lateral cymes and the terminal flower of the distal thyrsic zone have completed their formation. Thus the whole end of the inflorescence atrophies (Fig. 64 III). Cremers (1983/1986) reported that the thyrse of *Desmoscelis villosa* (Aublet) Naudin remains indefinite. This, however, may only happen facultatively; in several plants investigated terminal flowers of the thyrsoids were well developed (Fig. 45). On the other hand, proliferation is not infrequent.

The basic form of ramification is a pleiothyrsoid terminating in a leafy shoot, as in *Miconia argentea* (Sw.) DC. (Fig. 44). Such bracteose or frondo-bracteose pleiothyrsoids, diplothyrsoids, or even monothyrsoids (haplothyrsoids) can be found in a terminal position in nearly all the 1,000 species of the genus *Miconia* as well as in many other ligneous genera such as *Conostegia*, most species of *Tococa*, and the large genera *Leandra* and *Clidemia*. Elongate conical thyrsoids or diplothyrsoids are also typical of many species

FIGURE 43. *Penaeaceae.—I.* Endonema retzioides; *part of a branchlet with two uniflorous inflorescences.— II.* Saltera sarcocolla; *branchlet with terminal uniflorous inflorescence. (Both after Dahlgren, 1967c, 1968: I.* Hohenacker s.n.; *II. South Africa: S. Cape Peninsula,* Dahlgren & Peterson 652.*)*

of *Tibouchina.* In some species of *Tibouchina* and of *Heterocentron,* the thyrsoids get a somewhat botrytic appearance since the hypopodia of the paracladia of first order are long compared with the other internodes ("thyrsus racemiformis"). Many examples have been analyzed and figured by Cremers (1983/1986), who published a thorough study on inflorescence structures of Guianese Melastomataceae. His investigations also include interesting studies on growth forms. While the manuscript of the present article was in press, W. S. Judd (1986) published the results of studies on variation in inflorescence position in Miconieae.

The cymose ramification of the partial inflorescences usually remains limited, and the mode of ramification is different. Eichler (1878c: 483) observed a formation of a helicoid cyme (bostryx) by preferential ramification from the axils of the β-prophylls in *Tibouchina* (cited by Eichler as *Lasiandra*). A bostryx also is reported for *Centradenia floribunda* Planchon by Wydler (1878: 349), who supposed that ramification continued from the axils of the β-prophylls as in *Tibouchina.* Ziegler (1925: 410), however, observed a preferential ramification from the axils of the larger α-prophylls. The statement of Eichler (1878c: 483) that in the helicoids of *Centradenia* only the fertile prophylls are developed proved to be wrong (Troll, posthumous manuscript). Krasser (1893) reported helicoid cymes for *Miconia secundiflora* Cogn. Simple or double helicoids also occur in *M. hookeriana* Triana (Fig. 46 I) and *Fordiophyton.*

FIGURE 44. *Melastomataceae.* Miconia argentea; *monotelic pleiothyrsoid inflorescence. (El Salvador:* Weberling 2024.*)*

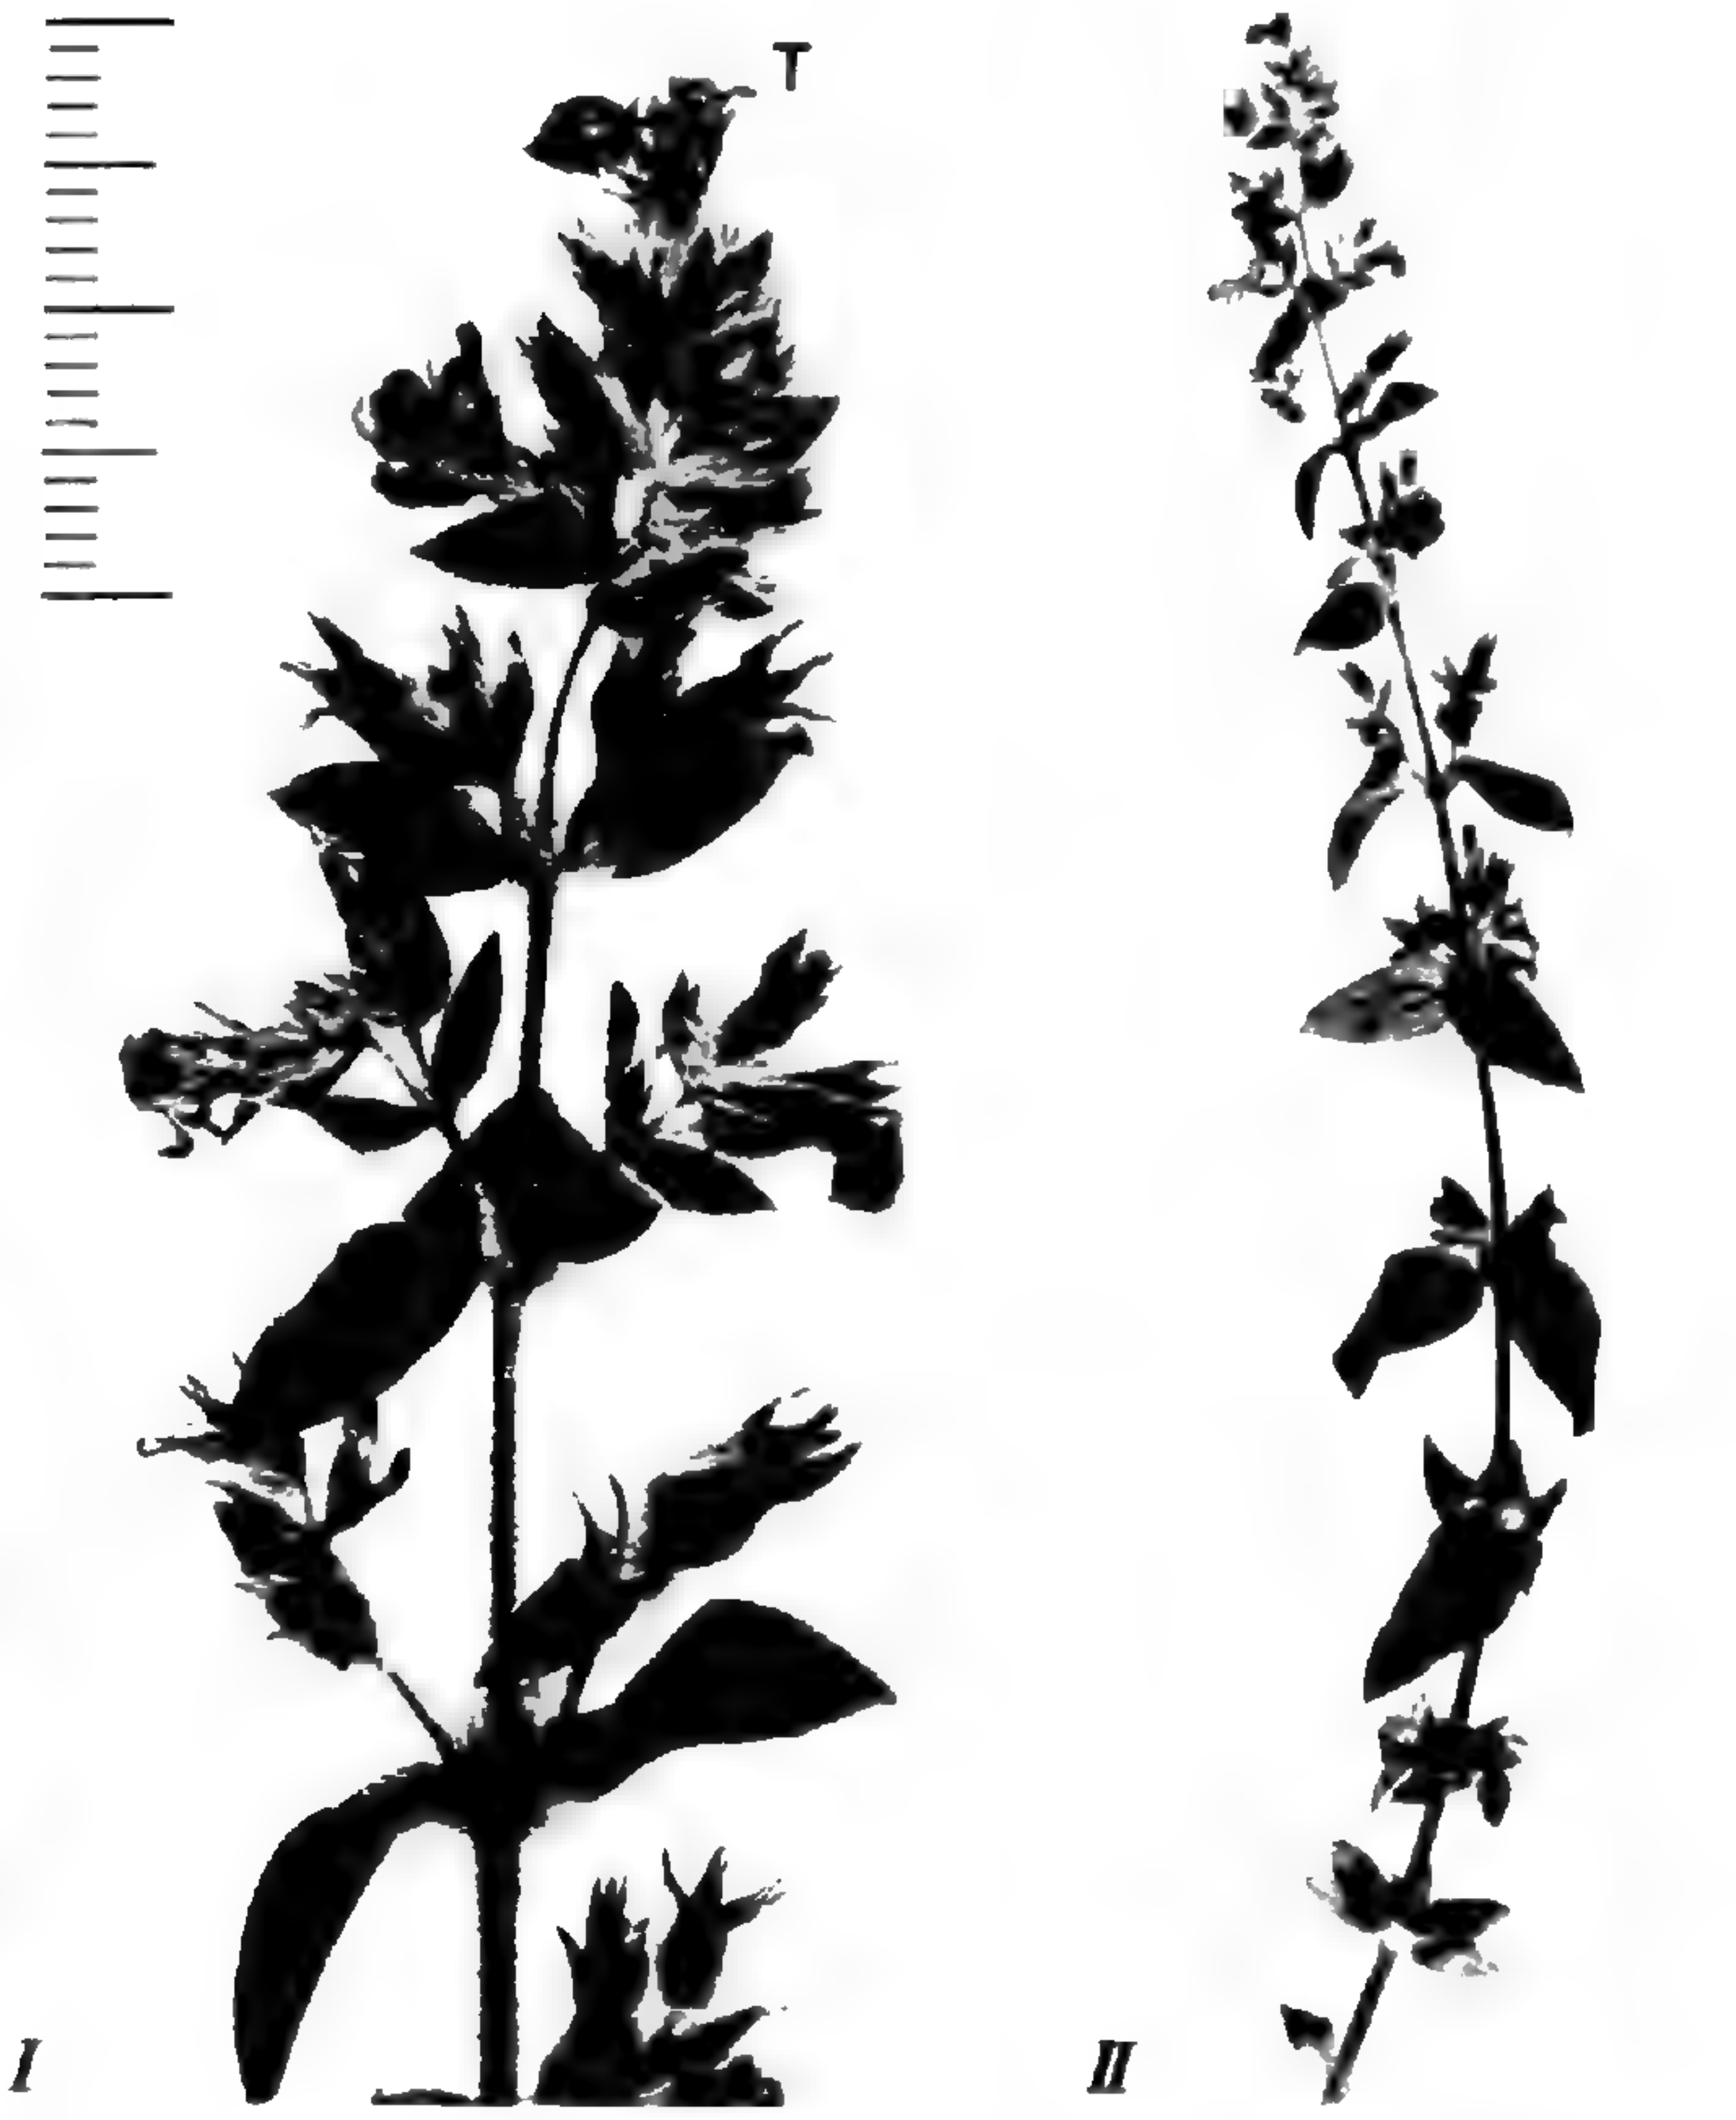

FIGURE 45. *Melastomataceae.* Desmoscelis villosa. *(N. Brazil:* Ph. v. Luetzelburg 22181 *(M).)—I. Distal part of II. T, terminal flower.*

The formation of scorpioid cymes (cincinni) by preference of the ramification from the axils of the α-prophylls was reported by Eichler (1878c: 483) for *Salpinga* and *Clidemia.* Scorpioid ramification of the cymose partial inflorescences is also known for *Rhynchanthera* (Wydler, 1851a: 370), the Bertolonieae and Sonerileae (see Krasser, 1893, and p. 278), *Arthrostema, Centradenia inaequilateralis* (Schldl. & Cham.) G. Don (see p. 282), *Amphiblemma cymosum* (Schrader & Wendl.) Naudin (see p. 272), *Appendicularia thymifolia* (Bonpl.) DC., and *Aciotis acuminifolia* (DC.) Triana, *A. acutiflora* (Martius) Triana, *A. longifolia* Triana, and others.

The cymose paracladia in the mono-thyrsoid inflorescence of *Miconia hookeriana* Triana are simple helicoid cymes in the distal part, and double helicoid cymes in the proximal part (Fig. 46 I). The inflorescence, which has only caducuous bracts, is preceded by several pairs of foliage leaves bearing vegetative buds in their axils. From the axils of older leaves sylleptic branches with several foliaceous leaves and a terminal thyrsoid can develop (Fig. 46 II).

In most of the ligneous Melastomataceae, the axillary buds of the leaf pairs preceding the terminal inflorescence develop innovation shoots some time after anthesis, as is shown here for *Miconia guatemalensis* Cogn. (Fig. 47 II). The order of precedence in this development can be indicated already by the size of the buds (Fig. 47 I).

On the other hand, there are ligneous members of the family with proliferating inflorescences. A favorable disposition for proliferation seems to be given with the occurrence of leafy pherophylls, as in *Huilea macrocarpa* Uribe (Fig. 47 III). After the production of long-peduncled axillary thyrsoids or cymes the apex of the inflorescence axis returns to vegetative growth, producing axillary buds that develop vegetative branches instead of flower-bearing paracladia (Mora Osejo, 1966). Among the numerous species of *Clidemia,* which mostly have terminal bracteose thyrsoid or diplothyrsoid inflorescences, there is *C. rubra* (Aublet) Martius

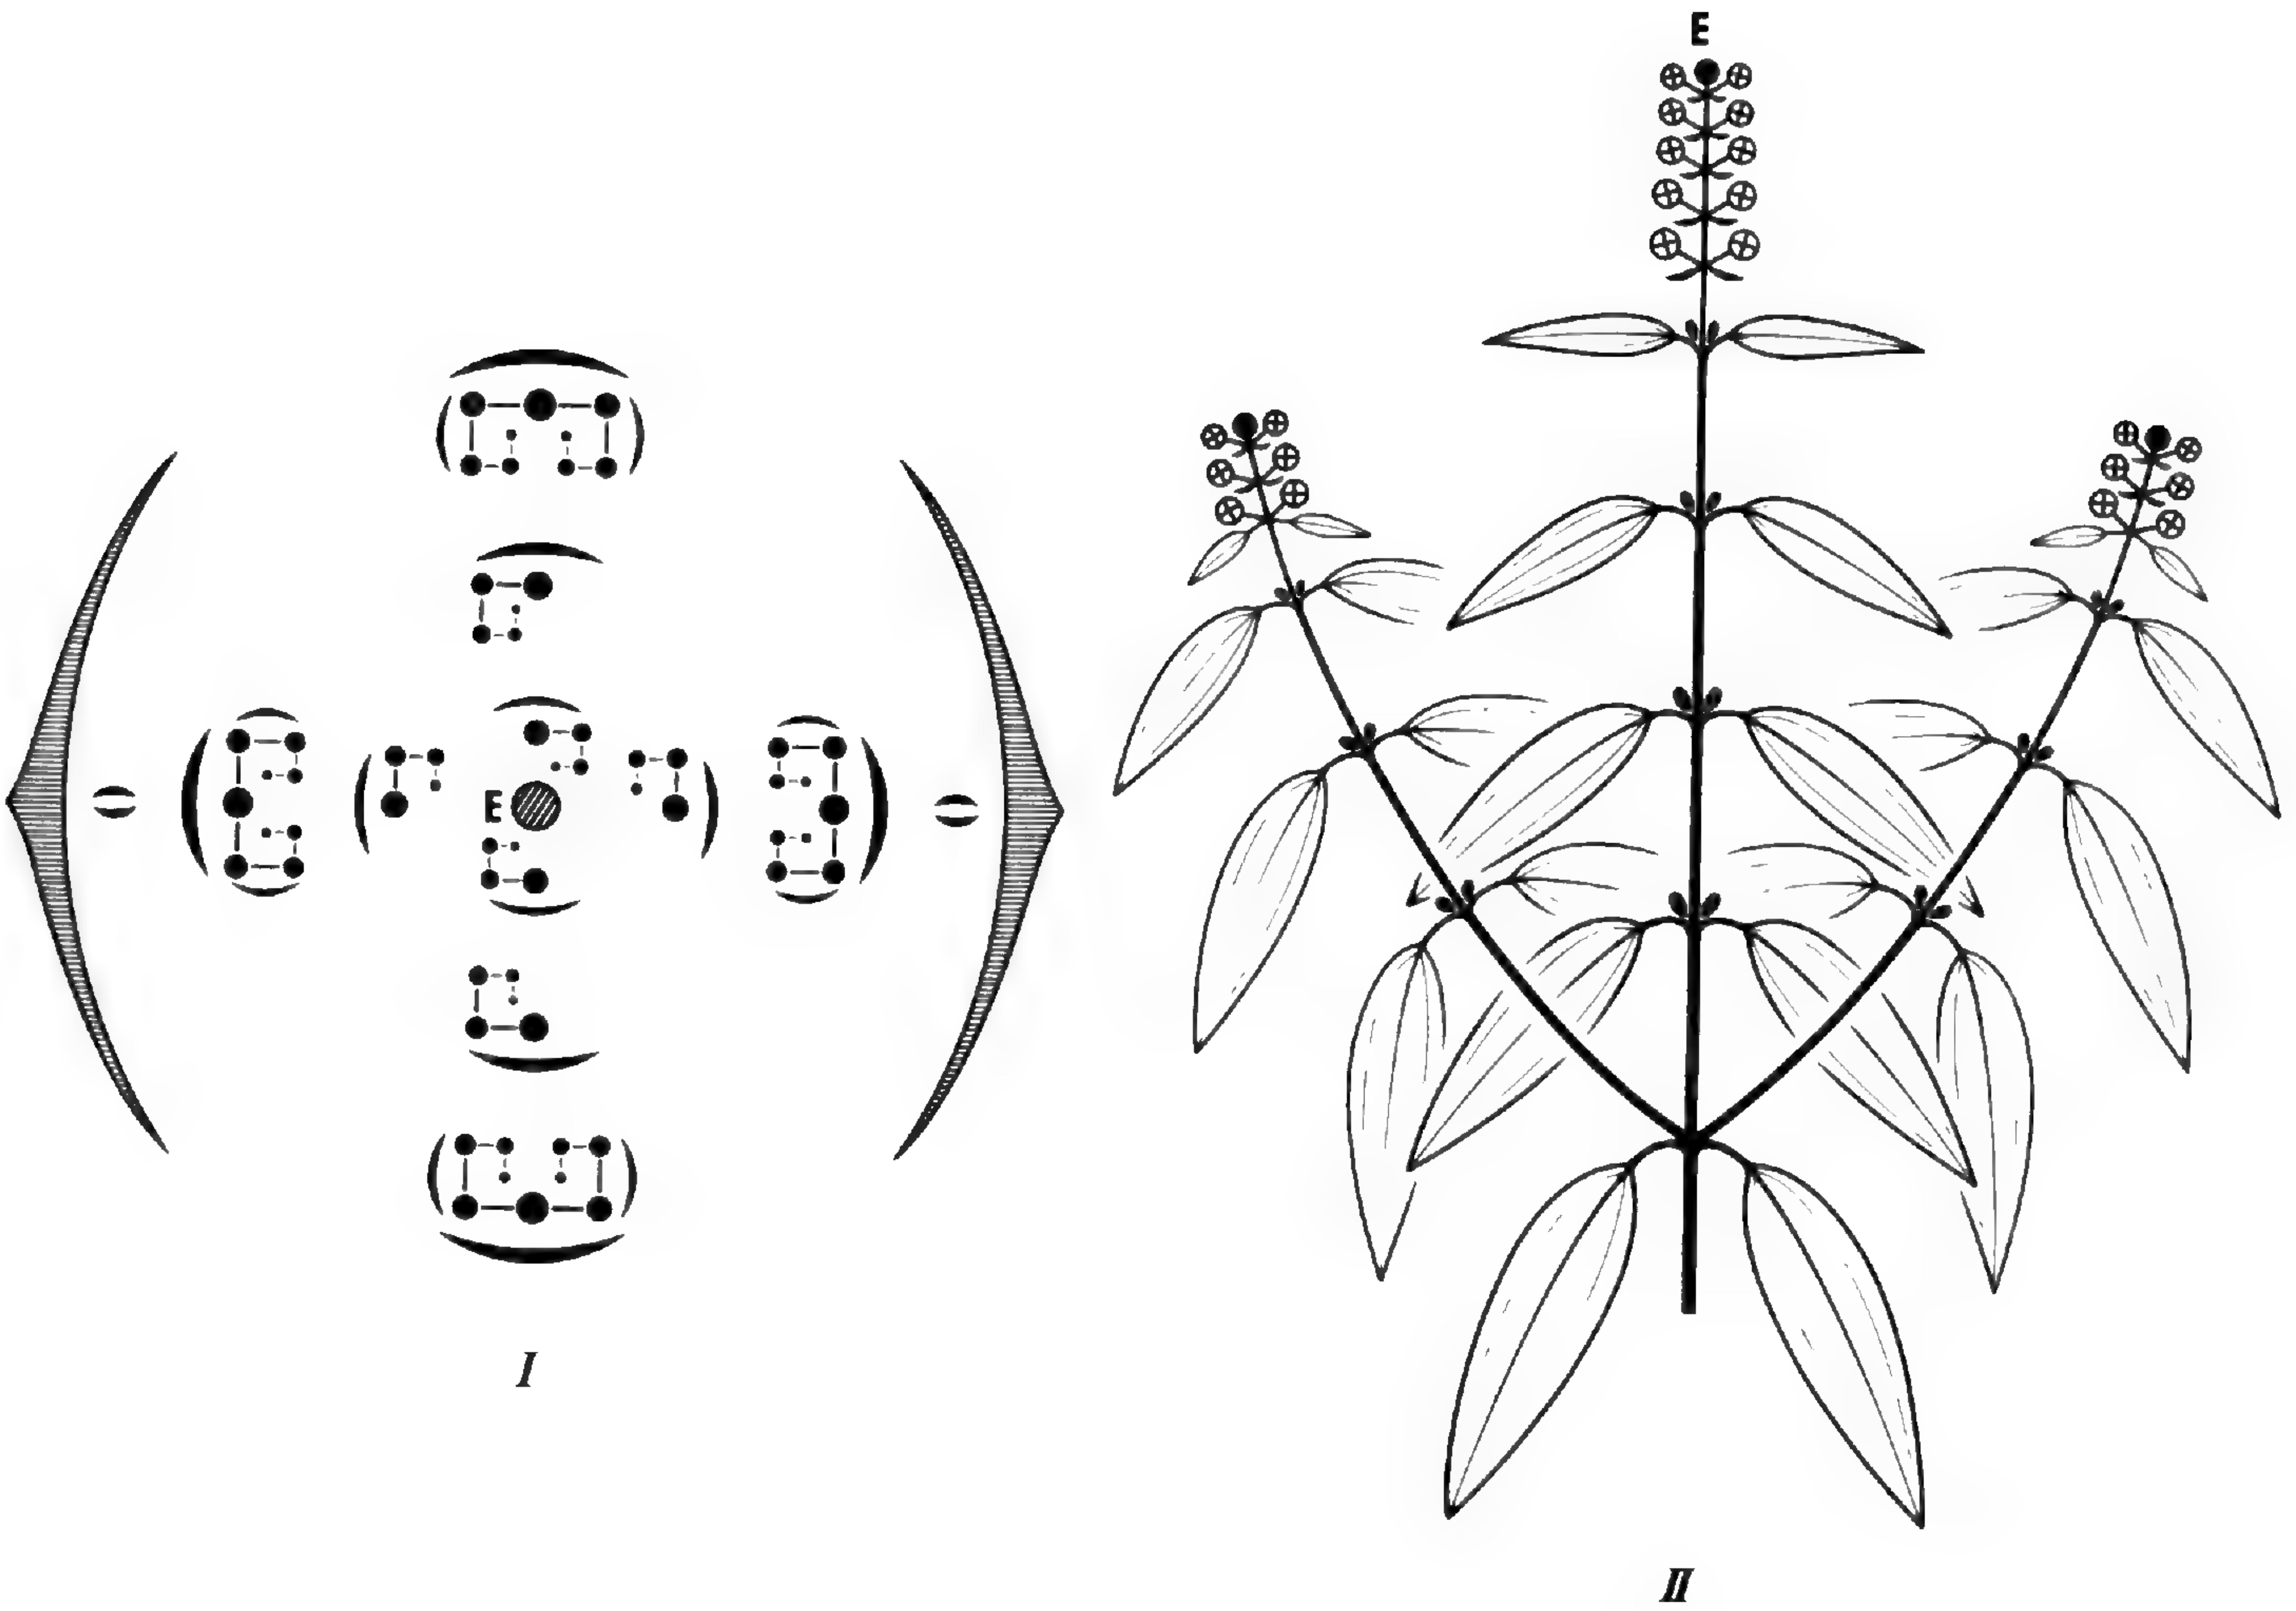

FIGURE 46. *Melastomataceae.* Miconia hookeriana.—*I. Horizontal projection of the ramification of a thyrsoid.—II. Vertical projection of a flowering branch system. (From Troll.)*

with leafy proliferating inflorescences (Fig. 48 I). In contrast to *Huilea macrocarpa*, however, the paracladia in *C. rubra* are reduced to sessile densely flowered cymes.

Proliferation also can be observed within the genus *Comolia*, which also comprises some herbaceous species with proliferating inflorescences (Cremers, 1983/1986). Proliferating inflorescences are characteristic of many or all species of many additional genera, including *Amplectrum* (*homoeandrum* Stapf), *Blastus, Bellucia, Cambessedesia, Ernestia, Maieta, Marumia, Mecranium, Meriania, Microlicia* (*M. pseudo-scoparia* Cogn.), *Microphysca, Myriaspora* (*M. egensis* DC.), *Myrmidone, Ochthocharis, Opisthocentra, Ossaea, Plethiandra, Tococa, Trembleya*, and others. In *Acanthella*, the paracladia of the proliferating inflorescence are reduced to single flowers; the same applies to species of *Blakea* (*B. spruceana* Cogn., see fig. 80 in Krasser, 1893), *Kibessia, Pyxidanthus*, and *Topobea*. *Topobea* and *Blakea* are placed in the Blakeae, which is characterized by the flowers bearing an involucrum of two or more pairs of bracts. This may be interpreted as the remnant of a formerly richer ramification. In addition, in many species of *Blakea* and *Topobea*, we found one to three accessory single flowers below the original one.

Delayed anthesis of the paracladia of proliferating inflorescences in such ligneous plants results in a more or less pronounced cauliflory. Thus in contrast to *Clidemia rubra*, which was mentioned above for its proliferating inflorescences, *C. septuplinervia* Cogn. is cauliflorous (Cremers, 1983/1986). The same applies to many Memecyloideae. Nearly all species of this subfamily are characterized by auxotelic (or sometimes anauxotelic) inflorescences or by more or less cauliflorous partial inflorescences. Transitional forms may be found even in the same plant. Only in *Memecylon cumingianum* Presl we found axillary and terminal thyrsoids. The latter, however, were terminating an older ligneous stem

FIGURE 47. *Melastomataceae. FIGURE 48. *Melastomataceae.—I.* Clidemia rubra; *proliferating flowering shoot. (El Salvador: La Palma,* Weberling 732.*)—II.* Tococa spadiciflora; *spadixlike inflorescence (from Troll).—III.* Henriettella macfadyenii; *cauliflorous branch (from Troll.)*

that was still bearing its foliage leaves. Cauliflory is also well known for the genera *Loreya, Henriettea, Henriettella* (e.g., *H. macfadyenii* (Triana) Alain (Fig. 48 III), and *H. glazioviana* Cogn., see fig. 79B in Krasser, 1893), *Bellucia* (e.g., *B. imperialis* Sald. & Cogn.), and *Myriaspora.* All of these genera belong to the Miconieae, which also includes *Clidemia.*

The contours and forms of terminal inflorescences can be modified by different features. Thus the conical thyrsoid, as mentioned already for *Conostegia* or *Miconia* (Figs. 44, 47 I), can be transformed into a corymboid by more or less effective suppression of the internodal growth of the inflorescence axis, combined with pronounced basitonic development of the paracladia and especially prolongation of their hypopodia. Two shrubs, *Fordiophyton fordii* (Oliv.) Krasser and *Dichaetanthera cormybosa* (Cogn.) Jacques-Félix (see Krasser, 1893: 156), may be mentioned as examples.

In *Amphiblemma cymosum* (Schrad. & Wendl.) Naudin (Fig. 49), a corymboid of pleiochasial structure is formed. The internodes in the distal part of the inflorescence axis, with the exception of the final internode, remain very short. As a result the insertions of the paracladia are crowded together (Fig. 49 I). The arrangement of these paracladia is not decussate as might be expected, but alternate, since phyllotaxis changes above the uppermost pair of foliaceous leaves, which is usually somewhat smaller. The bracteose pherophylls of the paracladia are shifted on their axillary paracladia by recaulescence. Usually there are five paracladia (maximum

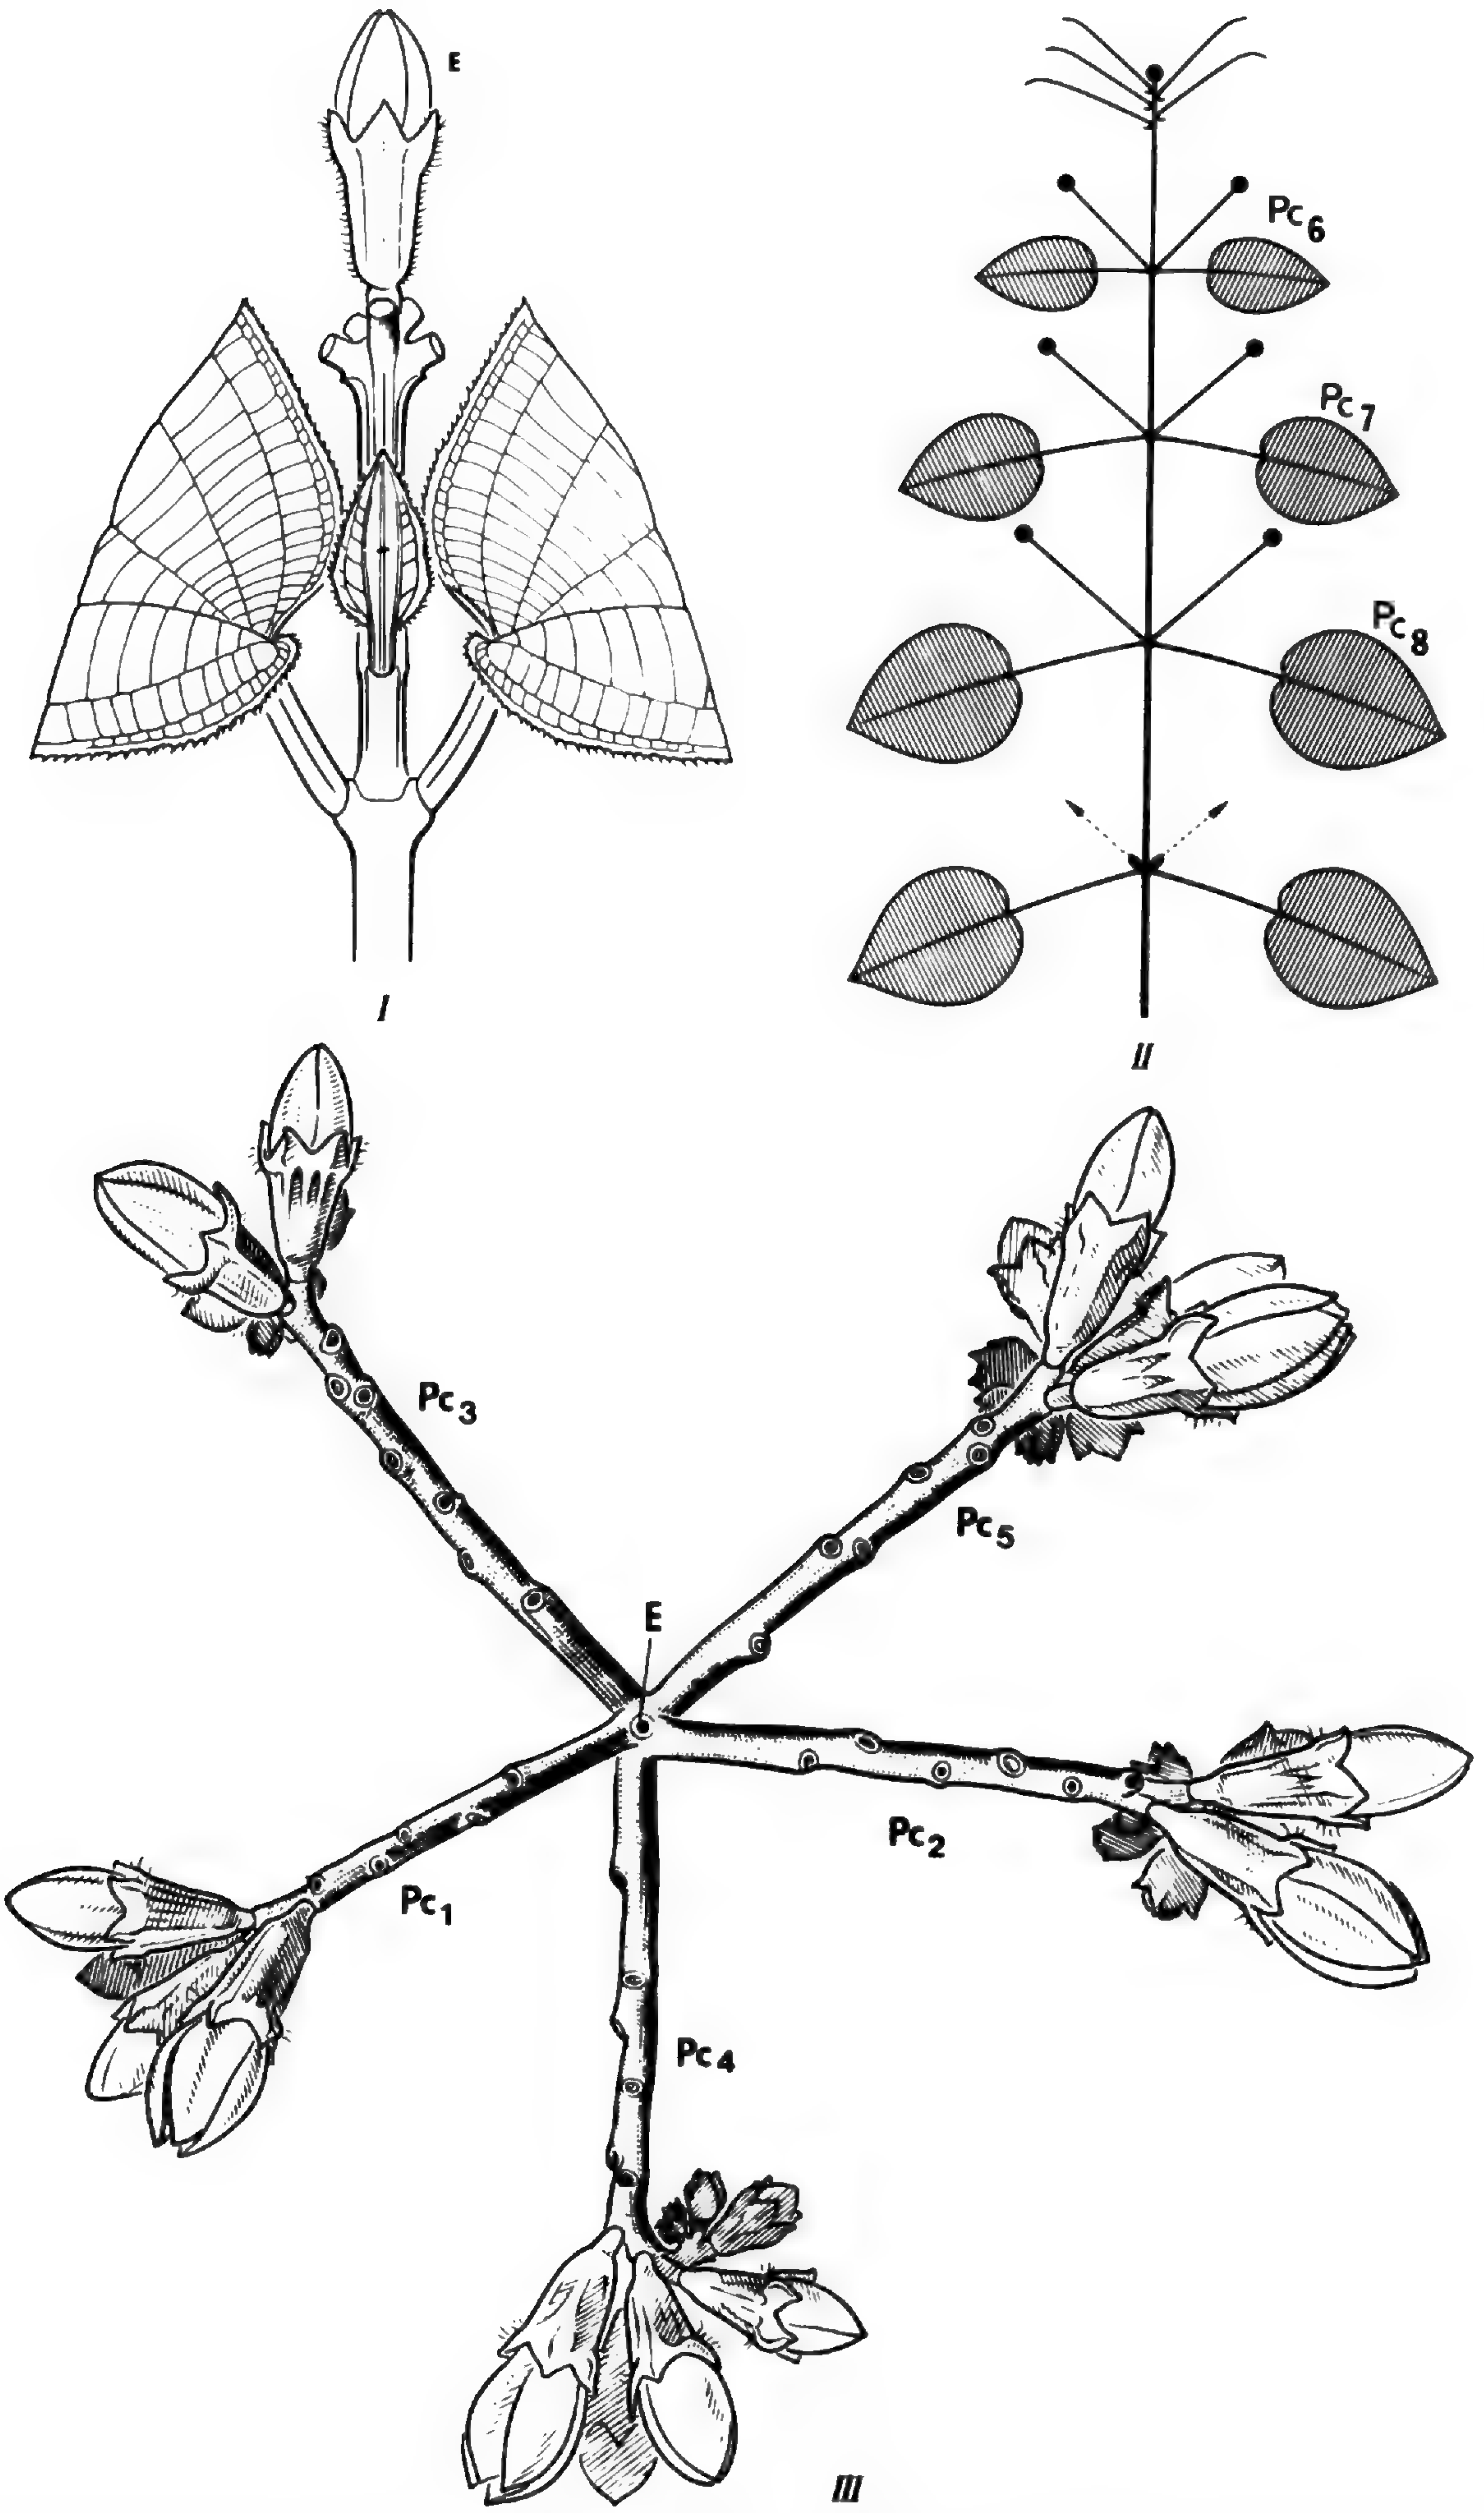

FIGURE 49. *Melastomataceae.* Amphiblemma cymosum.—*I. Inflorescence apex, the paracladia have been cut off.—II. Vertical projection at the beginning of anthesis of a flowering shoot.—III. Pleiochasial corymboid at the end of anthesis from above. Pc$_1$–Pc$_5$, paracladia of first to fifth order; E, terminal flower. (All from Troll.)*

eight) forming helicoid cymes. If there are more than five paracladia, the lower ones can form "paired" or "double helicoids," because in these more vigorous paracladia both first-order prophylls are fertile. Since the paracladia elongate considerably by the formation of many flowers, the position of the terminal flower finally is at the deepest point of the whole pleiochasium (Fig. 49 III). In older and vigorous plants more paracladia, mostly double-helicoid, can develop from the axils of the foliaceous leaf pairs in the lower part of the stem (Fig. 49 II, pc_6–pc_8).

The monotelic (pleio-)thyrsoid as the basic form of inflorescences in Melastomataceae can also be modified by reduction of 1) the ramification of the paracladia and 2) the number of paracladia.

1) Reduction of cymose ramification of the paracladia ultimately results in the formation of dibotryoids, as shown for *Leandra sylvatica* Cogn. or *Miconia sarmentosa* Cogn. by Cremers (1983/1986, figs. 25/3, 27/2; see also *Tibouchina frigidula* (DC.) Cogn., fig. 30/2), or in the formation of simple botryoids. A transitional stage on the way to formation of botryoids is exemplified by *Tococa guianensis* Aublet (Fig. 50 II). Compared with other elongate thyrsoids like that of *Tococa formicaria* Martius (Fig. 50 III) or *Allomorphia magnifica* Guill. (Fig. 50 I), its ramification appears to be much reduced, although the proximal paracladia are still three-flowered. If these paracladia are reduced to uniflorous elements, the inflorescence forms a simple botryoid, as occurs facultatively in *Tibouchina canescens* (D. Don) Cogn. (Cremers, 1983/1986, fig. 30/5), *Clidemia capitellata* (Bonpl.) DC. (Fig. 51 III), and *C. minutiflora* (Triana) Cogn. (Cremers, 1983/1986, fig. 32/7), or generally in *Adelobotrys spruceana* Cogn. (Cremers, 1983/1986, fig. 19/9) or *Castratella piloselloides* (Bonpl.) Naudin (Cremers, 1983/1986, fig. 19/9).

In another way the dense spikelike or nearly spadix-formed inflorescence of *Tococa spadiciflora* Triana (Fig. 48 II) can be derived from an elongate monothyrsoid: as indicated in Figure 50 III, the hypopodia of first and second orders (dotted lines) remain undeveloped. If this is combined with a shortening of the main axis, a capitulate inflorescence like that of *T. capitata* Cogn. (= *Sagraea capitata* Triana) results. According to Troll (posthumous manuscript), the inflorescence apex of *T. spadiciflora* probably remains indefinite.

If in contrast to the previous examples all internodes of the inflorescence are prolonged, a loosely branched thyrsoid results, as in *Nepsera aquatica* (Aublet) Naudin (Fig. 57 I).

As already mentioned for ligneous members of the family, foliaceous proliferating botrytic inflorescences are not rare (see also *Tibouchina axillaris* Cogn., Fig. 51 I). *Comolia purpurea* Miq. (Cremers, 1983/1986, fig. 22/1) and *Tibouchina petroniana* Cogn. (Cremers, 1983/1986, fig. 30/8), with its diplobotrytic inflorescences, are herbaceous examples.

2) This reduction of cymose ramification of the paracladia resulting in the formation of botryoids can be combined with diminution of the number of paracladia. Thus the botryoids of *Castratella piloselloides* mentioned above (Fig. 50 IV) bear two or three pairs of paracladia only. Reduction can go further, as in *Clidemia involucrata* DC., with sometimes only two uniflorous paracladia below the terminal flower (Cremers, 1983/1986, fig. 21/11). Ultimately a solitary terminal flower remains, as in the fruticose *Tibouchina sellowiana* (Cham.) Cogn. and *T. petroniana* Cogn. (Fig. 51 II; Cremers, 1983/1986, figs. 30/6, 7). Cogniaux (1888: 598) described the flowering system of the latter as "floribus ad apices ramulorum solitariis; bracteis saepius 6." Indeed, the main axis and a series of

foliaceous paracladia originating from the axils of foliaceous leaf pairs in the proximal part of the main axis bear a single terminal flower only. Each of these flowers is preceded by three pairs of sterile bracts—a remnant of the thyrsoid ramification system.

In the prevalently herbaceous genus *Salpinga* were found two-flowered inflorescences in *S. pusillum* (Gleason) Wurd. (= *Macrocentrum pusillum*) and uniflorous inflorescences in *S. glandulosum* (Gleason) Wurd., whereas within the related genus *Macrocentrum, M. cristatum* (L. C. Rich.) Triana apparently has cymoids with scorpioid paracladia (Krasser, 1893, fig. 75C); the same applies to *M. latifolium* Wurd. (Cremers, 1983/1986: 69). According to Cremers (1983/1986, fig. 25/5, 5'), *M. vestitum* Sandw. normally develops the terminal flower only, but in some exceptional cases this can be accompanied by two lateral flowers.

In such cases uniflory is obviously facultative. This especially applies to individuals of herbaceous annual species grown under unfavorable conditions. In such plants the ramification is more or less reduced, sometimes with the result that only the terminal flower is developed. According to Troll (posthumous manuscript), examples can be found within the genus *Pterolepis*, which is closely related to *Tibouchina*. Figure 50 shows vigorous (V) and reduced (VI) plants of *P. trichotoma* Cogn., which differ in the number and the vigor of their cymose paracladia. In Figure 50 V the lowest pair of paracladia has the longest hypopodia of first and second orders and is the most copiously branched. The uppermost pair of paracladia, however, is also vigorous and bears more flowers than the preceding one. This indicates a certain tendency of an acrotonic support of ramification. Therefore it is not surprising that in the reduced plant (Fig. 50 VI) the distal pair of paracladia is the only one fully developed. In *P. repanda* (DC.) Triana (Fig. 50 VII, VIII) the acrotonic support of ramification becomes so effective that only the distal pair of paracladia is developed and a more (VIII) or less (VII) copiously branched cymoid is formed. In *P. pauciflora* (Naud.) Triana pauperization of the inflorescence finally progresses to the formation of a three-flowered (Fig. 50 IX) or uniflorous (X) inflorescence. Some other examples have been given by Cremers (1983/1986), who analyzed species of *Acisanthera* and *Appendicularia* and found uniflorous individuals in *Acisanthera bivalvis* (Aublet) Cogn. (Cremers, 1983/1986, fig. 18/8); a similar diversity of inflorescence forms occurs in *Appendicularia thymifolia* (Bonpl.) DC. Altogether the inflorescences of the mostly or exclusively annual species of *Acisanthera*, *Appendicularia*, *Aciotis* (e.g., *A. amazonica*, *A. aequilaterialis*, *A. dichotoma* Cogn.), and probably also *Pterogastra* are very variable: plants with extremely acrotonic ramification forming "dichotomic" inflorescences (cymoids) can be found beside plants with extremely reduced, sometimes even uniflorous inflorescences. The herbaceous *Catacoryne linnaeoides* Hook. f. probably also can develop uniflorous inflorescences.

Obligatorily uniflorous inflorescences are known for some fruticose taxa, especially the genus *Chaetostoma* and some species of the genera *Marcetia*, *Lavoisiera*, and *Microlicia*.

A flower-bearing shoot system of *Marcetia sertularia* DC. (Fig. 52 III) shows the branches more vigorously developed in the distal zone, i.e., an acrotonic ramification system. Most of the densely foliate branches as well as their relative main axes end in a terminal flower (Fig. 52 II). Lateral flowers or even vestiges of lateral flowers inserted below the terminal flowers cannot be found, in contradistinction to some other species of the genus. The whole system, however, cannot be regarded as an entire inflorescence but must be interpreted as a ramification system comprising numerous uniflorous inflorescences.

Accessory buds or branches are very common within the family (see also Wagner, 1907). They form single flowers or dyads in the inflorescence of *Pterolepis trichotoma* (Rottb.) Cogn. (Fig. 50 V) and occur in the leaf axils of the main axis as well as of the paracladia and can even form triadic or many-flowered cymes, as in *Adelobotrys ciliata* (Naudin) Triana, *A. permixta* Wurd., *Leandra polyadena* Ule, and *L. rufescens* (DC.) Cogn. (Cremers, 1983/1986, figs. 19/2, 6, 24/1, 4), or even thyrsoid flowering systems, as in *Miconia kappleri* Naudin and *M. tillettii* Wurd. (Cremers, 1983/1986, figs. 26/1, 2). If there are two or more buds, they are always arranged in a phylloscopic sequence, as in *Topobea guianensis* Aublet (Cremers, 1983/1986, fig. 31/6) or *Creochiton* Bl. (see Wagner, 1907). Sometimes differentiation between the buds of the same axillary series can take place. In *Ernestia confertiflora* Wurd. the upper of two buds develops into a vegetative branch and the lower forms a flowering system, whereas in *Maieta guianensis* Aublet the reverse situation occurs (see Cremers, 1983/1986, figs. 23/5, 25/6). Troll (posthumous manuscript) found in an inflorescence of *Tococa symphyandra* (Triana) Cogn. that 92 of a total 220 flowers belonged to accessory branches (Fig. 47 IV).

The formation of cymoids has been mentioned already in the context of the reduction

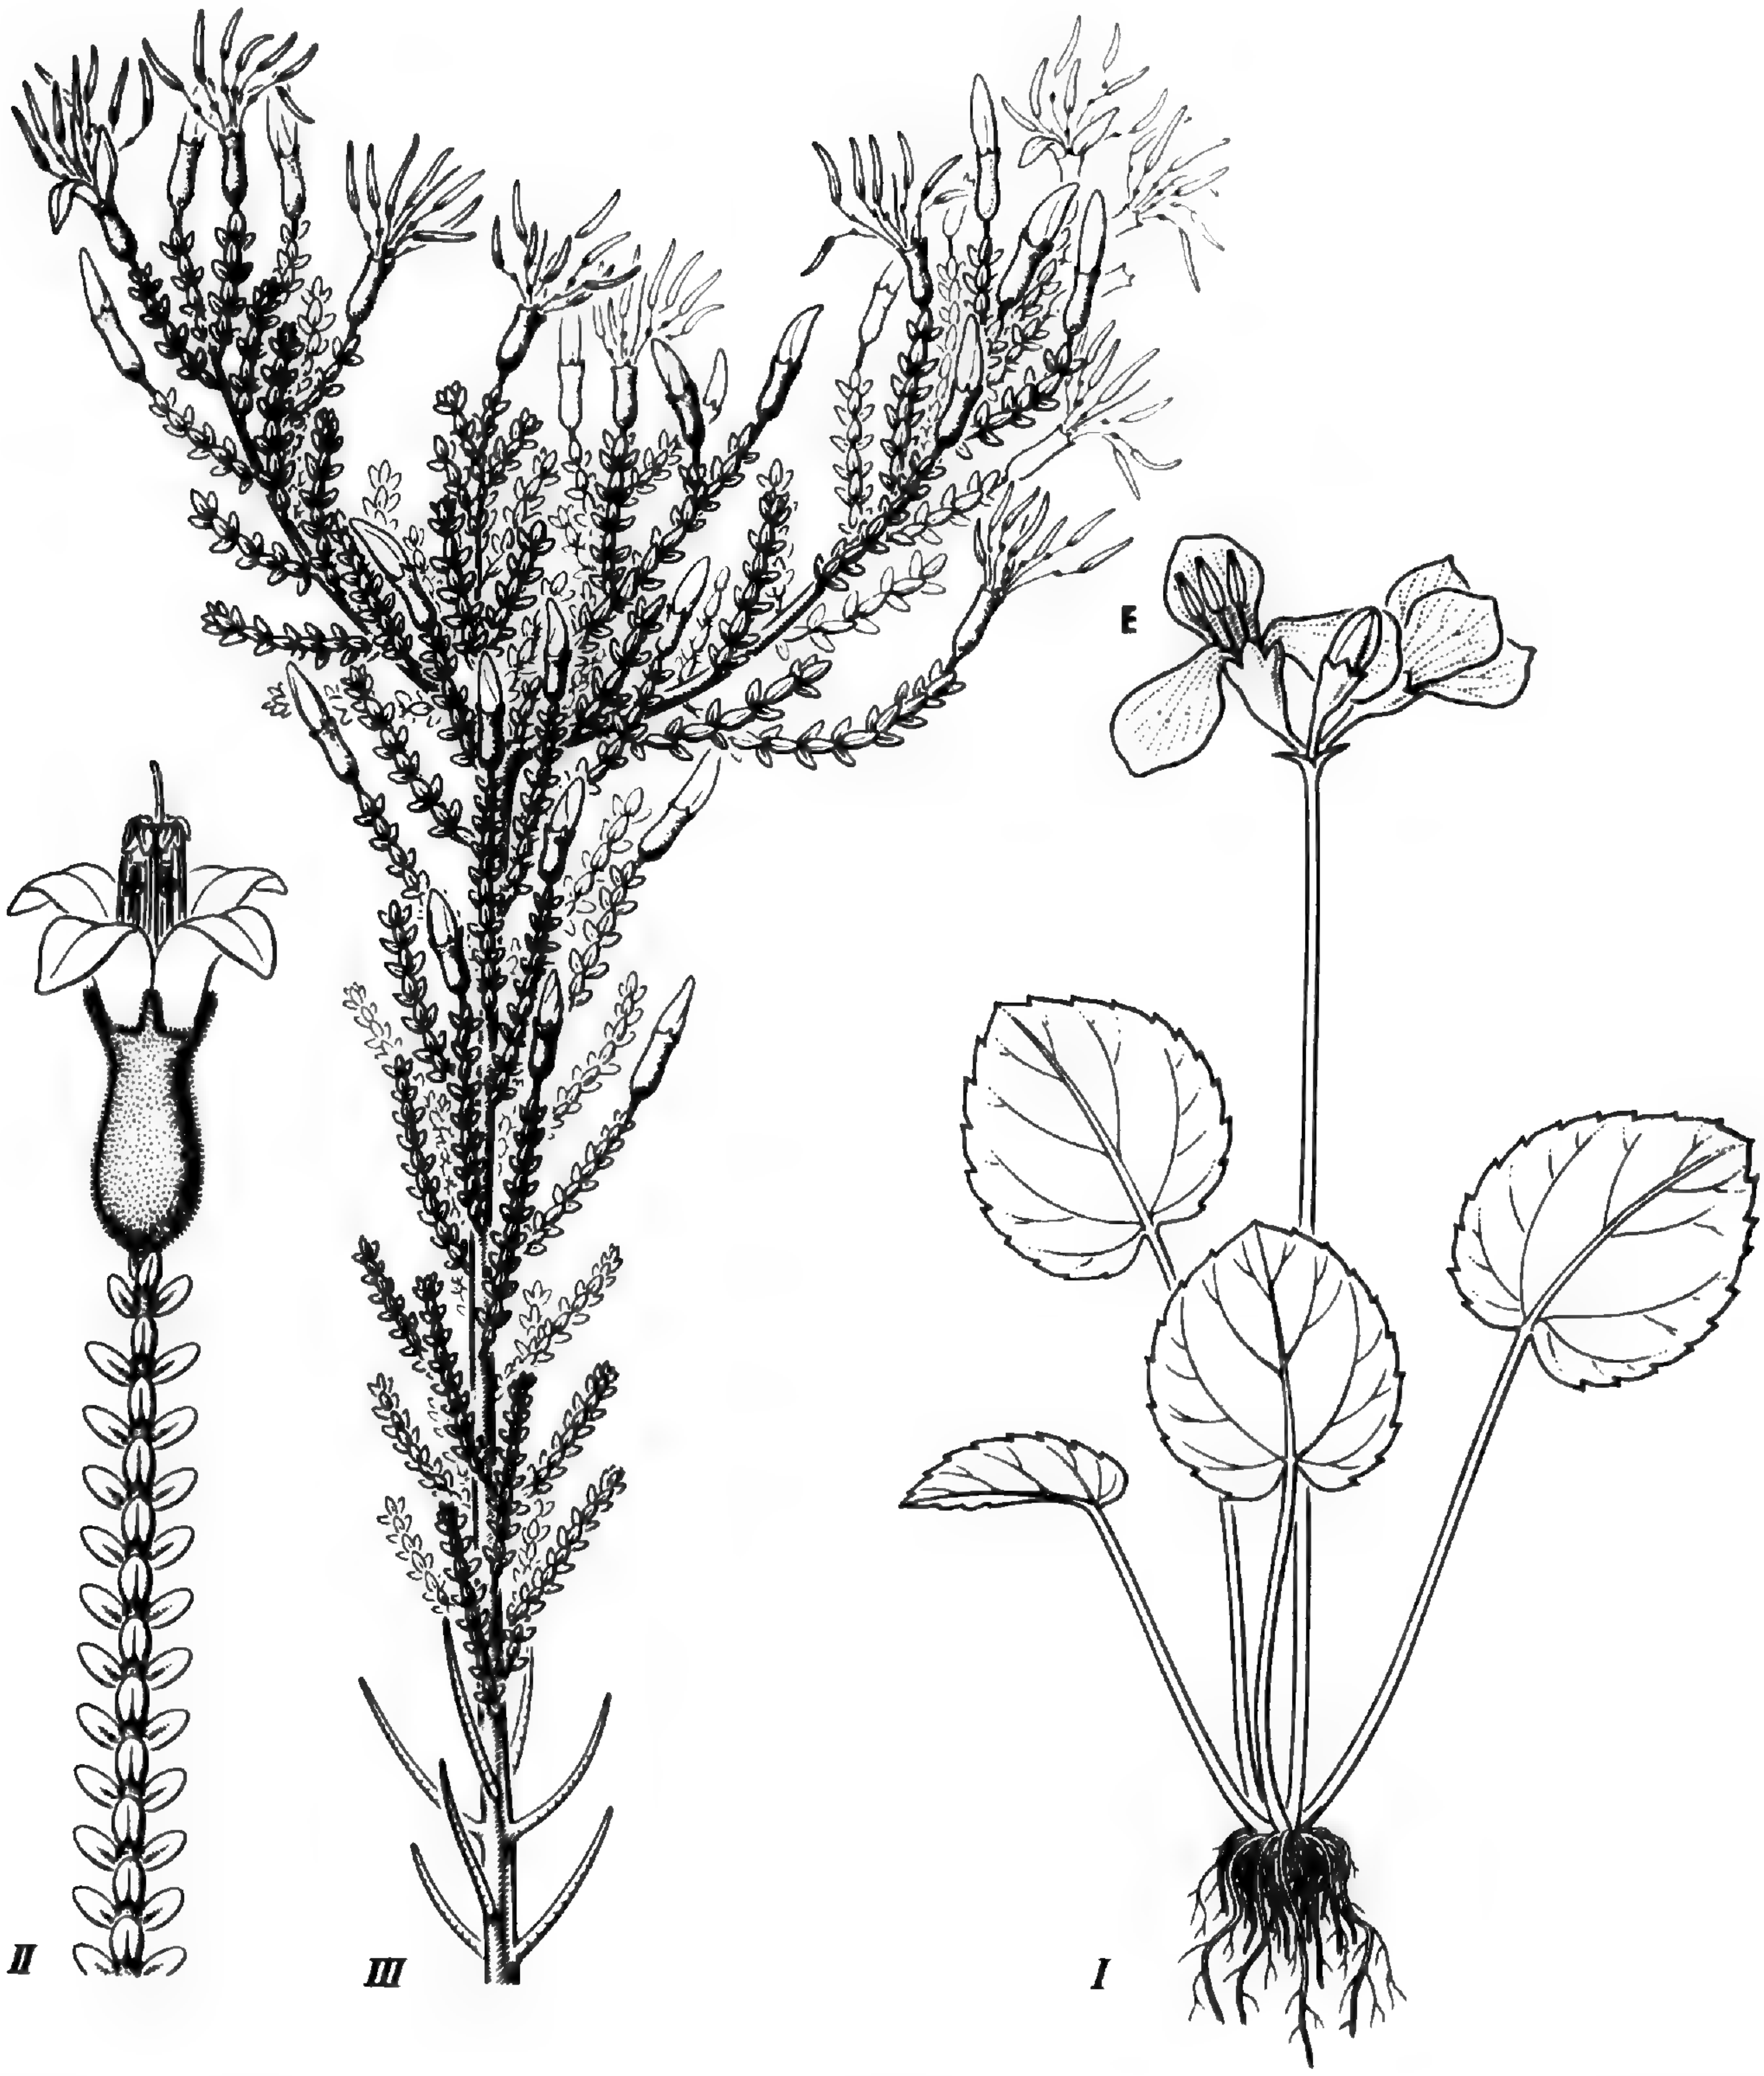

FIGURE 52. *Melastomataceae.—I.* Sonerila rotundifolia; *flowering plant (after Beddome). E, terminal flower. II, III.* Marcetia sertularia.*—II. Single branch with terminal flower (after De Candolle).—III. Flowering branching system.*

of inflorescences in reduced individuals of *Pterolepis* species (p. 277). Cymoids occur especially within the mostly herbaceous Sonerileae and Bertolonieae. Only a few examples are needed here.

In *Calvoa sessiliflora* Cogn. (Sonerileae) the cymoids are very conspicuous, especially in fruiting plants (Fig. 53 II). In this plant the leaves of the main axis are already lost. The foliation of the main stem is leafy and only the distal pair of leaves is bracteose (Fig. 54 I). These bracts are inconspicuous and by recaulescence united with their axillary branches, the uppermost paracladia, which form simple scorpioids. Between these two scorpioids the main axis ends with the terminal flower that is sessile because the final internode remains undeveloped. The same applies to the flowers of the scorpioid paracladia. The internode preceding the insertion of the

FIGURE 53. *Melastomataceae.—I.* Sonerila margaritacea.—*II.* Calvoa sessiliflora; *flowering plant. (From Troll.)*

scorpioid paracladia is very thin in proportion to the other internodes of the main stem. The same difference appears between the scorpioids and the preceding paracladia, which in thickness attain about double the size. These paracladia, which originate from the axils of foliage leaves, repeat the architecture of the main stem: they end in a cymoid and their foliation is leafy, with the exception of the pherophylls bearing the scorpioids. However, there is one important difference: the leaf pairs, especially that in the median position are anisophyllous, and the leaf pointing outwards by far exceeds the size and differentiation of its partner (Fig. 54 II). The trans-

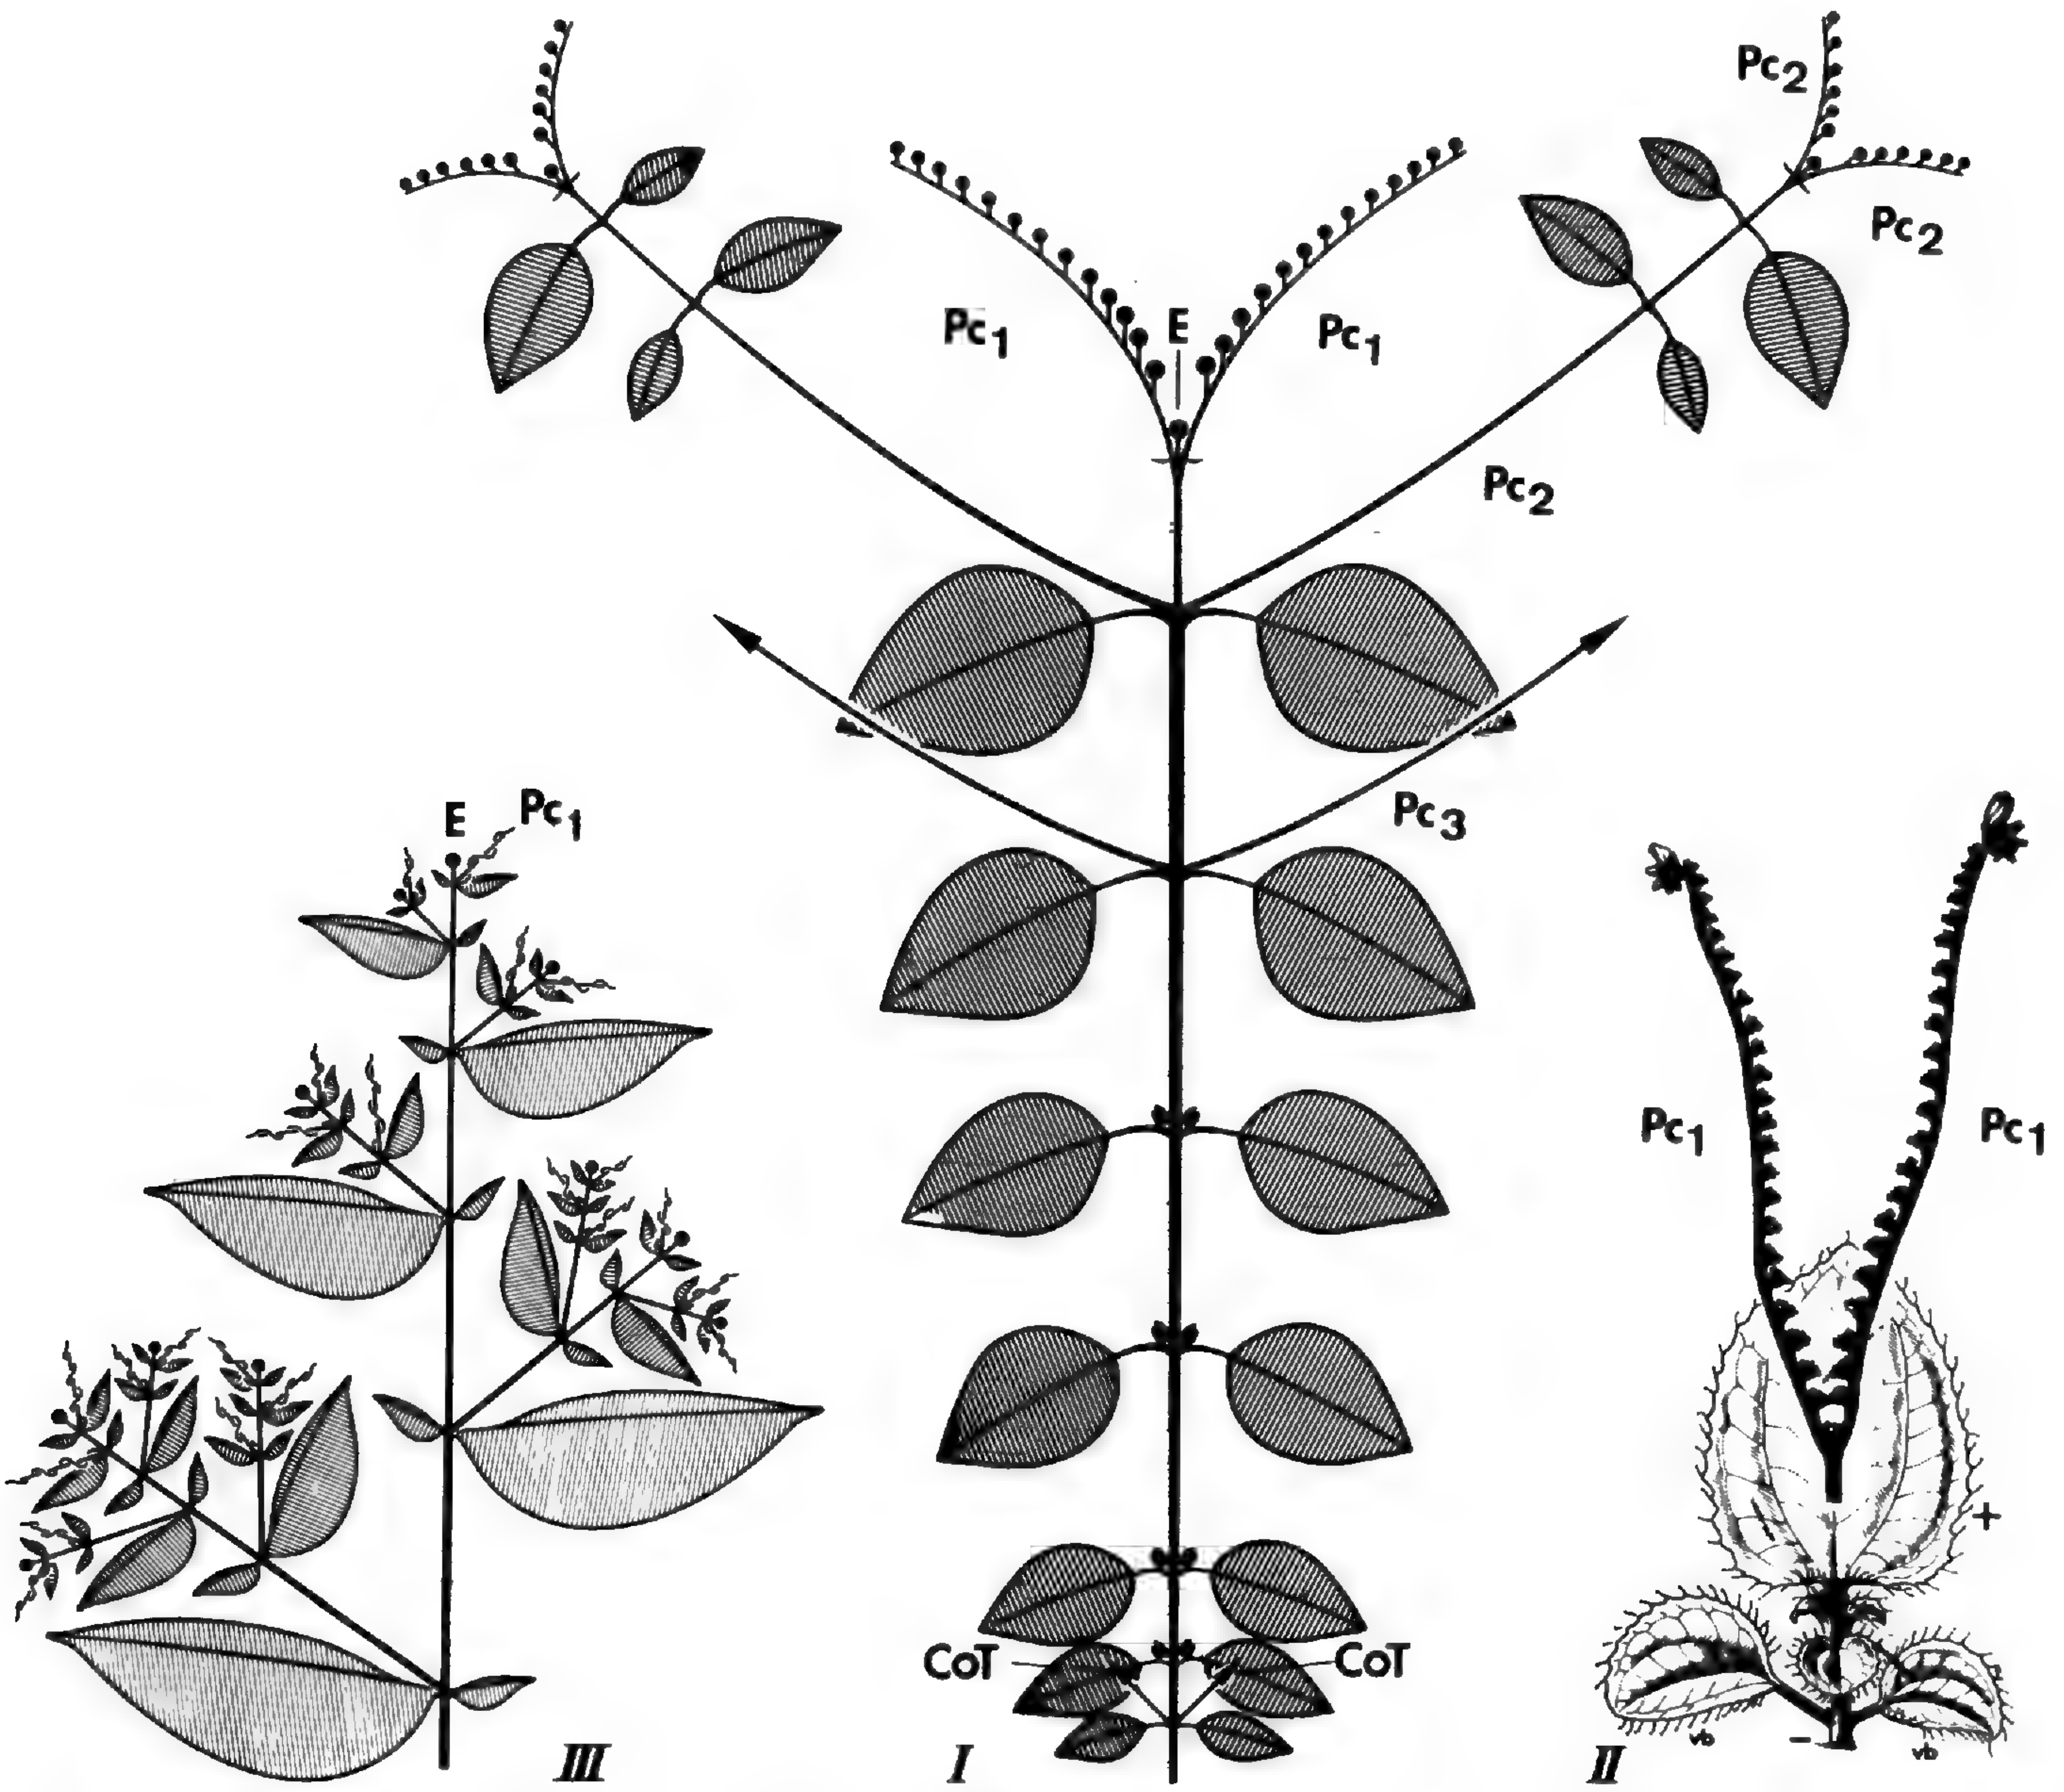

FIGURE 54. *Melastomataceae. I, II.* Calvoa sessiliflora.—*I. Vertical diagram of a flowering individual; E, terminal flower; CoT, cotyledonary branches.—II. Paracladium (Pc_2 from I), view from the ventral (upper) side; vb, prophylls; +, the larger leaf of the anisophyllous second leaf pair.—III.* Centradenia grandifolia; *analytical vertical diagram of a flowering branch. FIGURE 55. *Melastomataceae. Vertical inflorescence diagrams of* Sonerila margaritacea *(I) and* Bertolonia marmorata *(II). (From Troll.)* Pc_1–Pc_{10}, *first through tenth order paracladia; E, terminal flower; E′, secondary terminal flower; α, β = prophylls.*

versely arranged prophylls are asymmetric, the side pointing outwards (downwards) being larger. The whole paracladial zone comprises two or three pairs of paracladia and is preceded by an inhibition zone, within which only the cotyledonary branches show a slight tendency to unfold. In some way the species resembles *Amphiblemma cymosum* (Fig. 49), which belongs to the same tribe. In *A. cymosum*, however, the flower-bearing system that terminates the shoot comprises about five alternately arranged paracladia. The flowering system of *Sonerila margaritacea* Lindley (Fig. 53 I) is also similar to that of *Calvoa sessiliflora* inasmuch as there are two scorpioid paracladia originating from the axils of a pair of bracts below the terminal flower. The whole "double-scorpioid" is separated from the basal part of the plant by a long and comparatively thin internode. This scape is preceded by three pairs of frondulose to bracteose sterile leaves that form a transition between the preceding foliaceous leaf pairs and the uppermost pair of minute bracts. Since the preceding pairs of foliage leaves bear paracladia in their axils, the three pairs of sterile leaves form an intercalary inhibition zone within the flowering system. Each of the paracladia pc_5–pc_7 (pc_2–pc_4 are missing) in Figure 55 I nearly gives a complete copy of that part of the main stem that follows the point of its insertion, apart from the fact that all of them bear simple scorpioids. In *S. pilosula* Thwaites this also applies to the main axis.

Unlike previous species, *Sonerila rotundifolia* Bedd. (Fig. 52 I) is a rosette plant. The basal part of the main axis bearing the foliaceous rosette leaves is short and vigorous; only the distal part tapers and forms a flower-bearing scape. Since the plant is hapaxanthic, however, the vigorous basal part cannot be termed a rhizome. The umbellike inflorescence that is elevated above the rosette leaves by a long internode consists of two scorpioid paracladia that are inserted below the terminal flower. In *S. scapigera* Dalz. there are more long-peduncled umbellike flowering systems arising from the rosette. The morphol-

FIGURE 56. *Melastomataceae.* Bertolonia marmorata.—*I. Flowering plant.—II. Same, with most of the rosette leaves removed. (From Troll.)*

ogy of this plant has not been clearly elucidated, but we only can confirm that each of the flowering shoots bears its own basal rosette of foliage leaves.

A transitional form that connects *Calvoa sessiliflora* and *Sonerila margaritacea* on the one hand with *Sonerila rotundifolia* and similar species on the other hand is *Bertolonia marmorata* Naudin (Bertolonieae). In this semirosulate plant (Figs. 55 II, 56) the basal leaves are decussate, whereas the cauline leaves change over to alternate arrangement. In the distal part of the main axis there is only one scorpioid paracladium inserted below the terminal flower. Some more paracladia arise from the axils of the frondulose leaves in the lower part of the stem. These paracladia, however, can bear more than one scorpioid. The axillary buds of the upper rosette leaves can also produce paracladia, but most of them remain vegetative. The lowermost axillary buds ordinarily do not develop, nor do they function as innovation buds. Thus the plant is hapaxanthic. Since the scorpioid is formed gradually during anthesis and turns to the direction of the main axis, it can appear as a spike later on.

Eriocnema acaulis Triana, also in the Bertolonieae, seems to resemble *Bertolonia* in its growth form, but has long-peduncled umbel-like cymoids similar to those in *Sonerila rotundifolia.* On the other hand, *Cincinnobotrys oreophila* Gilg (1898, pl. VI), which belongs to the Sonerileae (Jacques-Félix, 1976), bears only one scorpioid paracladium below the terminal flower, which is elevated above the basal rosette by a long internode of the main axis (Fig. 57 II).

Finally *Monolena primulaeflora* Hook. f. may be mentioned here for its very peculiar architecture, which Troll investigated (posthumous manuscript). With regard to the architecture of the primary axis, this plant is similar to *Sonerila rotundifolia.* The main axis is short and vigorous in its basal part, which bears the rosulate foliage leaves. In its distal part the axis tapers and forms a long scape that bears the terminal inflorescence consisting of the terminal flower and one or two scorpioid paracladia. The latter originate in the axils of two broad bracts that fit very well to protect the young flowers. Below these broader bracts there is a pair of smaller bracts that remains sterile. The significant feature of this plant is that it develops plagiotropic paracladia from the axils of the basal foliage leaves. These paracladia are equal to the main axis especially in their vigor. Together with

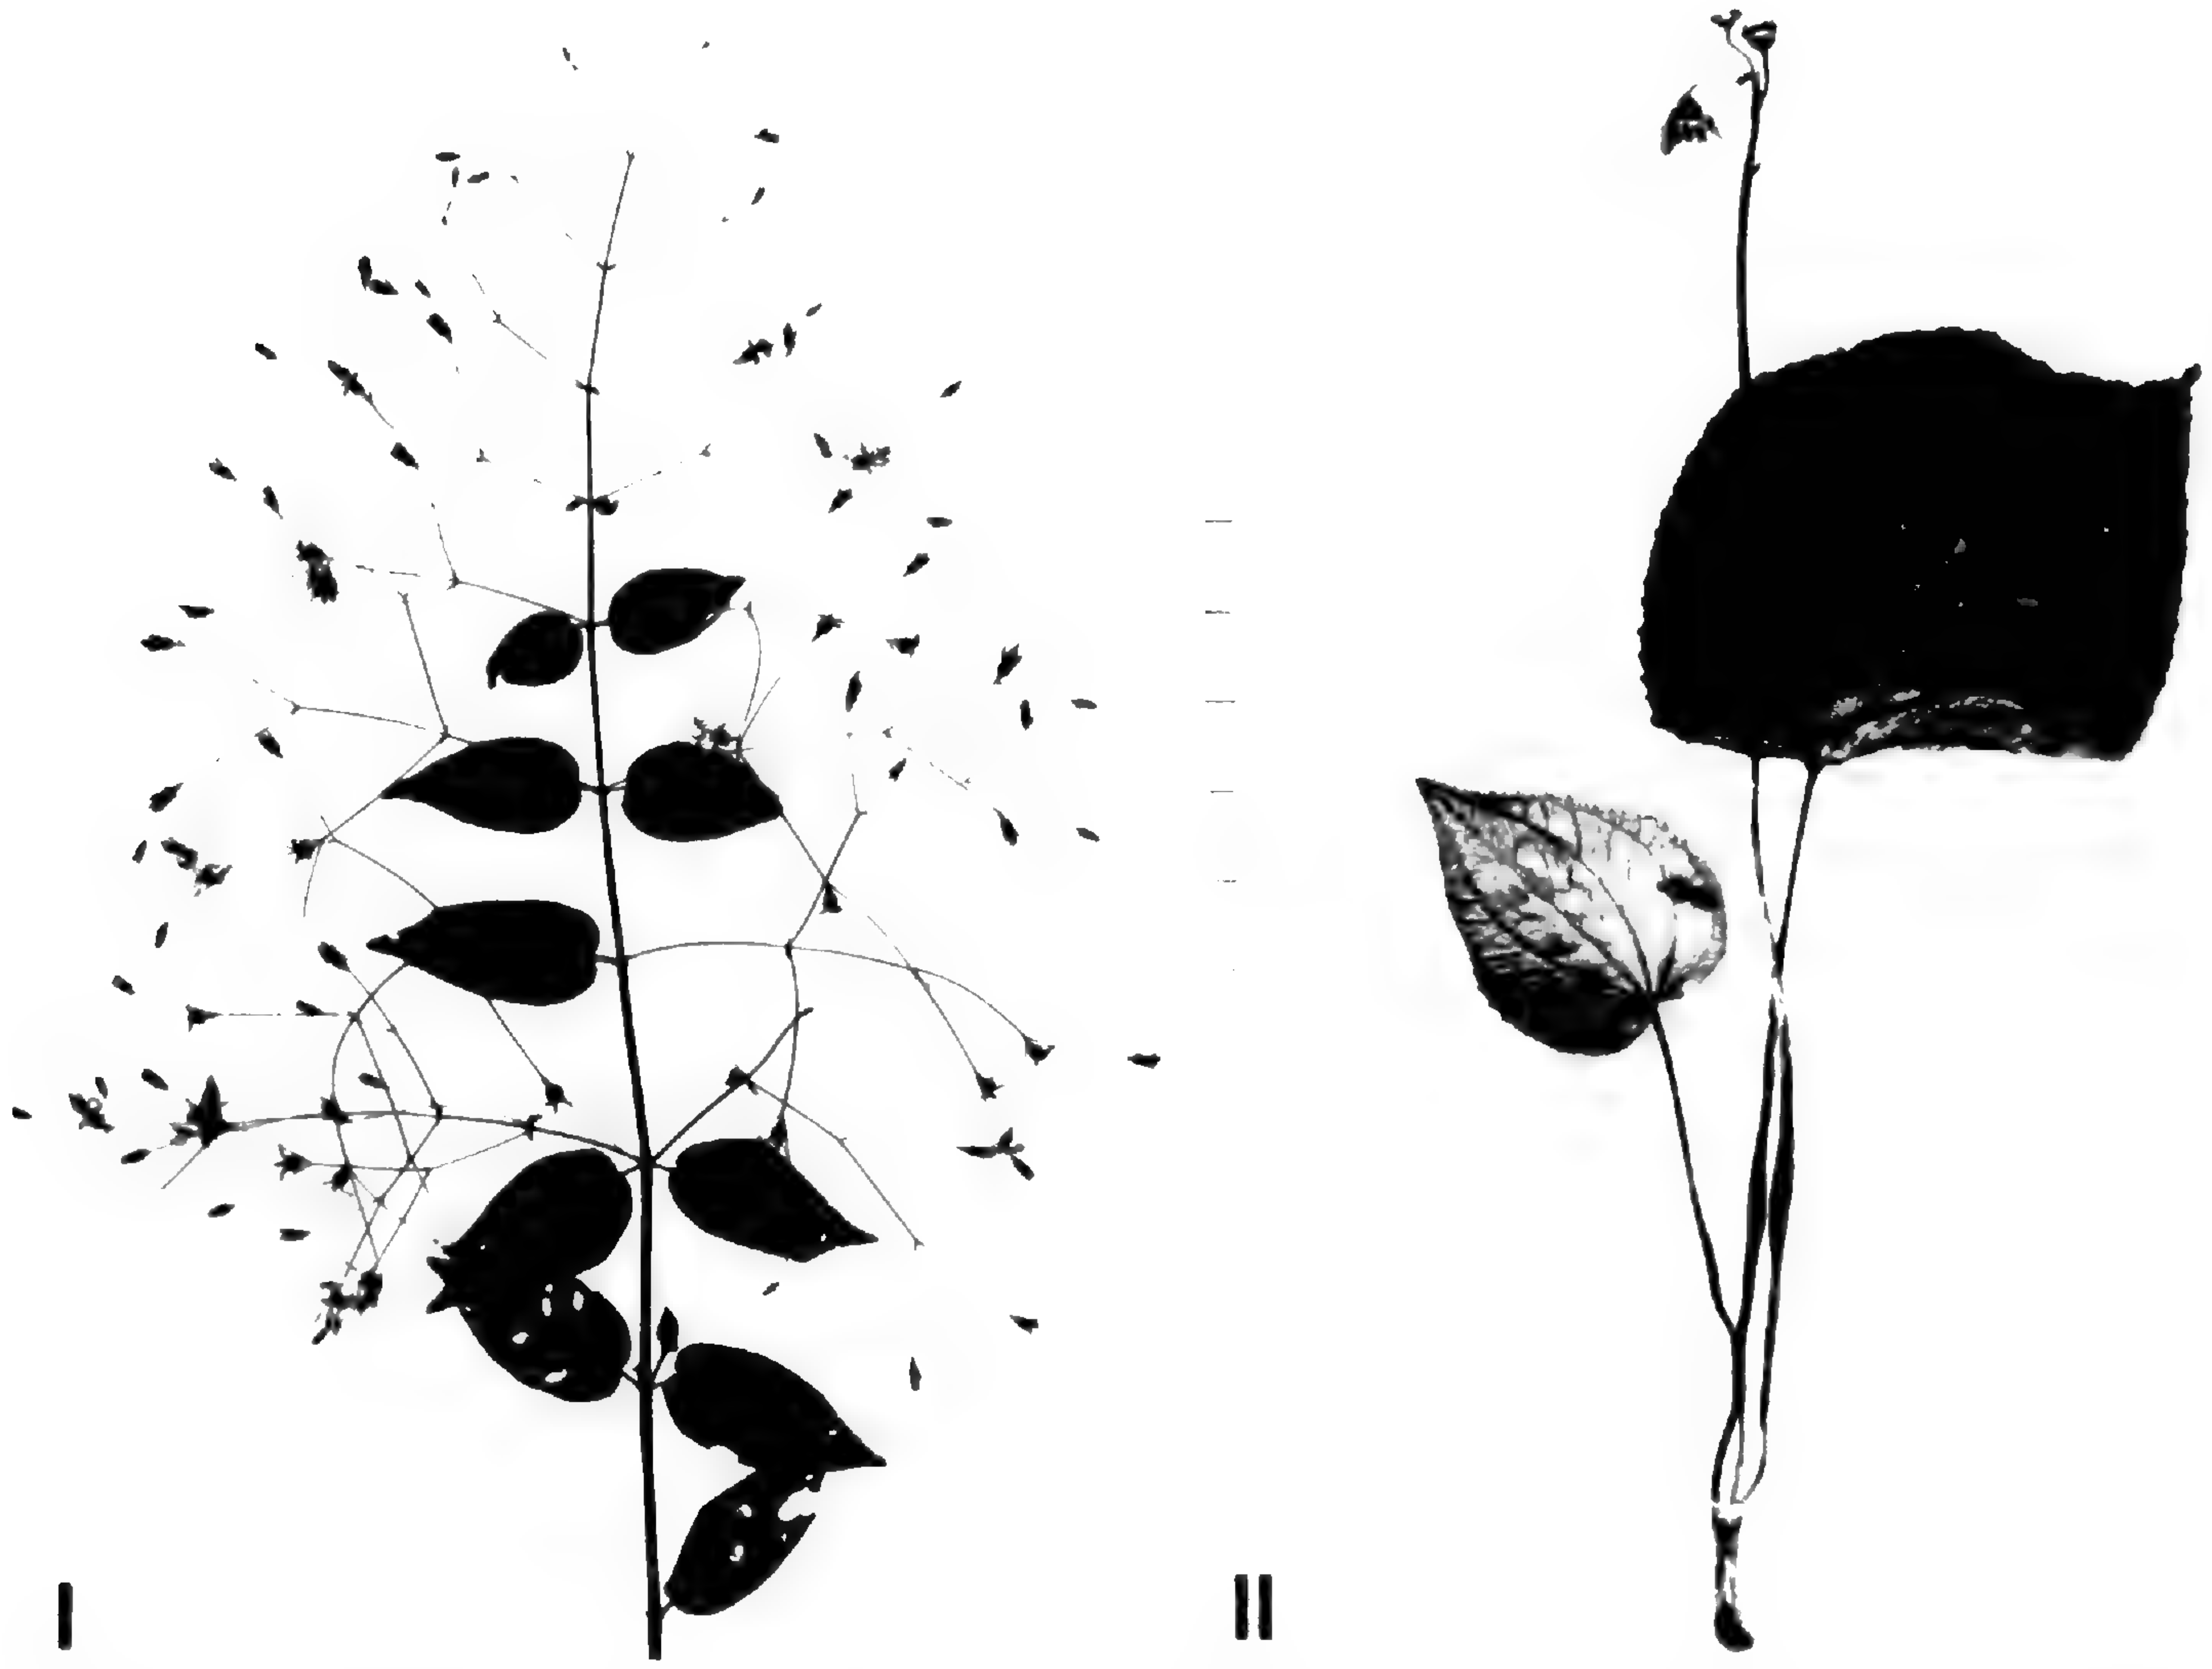

FIGURE 57. *Melastomataceae.—I.* Nepsera aquatica*; inflorescence. (Brazil. Amazonas: vicinity of Manaus,* Prance et al. *11645 (M).) —II.* Cincinnobotrys oreophila*; flowering plant. (Tanganjika Territory, distr. Morogoro, Ulugura Mts.,* Schlieben 2824 *(M).)*

the bulbous base of the primary axis they form a knobby lump. They remain short, and after the development of foliage leaves, finally taper into a scape bearing an inflorescence. The vigorous basal region of the paracladia can ramify repeatedly and form monochasial or dichasial sympodia. Thus the older plant gives the impression of a multiplicity of foliage leaves and inflorescences that extend and unfold in a centrifugal manner. The character of the plant becomes still more complex because of the anisophylly of the leaf pairs. One may suppose that the vigorous basal paracladia ought to be explained as proleptical innovation shoots.

A difference in size and/or form of paired leaves—commonly called anisophylly (Fig. 58)—already has been mentioned for some taxa. It is typical for a considerable number of species. It ensues from the dorsiventrality of the plagiotropic axis and is consequently often connected with the the development of the axillary shoots (see Troll, 1937: 608). This usually means that the leaves inserted at the underside of the axis are the larger ones (+ leaves), as shown here for *Centradenia grandifolia* (Schldl.) Endl. (Fig. 59 I and the diagram in Fig. 59 II). In *C. inaequilateralis* (Schldl. & Cham.) G. Don and *C. grandifolia*, which have very pronounced anisophylly, only the axils of the (+) leaves subtend axillary shoots. Thus there appear two rows of branches inserted on the underside of the mother axis. This is shown for *C. inaequilateralis* by Figure 59 III, IV. The flowering shoot ends in a terminal flower, which is accompanied by a scorpioid or rarely helicoid paracladium. This arises from the axil of the larger leaf of the small and scarcely anisophyllous leaf pair below the terminal flower (Fig. 59 V). The paracladia of the preceding leaf pairs differ from this uppermost paracladium by their leafy and more extended hypotagma. They repeat the architecture of their mother shoot by ending in a terminal flower (E′) and bearing one scorpioid paracladium (pc′) in one of the axils of the distal leaf pair. The effloration of the paracladia proceeds from base to top (Fig. 59 IV). In contradistinction to *C. inaequilateralis*, the paracladia (pc) of *C. grandifolia* (Fig. 54 III) develop flowering second-order paracladia (pc′) from the axils of all leaf pairs, and even third-order paracladia (pc″), which are all helicoids.

Generally in anisophyllous species the axillary shoot may be favored or inhibited in the same way as the subtending leaf, or rarely the favored (+) leaf bears a small (−) branch in its axil and the small (−) leaf a vigorous (+) branch. The latter case was described for *Dissotis rotundifolia* (Sm.) Triana by Troll (posthumous manuscript; see Fig. 64 I for explanation).

For the Blakeae (*Topobea* and *Blakea* including *Pyxidanthus*), it was mentioned already that their single flowers are enclosed by an involucrum formed by several pairs of bracts. The same applies to some species of *Dissotis* (e.g., *D. rotundifolia*) and many species of *Osbeckia*. In other species of this latter genus the involucrum is composed of large pherophylls of some paracladia that are crowded at the ends of the shoots, forming small heads. Often, as in *O. brachystemon* Naudin, *O. chinensis* L., and *O. capitata* Benth. ex Walp., we found the involucrum consisting of two leaf pairs which sometimes (in *O. capitata*) included only the terminal flower and one pair of uniflorous paracladia or even only the terminal flower. Many-flowered heads were observed in *O. chinensis*. The dense heads of *Dissotis capitata* (Vahl) Hook. f. (Fig. 60) consist of the terminal flower and one many-flowered monochasial-helicoid paracladium (Troll, posthumous manuscript). In the annual *Nerophila gentianoides* Naudin the involucrum is formed by foliaceous leaves.

FIGURE 58. *Melastomataceae.* Maieta guianensis *Aubl.; anisophyllous branch. (Brazil: vicinity of Pará,* Baker 91 *(M).)*

Well known for its large and showy pink bracts is *Medinilla magnifica* Lindley. This evergreen plant must be regarded as a shrub since it has a basitonic mode of ramification that is conspicuous even when young (Fig. 61 I). The inflorescences contrast sharply with the vegetative parts by the abrupt change of the leaf character and its pendulous position (Fig. 61 II). This position is produced primarily by an active incurvation of the lowermost pedunclelike internode (segregation internode); later it is the weight of the many-flowered inflorescence that keeps it in a hanging position, since the pink-colored segregation internode is very thin. The proximal part of the diplothyrsoid inflorescence bears mostly two pairs of thyrsoid paracladia; in vigorous inflorescences there may be three or even four or five pairs. Sometimes the lowermost pair of bracts remains sterile. The bracts of the lowermost pairs commonly form false tetramerous verticils by an abbreviation of the internode between two dimerous verticils. In the distal and thyrsoid part of the inflores-

FIGURE 59. *Melastomataceae. I, II.* Centradenia grandifolia.—*I. Anisophyllous branch.—II. Horizontal diagram; L (as in I), the larger, fertile leaves; l, the smaller, sterile leaves.—III–V.* C. inaequilateralis; *distal part of main shoots with terminal flower (E) and the distal paracladium at the beginning of effloration (E′ its terminal flower); the small (−) and large (+) leaves.—V. Distal paracladium (pc_1) with its terminal flower (E) and scorpioid pc. 1–4 = sequence of effloration. (From Troll.)*

cence the phyllotaxis changes to the formation of proper tetramerous verticils. Sometimes trimerous or hexamerous verticils occur; this also applies to *M. sieboldiana* Planchon. In the distal region of the thyrsoid part of the inflorescence the bracts become smaller and inconspicuous.

The ramification of the paracladia within the thyrsoid region decreases gradually from the formation of maximally seven-flowered cymes in the proximal part to uniflorous paracladia in the distal part. The inflorescence can be closed by a terminal flower but often remains indefinite, and the ultimate lateral flowers atrophy (Fig. 64 III). In this case the result is a truncate monotelic synflorescence. If the terminal flower is present, its development is slightly precurrent in relation to the neighboring lateral flowers. Generally the effloration of the whole synflorescence is acropetal.

The thyrsoid paracladia at the base of the

FIGURE 60. *Melastomataceae.* Dissotis capitata.—*I. Shoot with terminal inflorescence.—II. Headlike inflorescence from above. (From Troll.)*

inflorescence more or less repeat the structure of the distal part with some alterations due to their lateral position and consequently their dorsiventrality. Their foliation starts with dimerous verticils of large bracts, especially the prophylls, that in their axils can bear thyrsoid paracladia of second order. The whole inflorescence is then a triple thyrsoid.

In the distal part of the thyrsoid paracladia the bracts become smaller. The conformity of the paracladia with the distal thyrsoid part of the inflorescence also refers to the possibility that the apex can atrophy without the formation of a terminal flower.

The inflorescences of *Medinilla sieboldiana* are also pendulous (Fig. 62 I) but differ from those of *M. magnifica* by their very inconspicuous bracts and by the lack of thyrsoid paracladia. The inflorescence thus is a monothyrsoid. It resembles *M. magnifica* in having tetramerous verticils of bracts. In the proximal part the cymose paracladia can comprise 15 flowers, but distally they are gradually reduced to triads. The development of the terminal flower is conspicuously precurrent to the neighboring lateral flowers. *Medinilla pendula* Merr. is another species with long-peduncled hanging diplothyrsoid inflorescences. There are, however, also species of *Medinilla* with upright inflorescences, as in *M. javanensis* Bl. (Fig. 62 II) and *M. venosa* Bl. (Fig. 63 I). In the latter species and in *M. magnifica* there sometimes occur cauliflorous inflorescences from the axils of leaves that have fallen off already (Fig. 63 II).

Species with proliferating inflorescences are not rare, and some of them show a more or less pronounced tendency to cauliflory. *Medinilla myrtiformis* Triana bears few-flowered botryoids and triadic accessory branches (perhaps even botryoids) in the axils of foliage leaves of proliferating axes. *Medinilla parviflora* Baker and *M. papillosa* Baker are

FIGURE 61. *Melastomataceae.* Medinilla magnifica.—*I. Basitonic ramification of a young plant.—II. Inflorescence, thyrsoid paracladia. (From Troll.)*

similar, the latter showing a slight tendency to cauliflory. In *M. monantha* Merr. the axillary flowering systems are reduced to their terminal flower, which, however, is preceded by two pairs of small bracts. On the other hand, the axillary partial inflorescences of *M. ericarum* Jum. & Perrier are long-peduncled diplothyrsoids.

In *Medinilla ramiflora* Merr., the axillary glomerate thyrsoid flowering systems effloresce when their foliaceous pherophylls have fallen off, and *M. tawaensis* Merr. with likewise thyrsoid partial inflorescences is evidently cauliflorous. The same probably applies to *M. clarkei* King.

Medinilla sedifolia Jum. & Perrier, an epiphytic plant with succulent foliage leaves, is another example with proliferating inflorescences. A zone with a few single flowers in the axils of foliaceous leaves is followed by a zone with vegetative axillary shoots (Troll, 1973: 105, who partly refers to W. Rauh). Probably after a while the main axis can return to the production of lateral flowers again. The foliation of the uniflorous paracladia normally consists only of the scalelike prophylls. Sometimes, however, the prophylls are foliaceous and are followed by two pairs of scales, which in all cases investigated remain altogether sterile.

There is also one case of "epiphyllous inflorescences" reported for the family: *Phyllagathis scortechinii* King, which was investigated by Weber (1982). Among the ca. 35 species of *Phyllagathis* Bl. with essentially terminal "umbel-shaped" or "headlike" inflorescences, *P. scortechinii* is an exception. Its foliage leaves "are posed terminal on woody, axis-like structures ('carriers'), from which they fall off after their life span. Additionally the 'carrier' bears several inflorescences and/or vegetative buds along its upper side" (Fig. 64 II). Weber showed "that this structure is no axis, but a basal, anatomically

FIGURE 62. *Melastomataceae.—I.* Medinilla sieboldiana; *shoot with pendulous terminal inflorescence.—II.* M. javanensis; *terminal inflorescence. (From Troll.)*

distinctly differentiated part of the leaf, onto which the axillary shoots (multiplied by accessory shoot formation) are displaced."

PSILOXYLACEAE

Psiloxylon mauritianum Baillon, now recognized to represent a separate family Psiloxylaceae, "has small axillary racemiform inflorescences; these are perhaps anthotelic (botryoids?), but the limited available material (all dried) is insufficient to determine whether the apparently terminal flower is indeed truly so. Disperse phyllotaxy in the inflorescence (as well as in vegetative regions) and general recaulescence of the bracts increase the difficulty of interpretation." We cannot add much to this statement given by Briggs & Johnson (1979: 181) for the same reason: scantiness of material. It does appear, however, that there is no terminal flower. In this case the inflorescence could be termed a botrytic florescence. According to our observations, the flowers are subtended by bracteous pherophylls and bear bracteous prophylls. In the material investigated (Fig. 65) the flower-bearing systems are brachyblasts reduced to their florescence and inserted on older axes. Thus the plant might be called cauliflorous.

MYRTACEAE

In Myrtaceae, the "central type" and perhaps the phylogenetically primitive form of inflorescence is a monotelic thyrsoid (i.e., a thyrsic inflorescence with terminal flower) or panicle terminating a leafy shoot. Inflorescences of this type can be found among the Myrtoideae (species of *Syzygium* and *Eugenia*) and the Leptospermoideae (species of *Metrosideros*, *Eucalyptus*, and *Angophora*), and they are characteristic of the Heteropyxidoideae (*Heteropyxis natalensis* Harvey, Fig. 66; see also Weberling, 1963). A

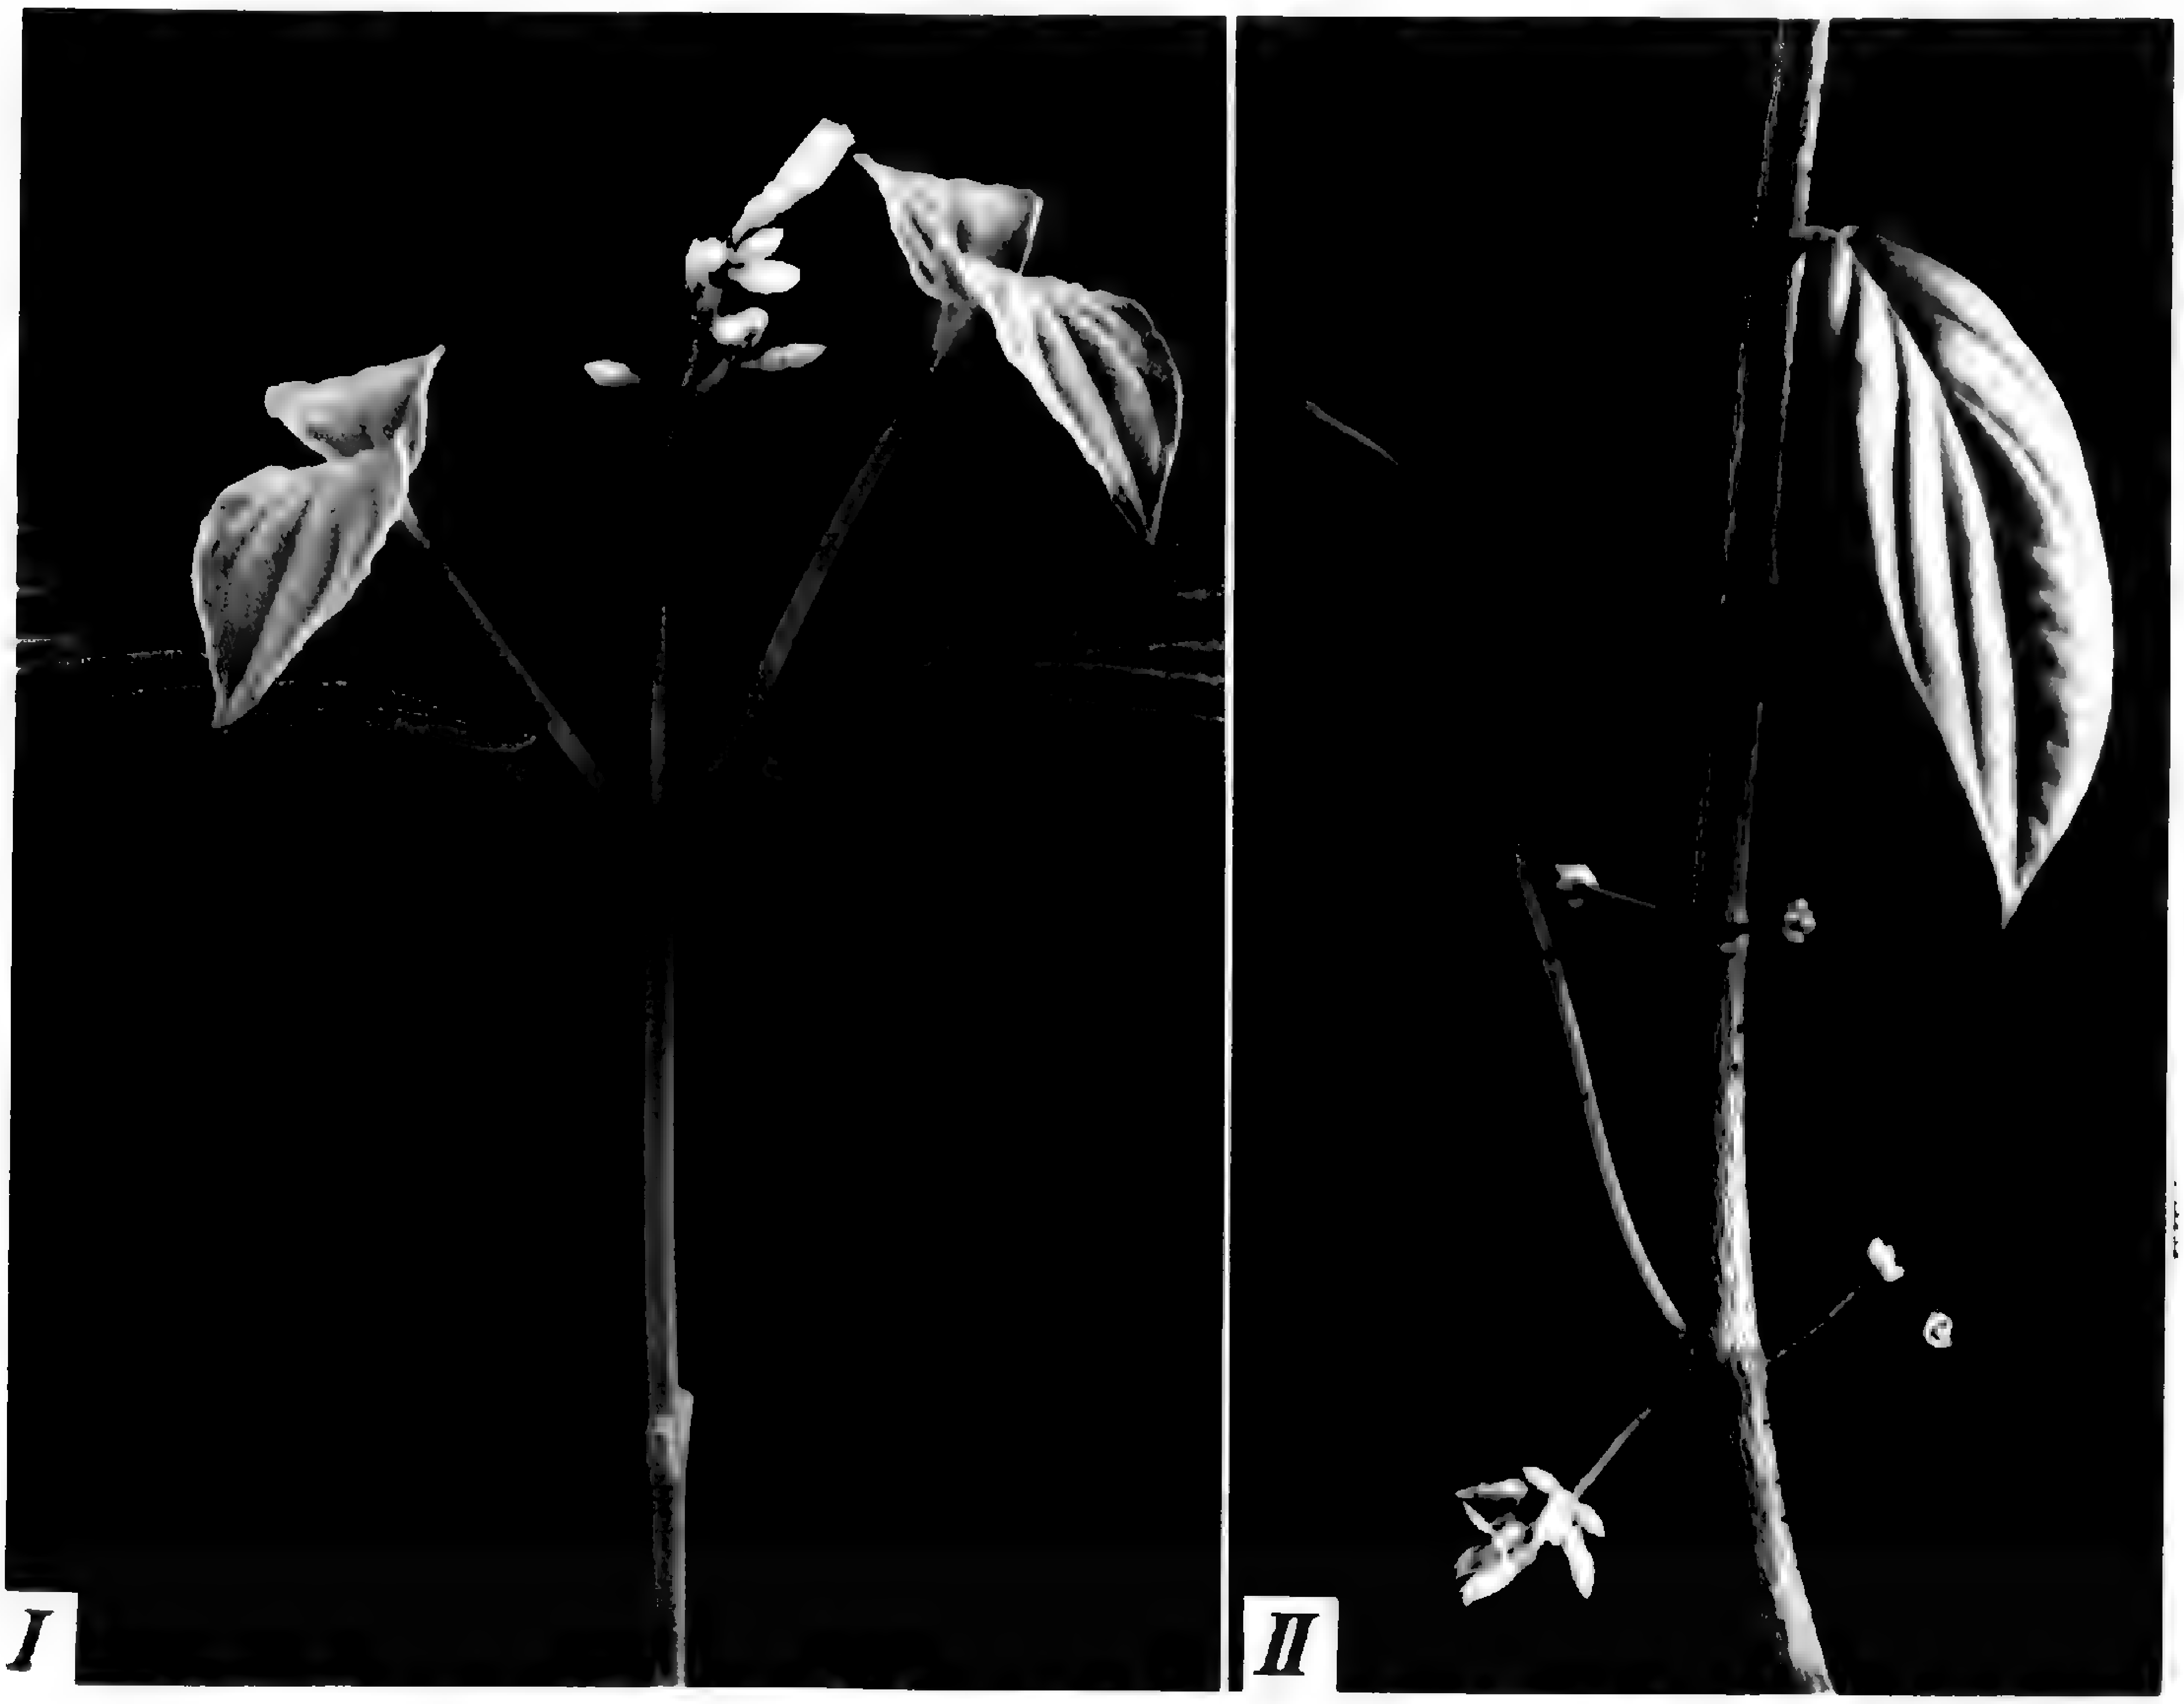

FIGURE 63. *Melastomataceae.* Medinilla venosa.—*I. Terminal inflorescence.—II. Cauliflorous inflorescences. (From Troll.)*

typical monotelic inflorescence is exemplified by *Syzygium aromaticum* (L.) Merr. (Figs. 67, 68 I). The inflorescence axis ends with a terminal flower. This also applies to all floral branches below the terminal flower. All these branches, whether branched or not, are homologous and all are referred to by the term paracladia. Accordingly the ramifications of these paracladia are called paracladia of second to n^{th} order (pc′, pc″, . . .).

As is well known, the complexity of such an inflorescence, that is, the degree of ramification of the paracladia and the extension of the enrichment zone, may be modified to a certain extent in the same species. On the other hand, the differences in complexity may be a distinguishing character between different taxa. Thus in contrast to *Syzygium aromaticum,* in *S. paniculatum* Banks & Gaertner (Fig. 67) the paracladia of first order are uniflorous throughout (Troll, 1969: 258). This results in the formation of a botryoid. In this species, reduction may even go further until only the terminal flower remains.

In *Syzygium aromaticum,* frequently in *S. paniculatum,* as well as in many other Myrtaceae, a pair of sterile bracts (metaxyphylls, Zwischenblätter) preceding the terminal flower can be observed. In *S. paniculatum* they may be replaced by more foliaceous leaves that bear single-flowered (monadic) paracladia in their axils (Troll, 1969: 258–259).

In *Eugenia lanceolaria* Roxb. (now *Syzygium lanceolarium*) and *E. macrocarpa* Roxb. (*Syzygium macrocarpum*) the usual form of the inflorescence seems also to be a botryoid, whereas in *S. thumra* (Roxb.) Merr. & Perry the ramification of the floral branches is increased (Fig. 69). To a certain extent

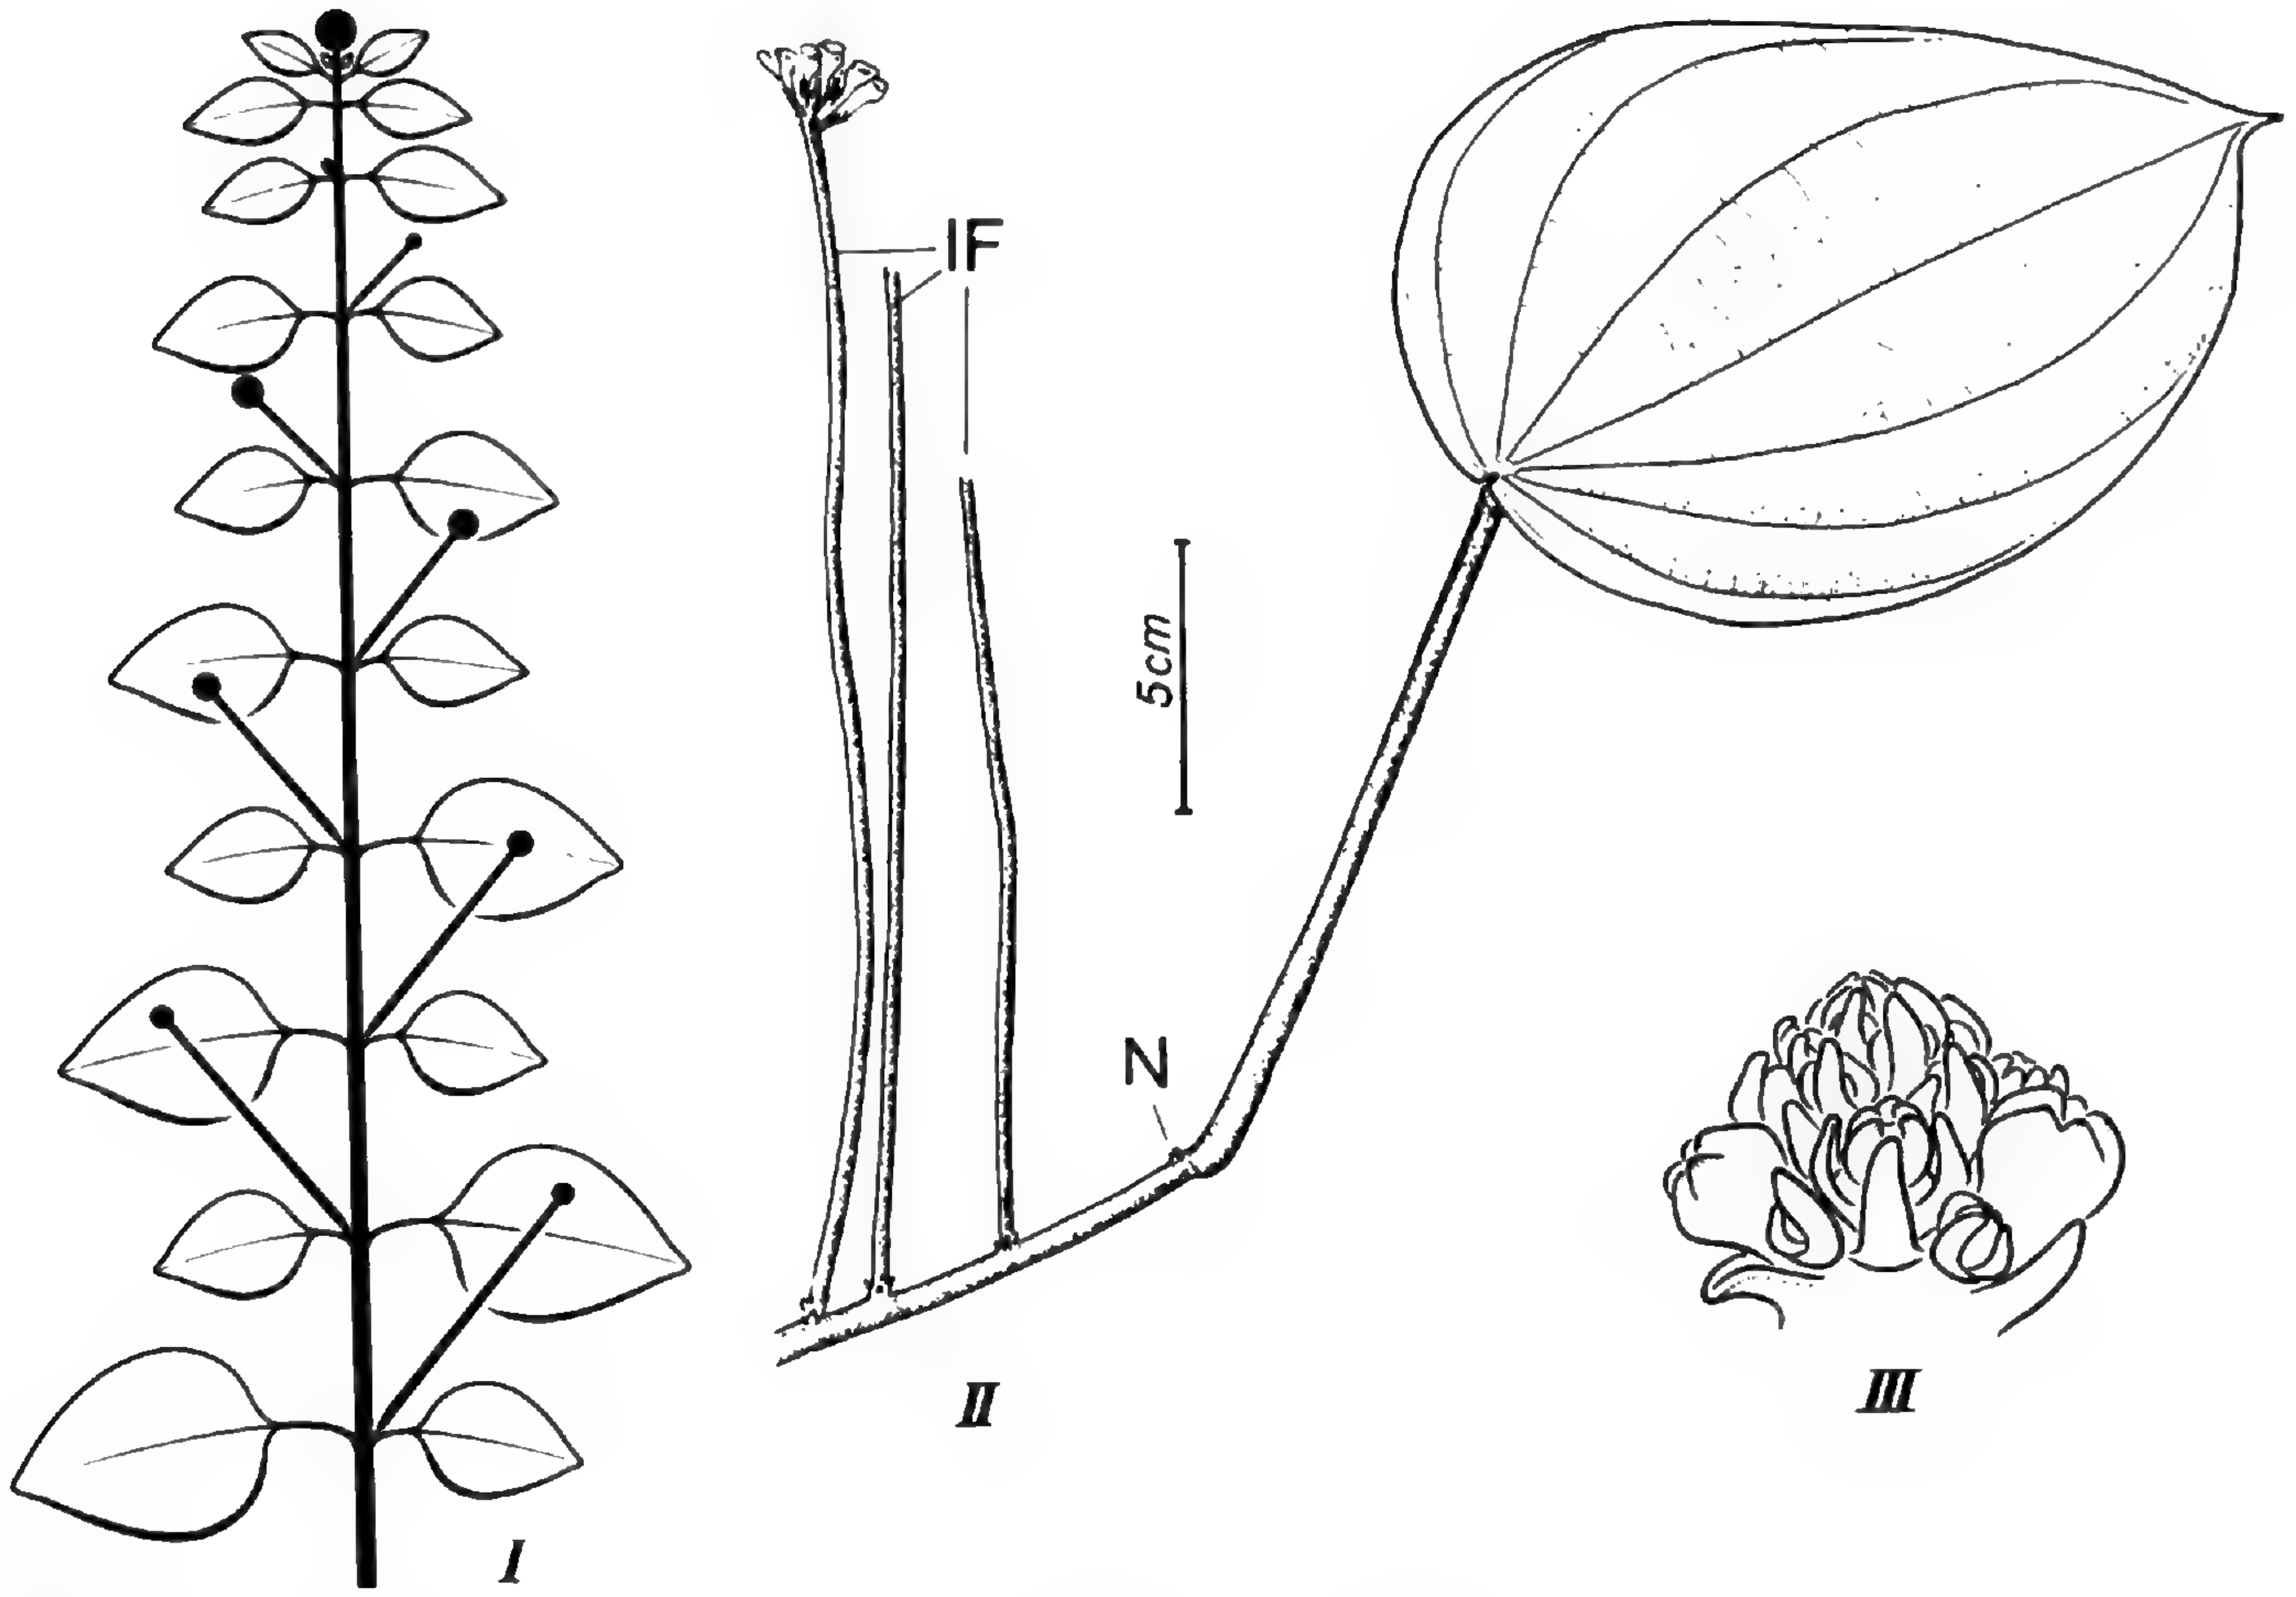

FIGURE 64. *Melastomataceae.—I.* Dissotis rotundifolia; *vertical diagram of an anisophyllous flowering shoot.—II.* Phyllagathis scortechinii; *"carrier" with foliage leaf and some (partly incomplete) inflorescences/infrutescences (IF) and leaf scar (N).—III.* Medinilla magnifica; *inflorescence apex in state of truncation. (I, III from Troll; II from Weber, 1982.)*

this is due to a high degree of cymose branching, which means a consecutive ramification from the axils of the prophylls. An inflorescence with the main axis bearing lateral cymes is defined as a thyrsoid; in this sense the inflorescence of *S. thumra* as well as of *Heteropyxis* (Fig. 66) is a pleiothyrsoid.

As already shown by the few species mentioned here, the foliation of the flower-bearing system may consist of bracts only (bracteose), or there may be a transition from foliage leaves at the base to distal bracts (frondo-bracteose), or the foliation may be leafy throughout (foliose, frondose). The latter applies to the inflorescence of *Syzygium acuminatum* (Roxb.) Miq. (Fig. 70). This inflorescence also presents another feature that is significant for many Myrtaceae: the main axis of the inflorescence is not closed by a terminal flower but ends in a bud (*blastotelic* in the sense of Briggs & Johnson, 1979: 176). Nevertheless, all of the paracladia, including those with more than one pair of flower-bearing branches, are provided with terminal flowers, thus demonstrating the monotelic character of the inflorescence (Troll, 1969: 255; Radlkofer, 1890: 184).

The close morphological relations between these different forms of monotelic inflorescences becomes evident by the comparison of closely related taxa, as among the various species of *Metrosideros* sensu lato that Dawson (1968) investigated. Among these, *M. albiflora* Sol. ex Gaertner (Fig. 71 I) has a bracteose (thyrso-paniculate) inflorescence, and *M. carminea* W. Oliver (Fig. 71 II) a frondose diplobotryoidal inflorescence; both still terminate in an apical flower. As a result of further reduction, the inflorescence of *M. diffusa* Sm. (Fig. 71 III) consists of several densely contracted pairs of triadic paracladia only but still ends in a terminal flower. In the similar inflorescence of *M. perforata* A. Rich. (= *scandens* Sol. ex Gaertner?), the terminal flower is replaced by a vegetative bud (Fig. 71 IV). Moreover, in the loose inflorescences

FIGURE 65. *Psiloxylaceae.* Psiloxylon mauritanicum. *(Mauritius: 1825,* Sieber s.n.; *Fl. Maurit. II, No. 123; G.)*

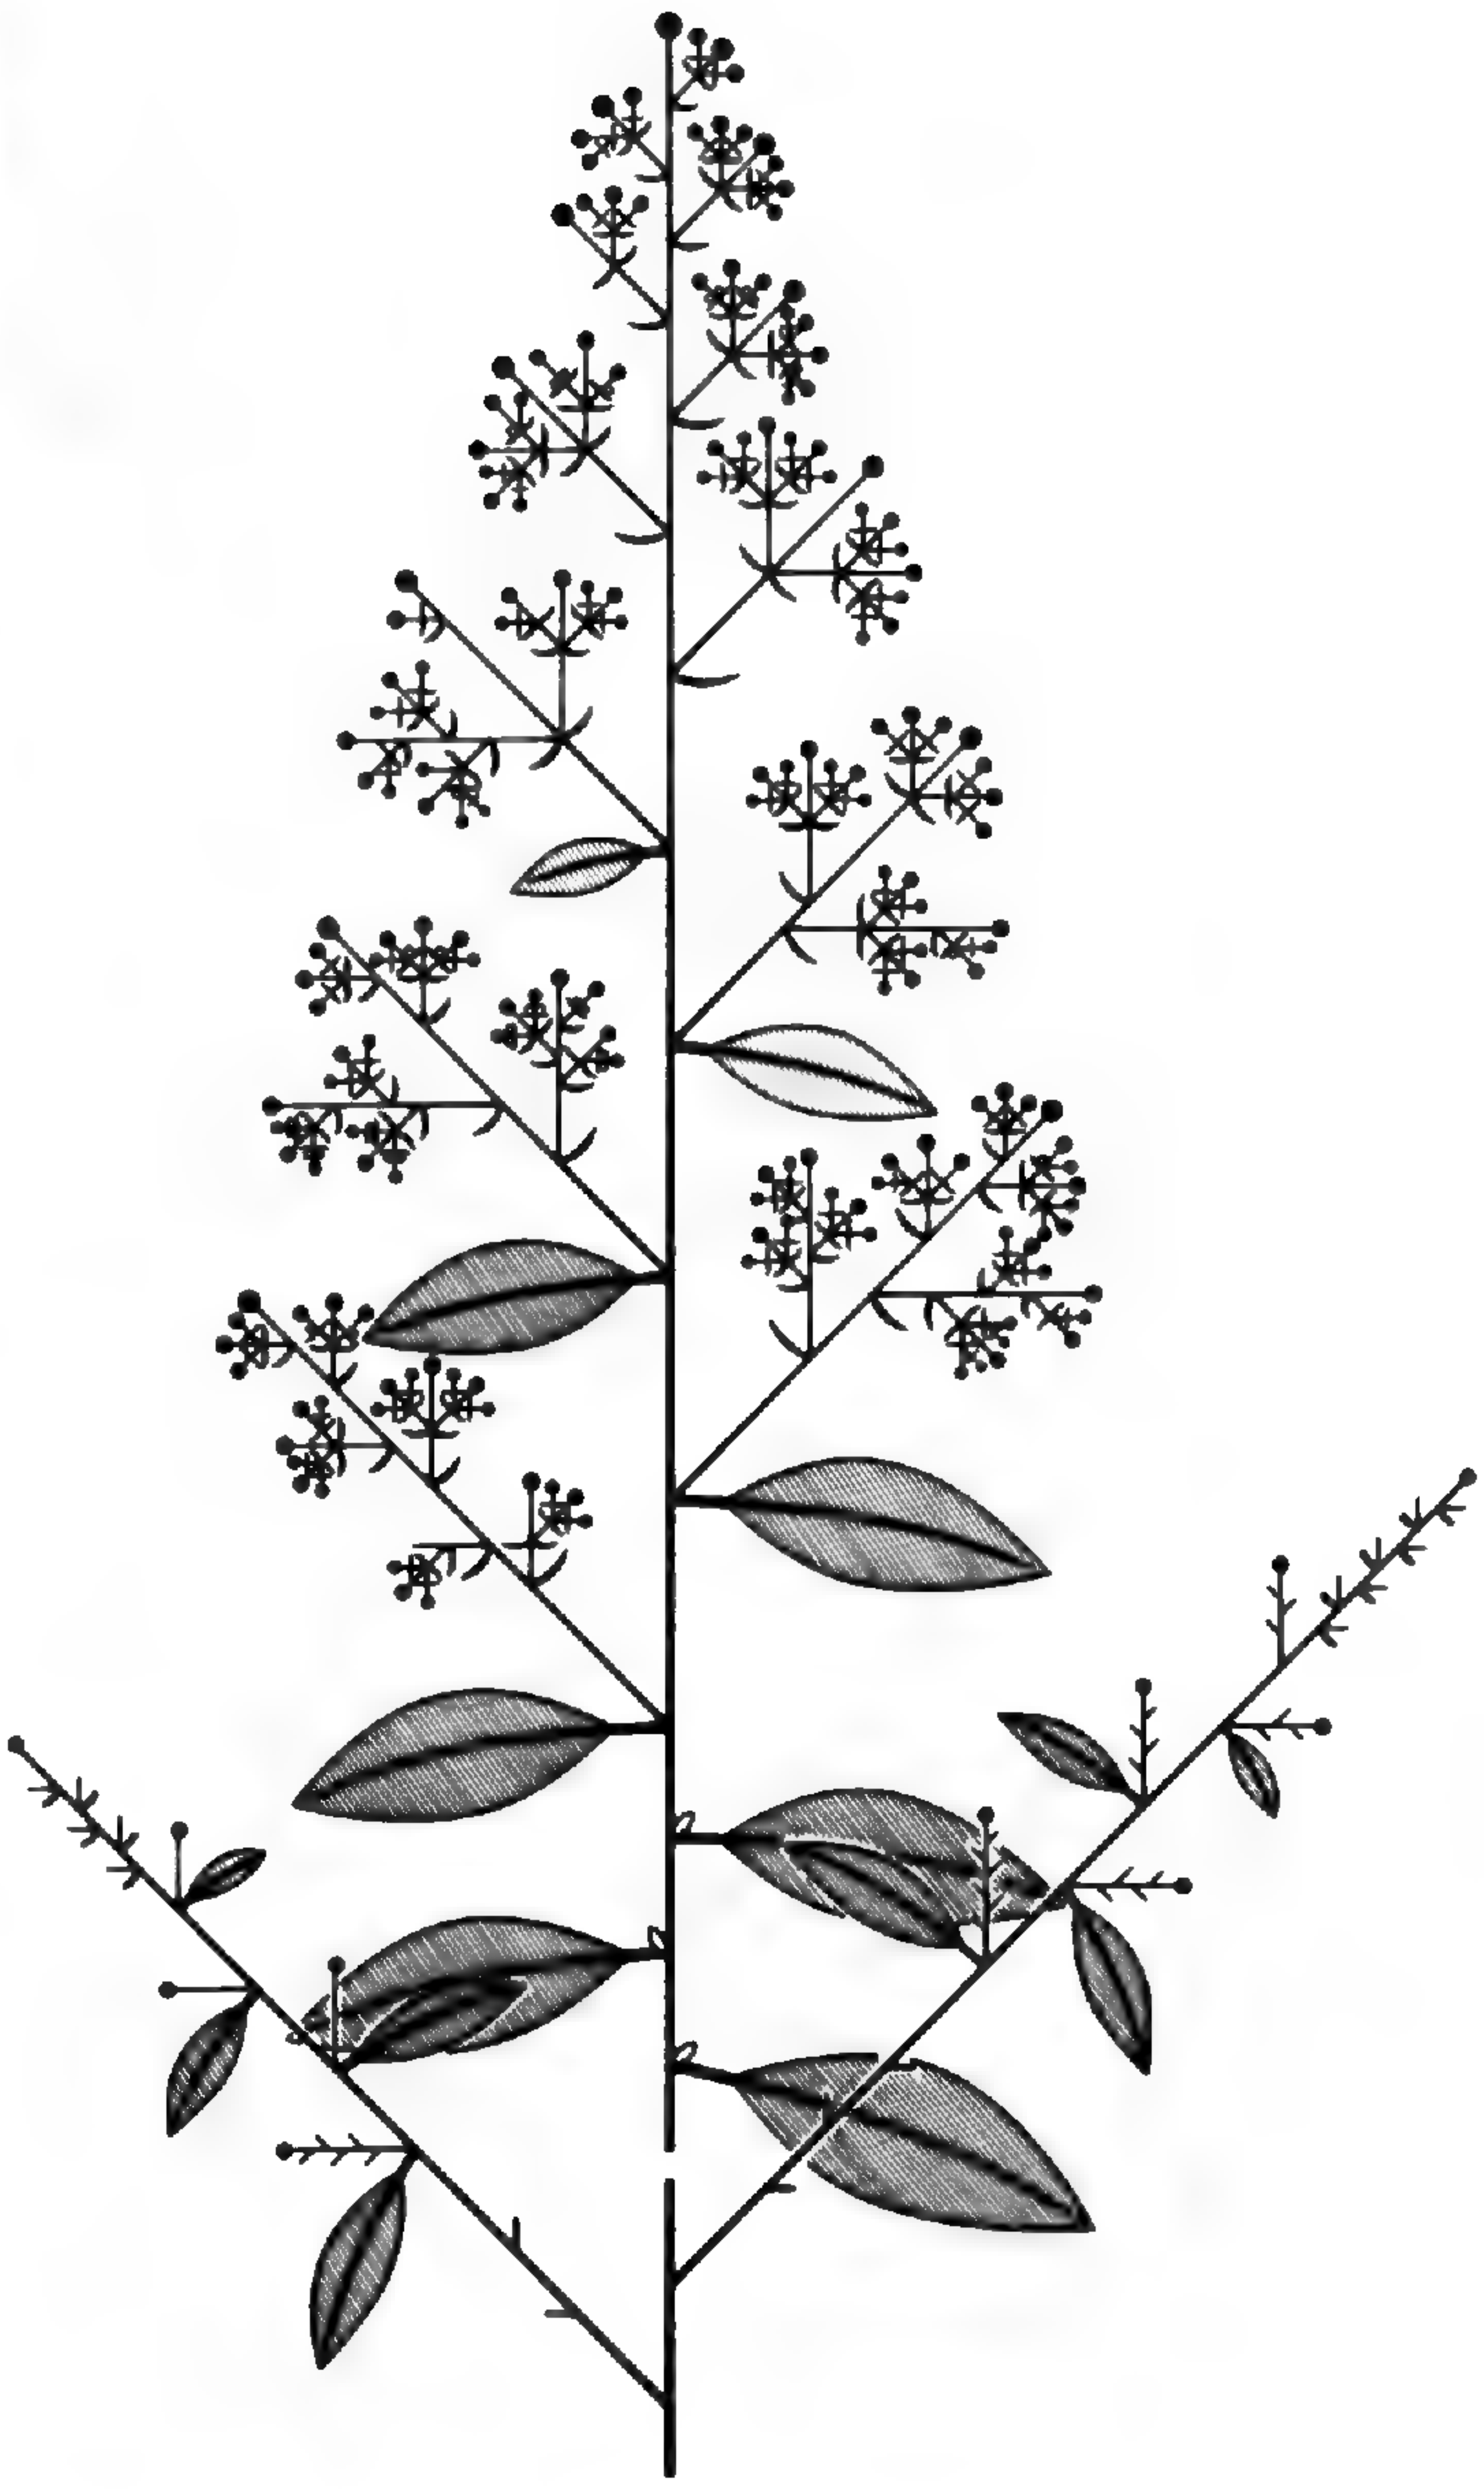

FIGURE 66. *Heteropyxidaceae.* Heteropxyis natalensis; *diagram of a flowering shoot. At the interruption of the main axis three foliaceous leaves and their internodes have been omitted, and the ramification of the vigorous basal branches was not carried out in detail. (South Africa: koppie in the area of the University of N. Transvaal,* Weberling 7644.*)*

of *M. kermadecensis* W. Oliver (= *M. polymorpha* Hook.?), not only the terminal flower closing the inflorescence axis, but also those of the paracladia of first order are replaced by buds (Fig. 71 V). The same applies to *M. umbellata* Cav. (= *M. lucida* A. Rich.?) with more contracted (Fig. 71 VI) or reduced inflorescences (Fig. 71 VII).

Similar differences can be found among species of *Angophora.* While in *A. hispida* (Sm.) Blaxell, *A. floribunda* (Sm.) Sweet, *A. costata* (Gaertner) Britt., *A. melanoxylon* Bak., and *A. subvelutina* F. Muell. the main axis of the (thyrso-)paniculate inflorescences is closed by a terminal flower, the thyrsopanicula of other species end in a bud.

These terminal buds, which appear "to consist of vegetative rather than floral organs," become abortive in many cases (the inflorescence being *anauxotelic* in the sense of Briggs & Johnson, 1979: 176). In many other cases sooner or later the terminal bud continues growth beyond the flowering region, producing a vegetative shoot (for inflorescences of this kind the term *auxotelic* is used by Briggs & Johnson, 1979). In *Angophora costata,* Briggs & Johnson (1979, fig. 6b, c) observed inflorescences closed by a terminal flower ("anthotelic" inflorescences) as well as those ending in a terminal bud, which sometimes aborted and sometimes continued growth. The inflorescence of *A. subvelutina* was found with a terminal flower (Briggs & Johnson, 1979), while Troll (unpubl. data) found a terminal bud continuing growth in the same species. Thus especially within *An-*

FIGURE 67. *Myrtaceae. Inflorescences.—Left.* Syzygium aromaticum *(from Köhler, 1923).—Right.* S. paniculatum. *(From Troll.)*

gophora (and in some other taxa of the *Eucalyptus* alliance) a high degree of flexibility in the formation of terminal flowers is revealed.

Dawson (1968: 48) pointed out that in those species of *Metrosideros* that bear terminal buds, the "bud is inactive during flowering, but may later develop into a leafy branch." As will be shown later, however, the moment in which the apical vegetative bud turns to continue growth may be sooner or later.

The reversion of the inflorescence apex to vegetative growth, commonly called *proliferation* (Troll, 1959a: 116), is characteristic for many Myrtaceae, perhaps even for the majority of species.

Parkin (1914: 556) regarded proliferating inflorescences as a separate type of inflorescence, which he called "intercalary inflorescences," because "the flower-bearing part of the axis is . . . intercalated between two foliage-bearing portions." In using this term he especially referred to the Australian (or prevalent Australian) genera *Callistemon*, *Melaleuca*, and *Metrosideros*. Indeed the appearance of the flowering shoots of *Melaleuca* (Fig. 72) and *Callistemon* (Fig. 72) suggest this term, all the more as the process of the formation of a terminal inflorescence and proliferation can recur in regular intervals of development, mostly in connection with climatic factors.

We must emphasize, however, that there are many taxa (e.g., *Veronica, Lysimachia,* several ligneous Melastomataceae or Rubiaceae) that include species with terminal bracteose and terminal foliose inflorescences as well as species with proliferating leafy inflorescences. Often these forms are connected by continuous series of intermediate forms. Thus the so-called "intercalary inflores-

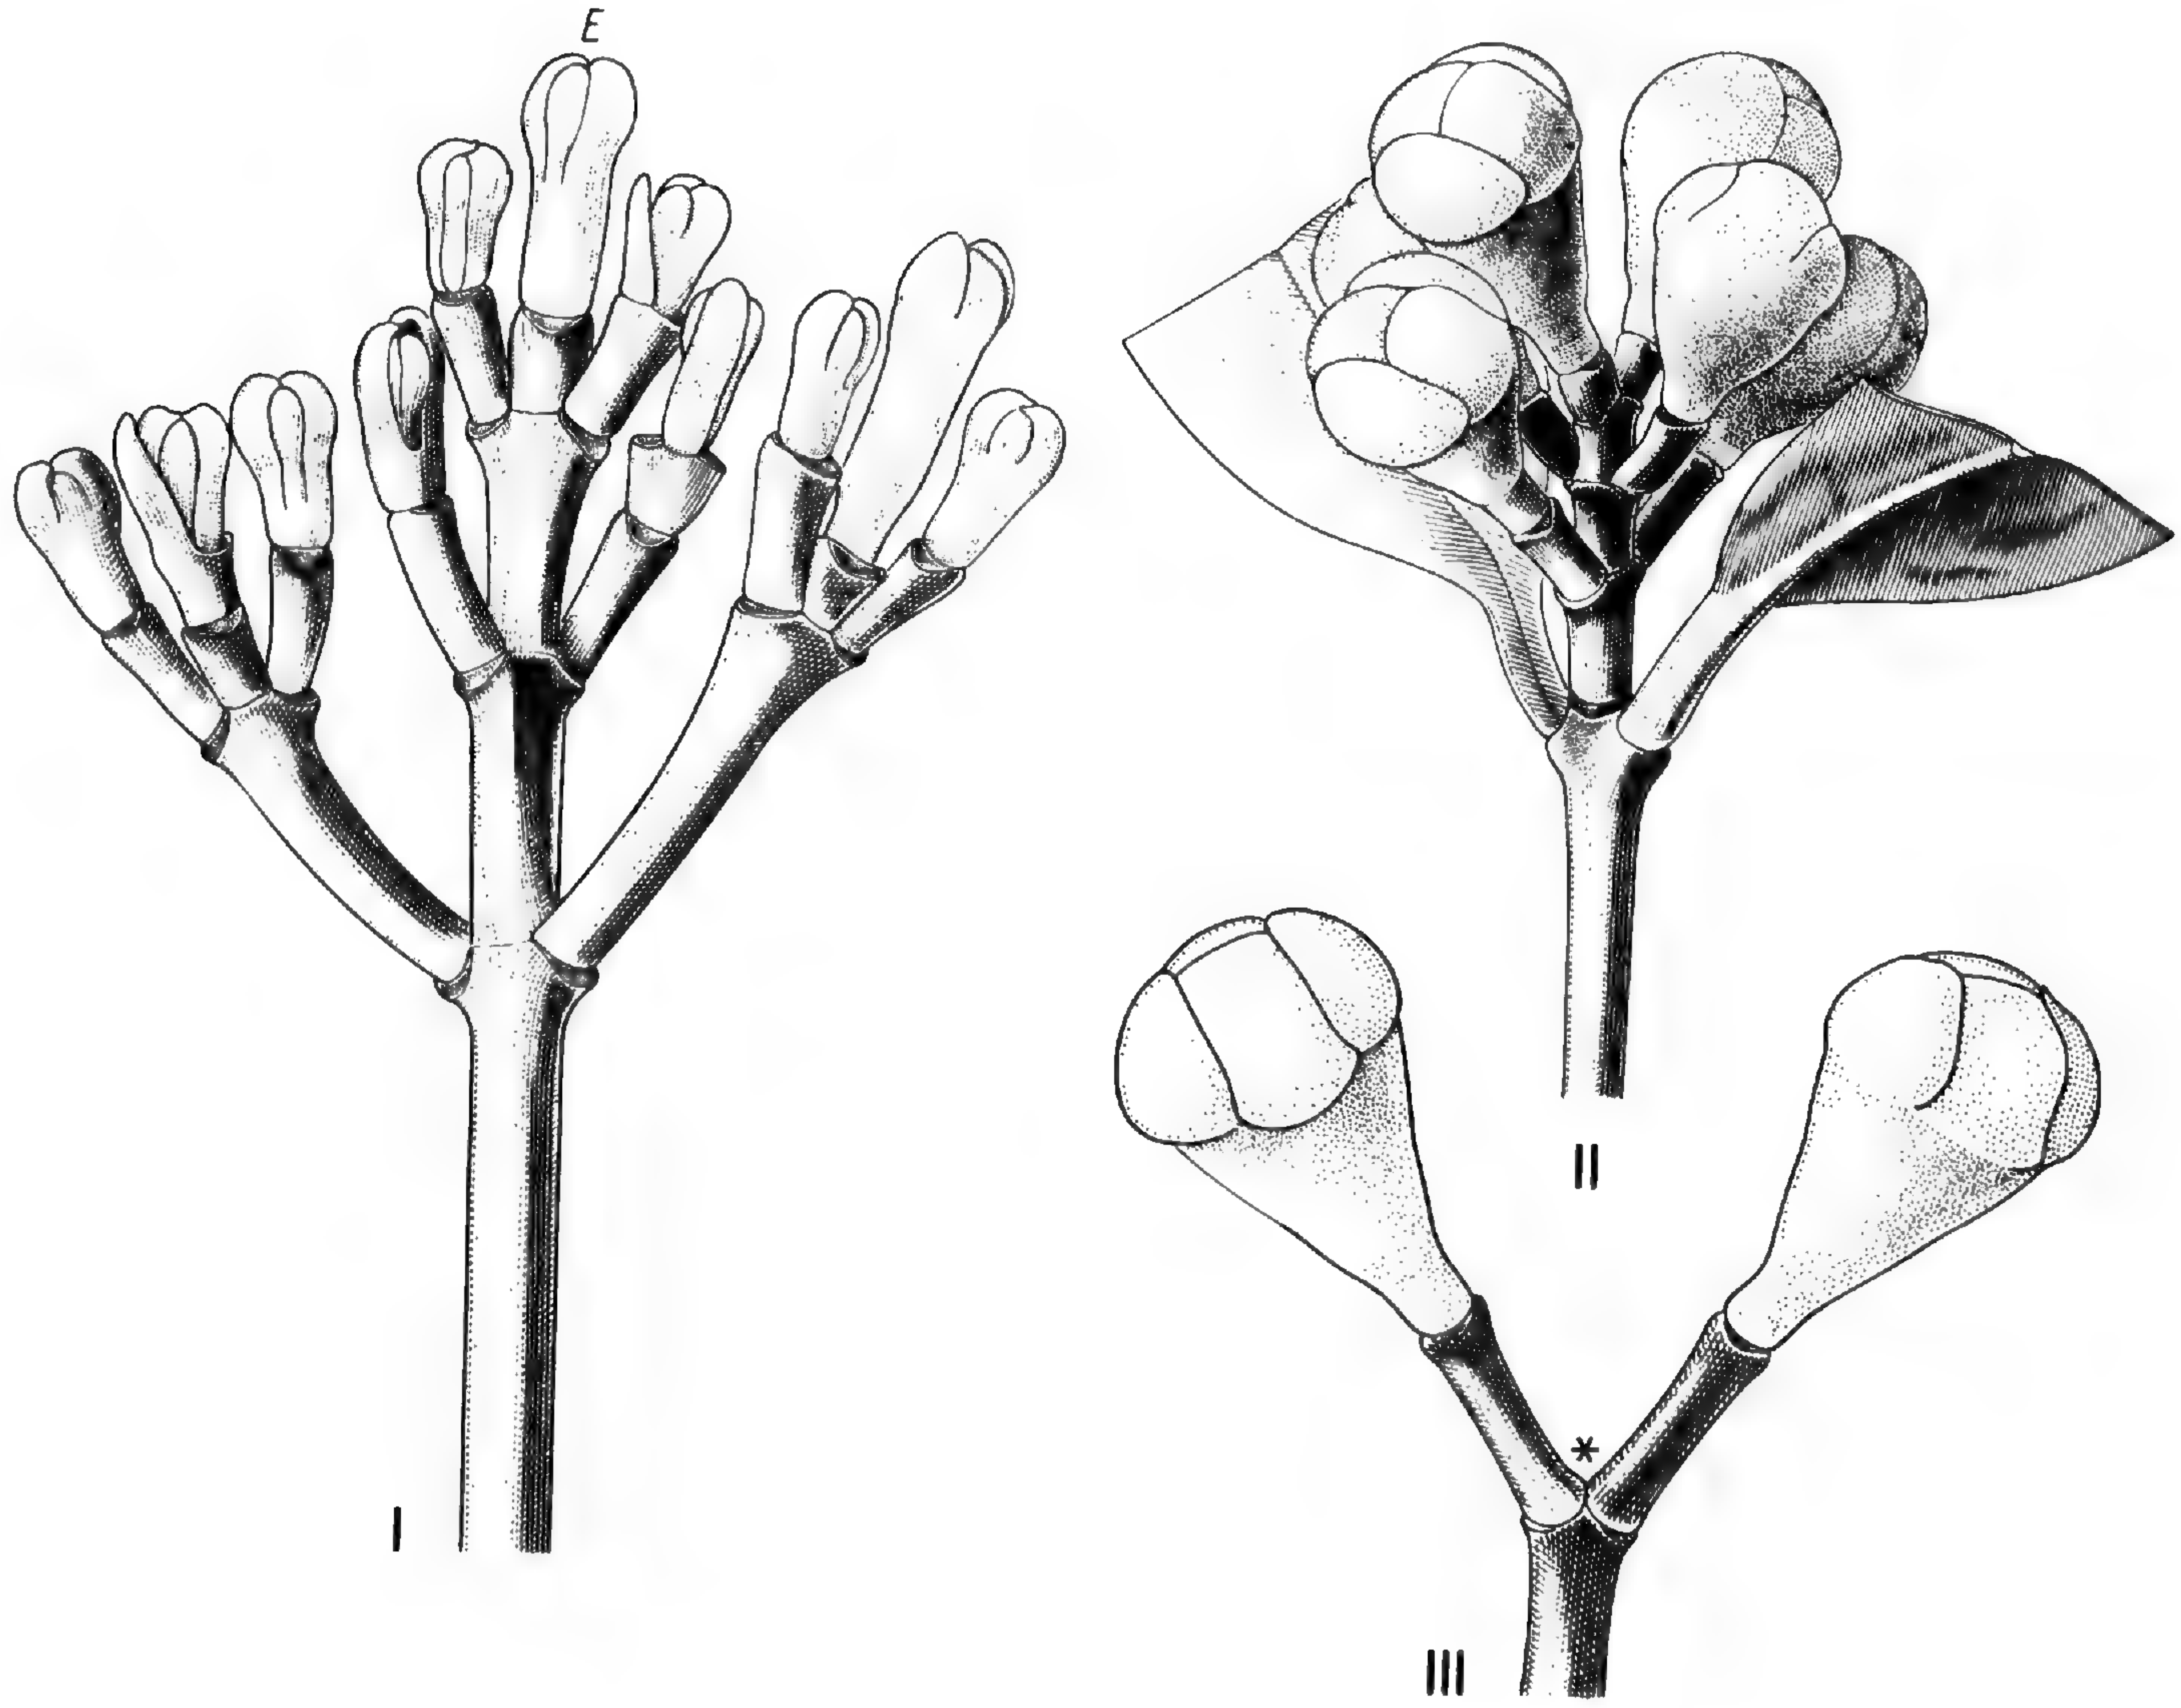

FIGURE 68. *Myrtaceae.—I.* Syzygium aromaticum; *few-flowered inflorescence, the bracts fallen off. II, III.* S. jambos.*—II. Inflorescence, the terminal flower aborted (truncate monotelic synflorescence).—III. Distal part of the inflorescence in detail. Asterisk indicates place of the aborted terminal flower. (From Troll.)*

cences" are regarded as derived from the terminal ones.

The fact that the development of flower-bearing systems and vegetative zones occurs successively in the same shoot, which continues growing over a long time, may prove to be favorable under certain conditions, especially for plants with enduring leaves.

In the examples mentioned above, the proliferation takes place after or during the efloration of the inflorescence. The efloration, however, may be delayed somewhat more while the shoot apex reverts to vegetative growth and may even form branches, as in *Beaufortia decussata* R. Br. (Fig. 73 II).

In such cases the normal zonation in the flowering systems of monotelic as well as of polytelic character (Fig. 3) seems to be reversed, since the continuation of the vegetative ramification system takes place above the flower-bearing zone. On the other hand, the extreme retardation of formation and anthesis of the flowers may result in different manifestations of cauliflory. Thus in *Calothamnus rupestris* Schau. and *C. villosus* Ait., anthesis can be delayed so long that the resting flower buds are occluded by peridermal tissue.

The degree of ramification of the flower-bearing systems can be very different, and this applies to proliferating inflorescences as well as to nonproliferating inflorescences. Thus in the proliferating inflorescence of *Pimenta dioica* (L.) Merr. (Fig. 74), *Gomidesia hookeriana* Berg, *Krugia ferruginea* (DC.) Urban, or *Calyptranthes chytraculia* (L.) Swartz, the partial inflorescences that originate from the axils of foliage leaves are highly ramified and present themselves as thyrsoid-paniculate systems. In contrast to the leafy

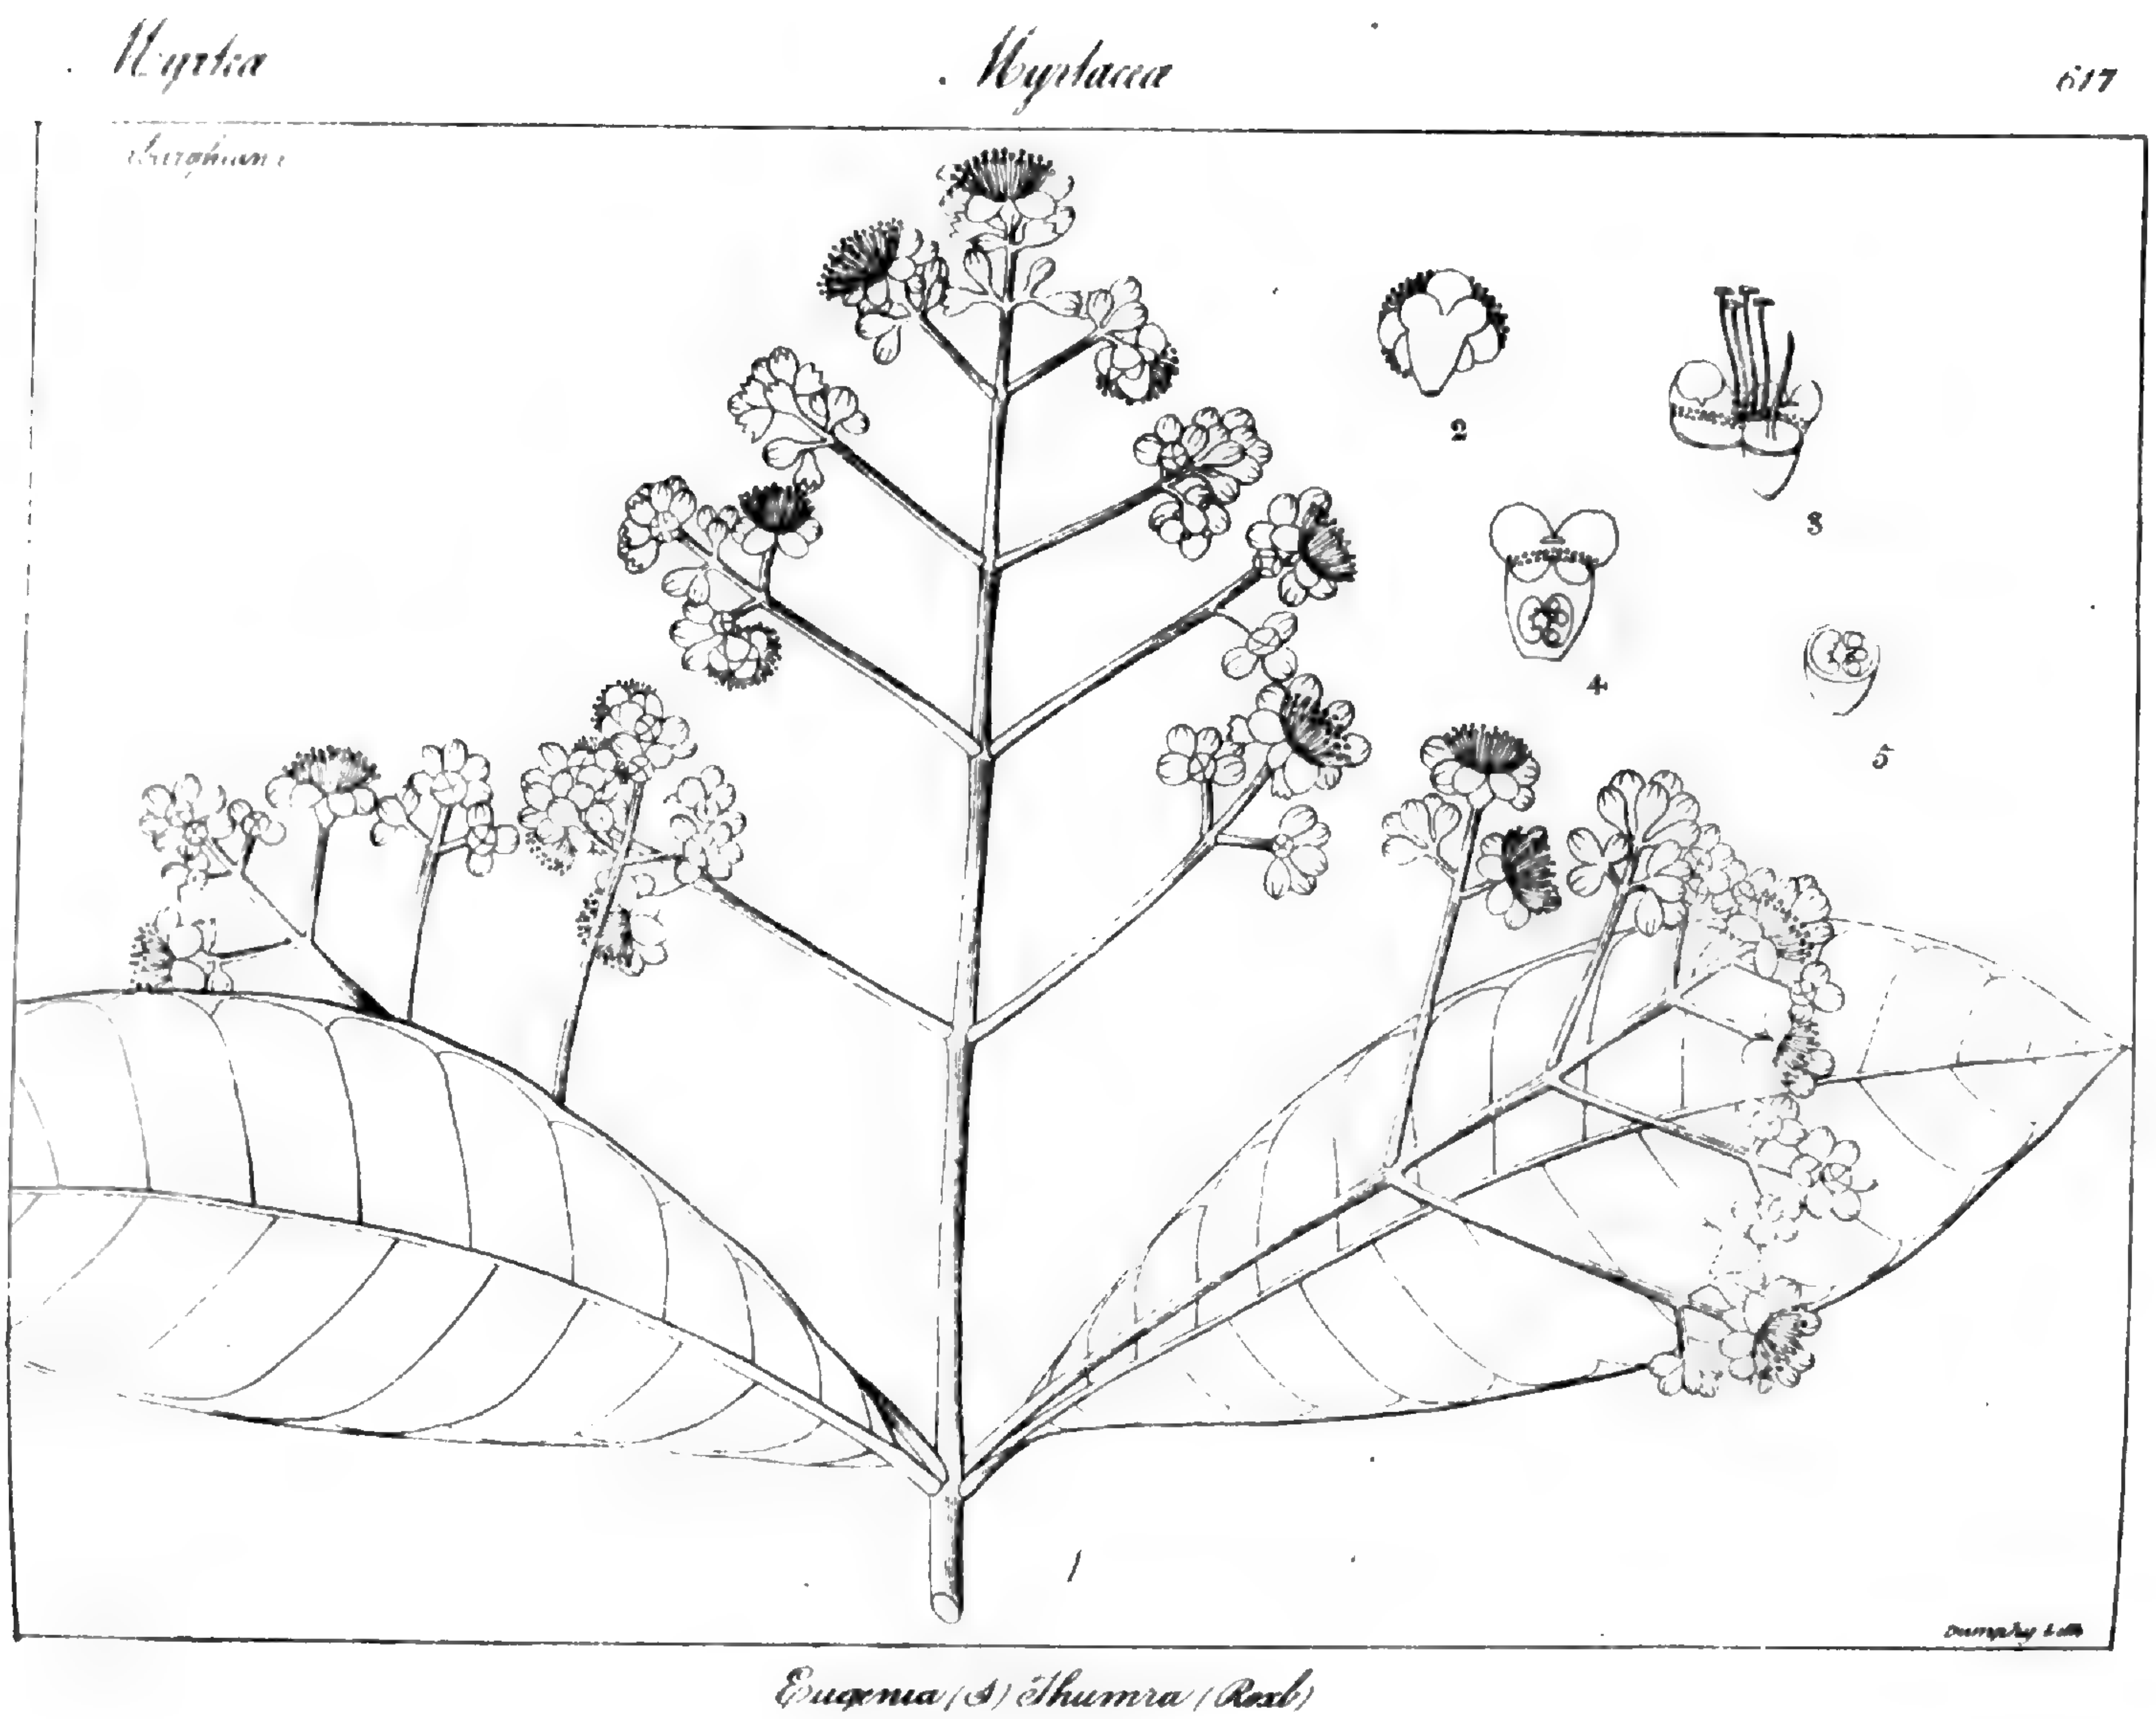

FIGURE 69. *Myrtaceae.* Syzygium thumra; *flowering branch. (From Wight, 1843.)*

main axis, they end in a terminal flower, thus revealing the monotelic character of the whole inflorescence. The same applies to some species of *Marlierea* and *Myrcia,* which produce more or less ample ramified thyrsoid-paniculate paracladia, whereas other species of these genera, as well as *Mitranthes eggersii* and *Myrrhinium loranthoides* (Cabrera, 1978: 78), only bear simple thyrsoids in the axils of foliage leaves.

A high degree of flexibility in the alternative formation of terminal flowers or terminal auxotelic or anauxotelic buds is represented by *Decaspermum paniculatum* Lindley. As reported by Briggs & Johnson (1979: 187) "the second-order and higher-order axes may produce: a) both terminal and lateral paniculate shoots . . . or b) lateral paniculate shoots only, the apical bud retaining the capacity for continued growth." Figure 75 I, which illustrates the results of Briggs & Johnson, resembles Figure 75 II, reporting our own results. The somewhat contradictory examples of inflorescence structure, however, can be elucidated in an acceptable way as being derived from a monotelic thyrsoid-paniculate base type. In *D. parviflorum* Kurz, we observed an indeterminate main axis bearing axillary loosely branched monothyrsoids with slightly disperse phyllotaxy.

Figure 75 I and II also represents examples of the development of *accessory branches.* Within the Myrtaceae these accessory branches are mostly phylloscopic. They occur as single accessory flowers (Fig. 75 I, II), triadic branches (Fig. 75 I), or even as botryoids (Fig. 75 I) and perhaps also as thyrsoids. Sometimes several accessory axes in a

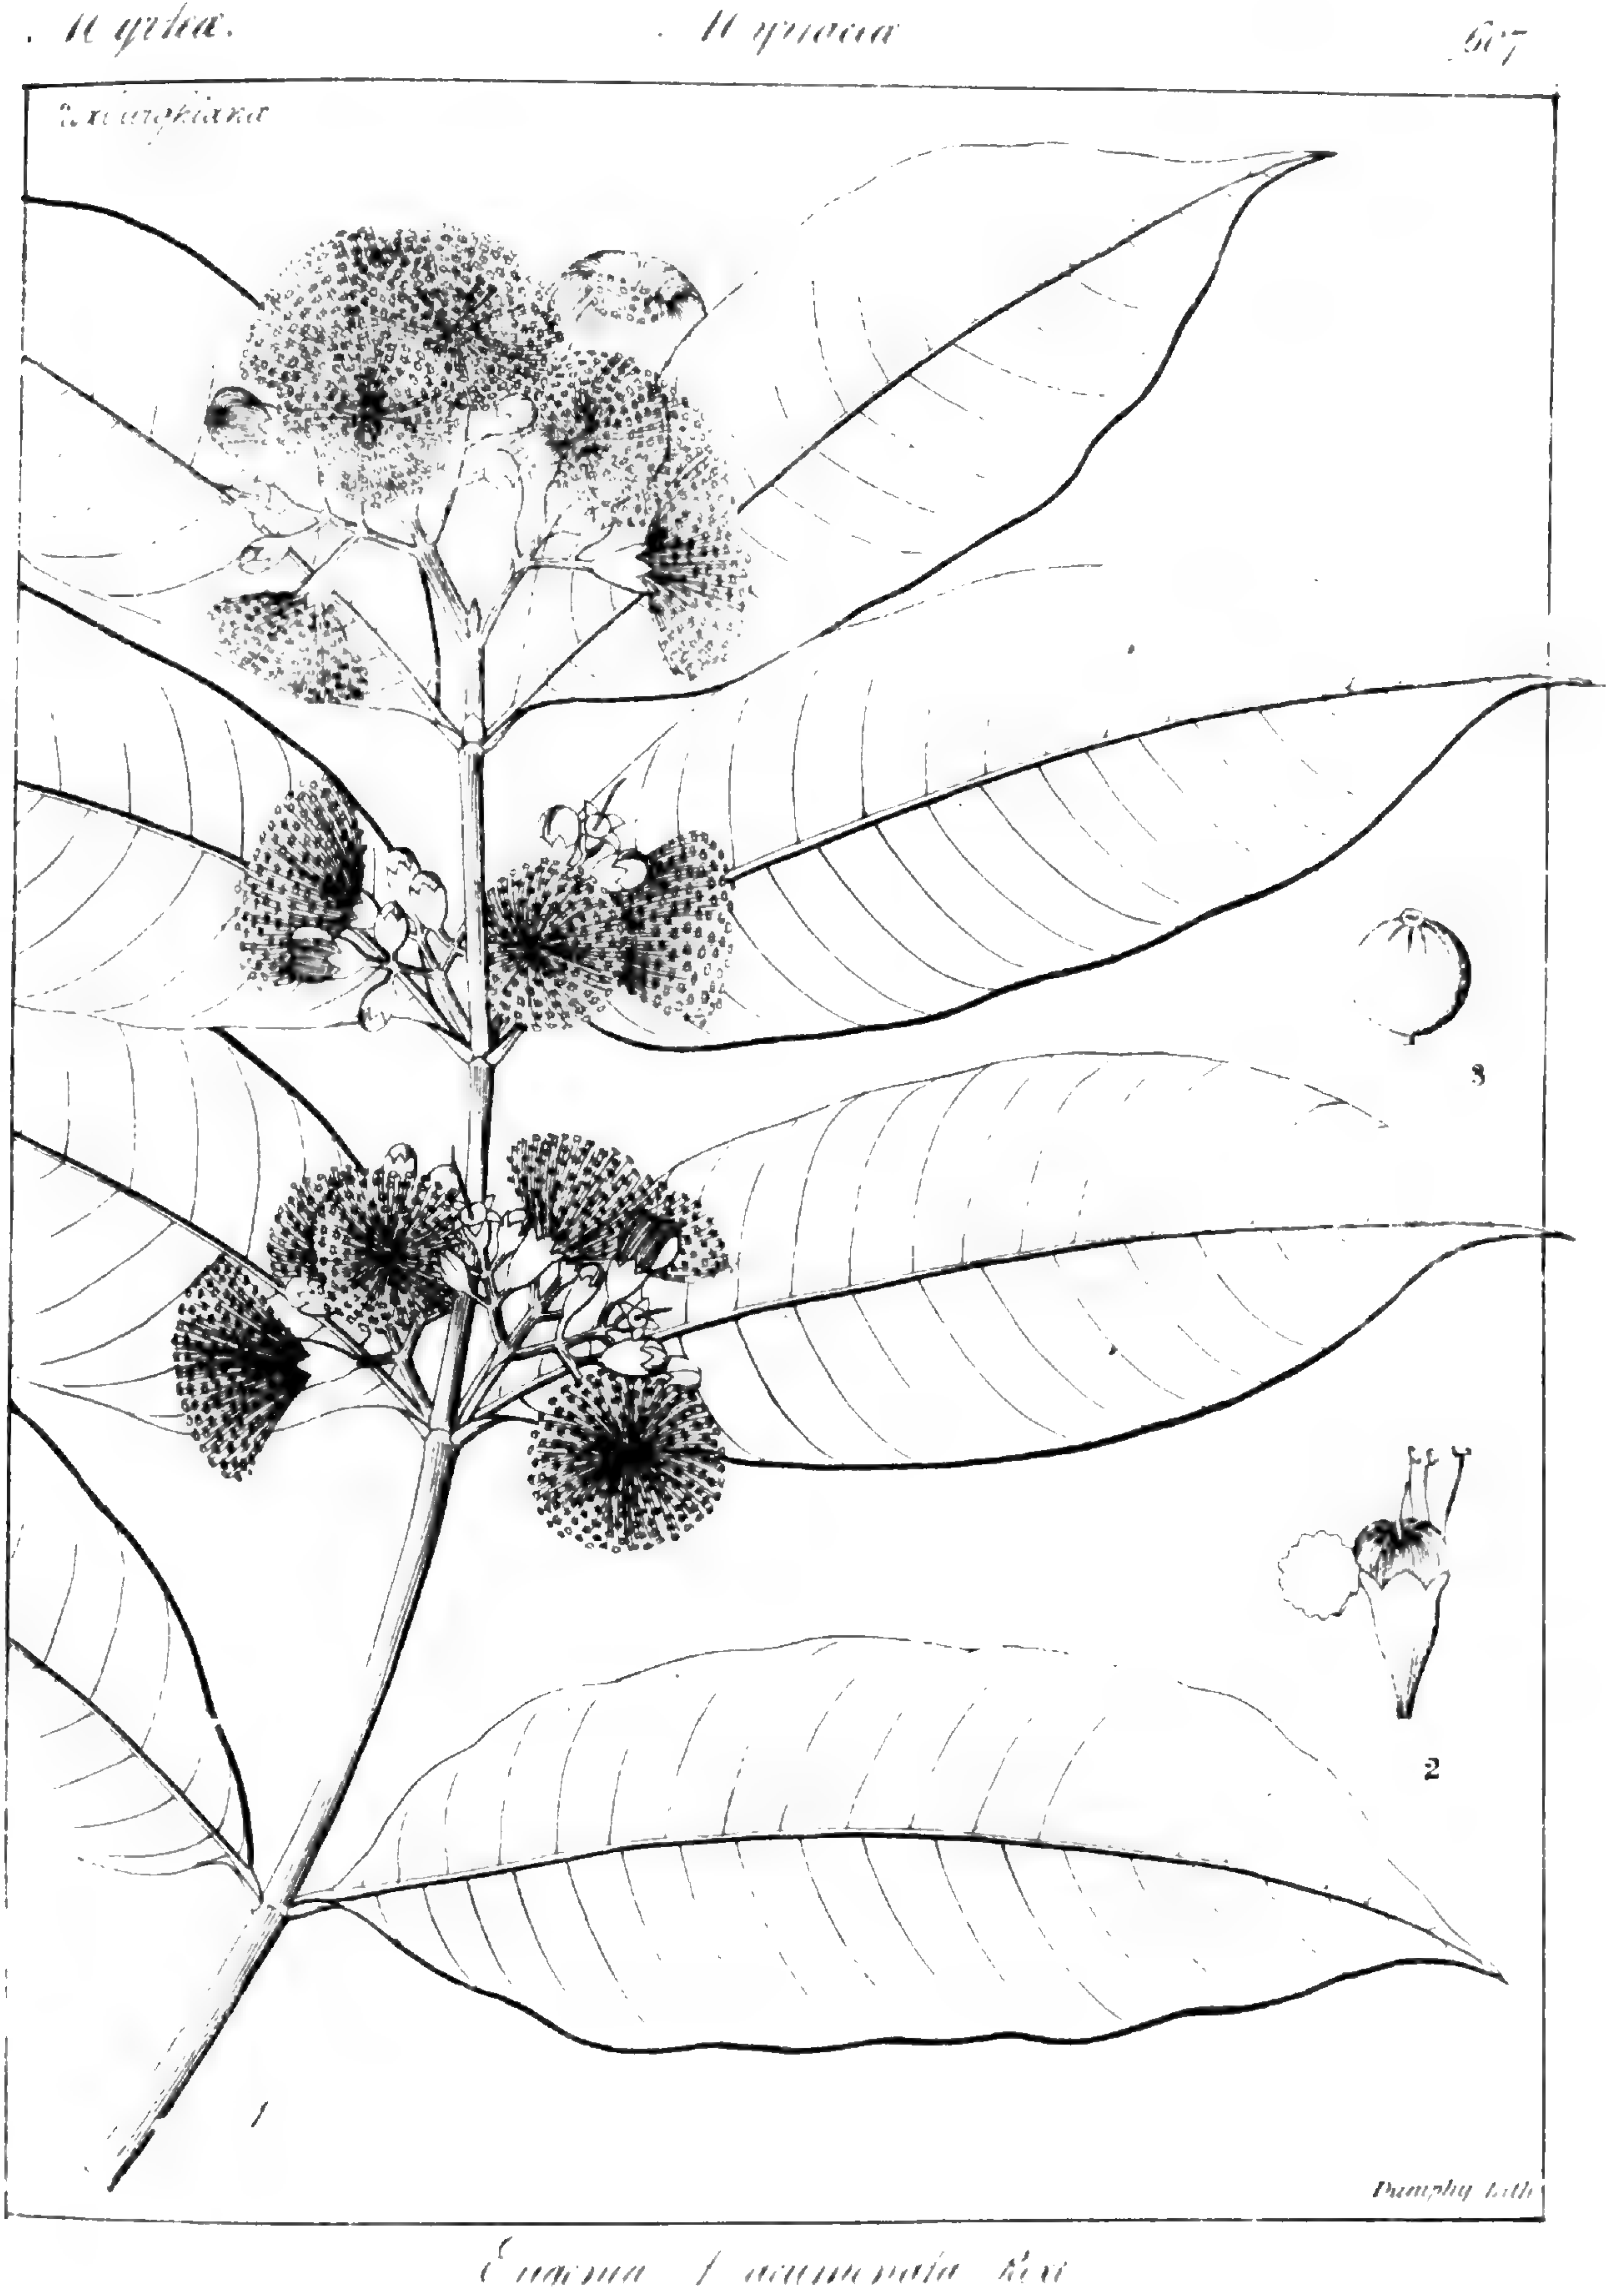

FIGURE 70. *Myrtaceae.* Syzygium acuminatum; *flowering branch. (From Wight, 1843.)*

vertical series are developed in the same axils. In this case they may be different in their degree of ramification or not, both demonstrated in *Myrceugenia exsucca* (DC.) Berg (Fig. 80 IX).

Within the large genus *Eucalyptus,* terminal thyrsoid-paniculate inflorescences ending in a terminal flower as well as proliferating inflorescences can be observed. Although some sections of the genus may exclusively follow

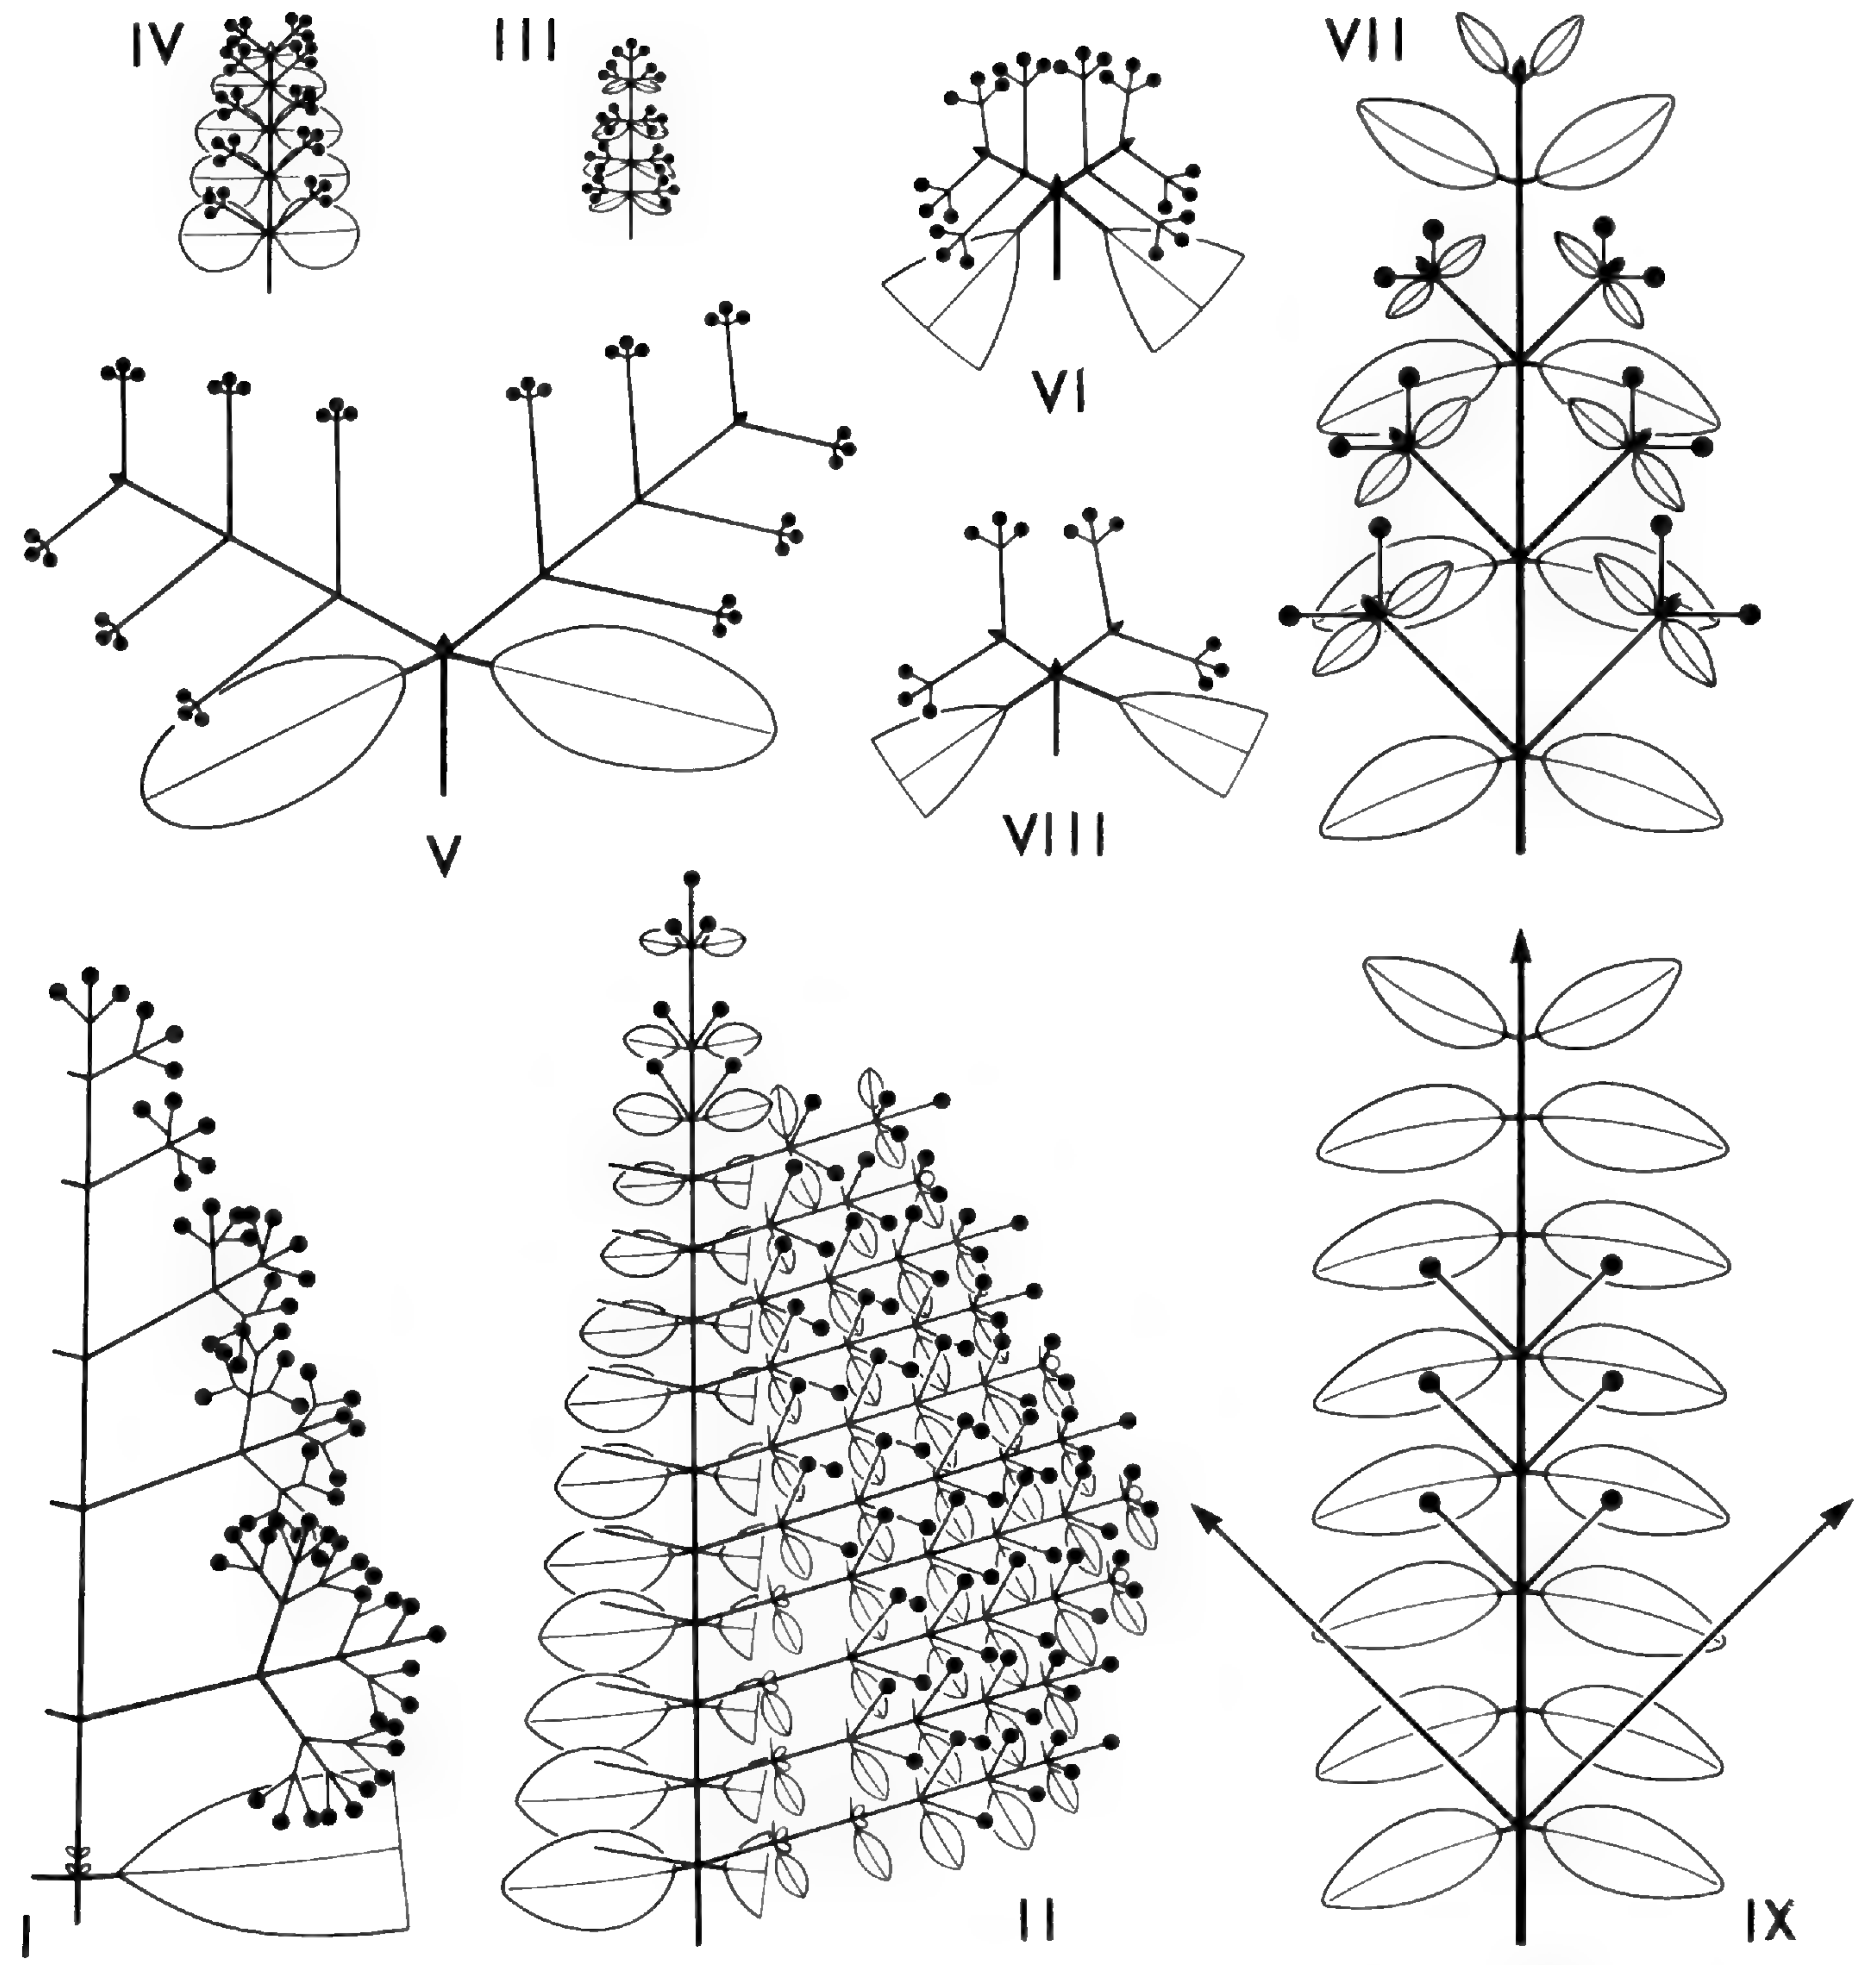

FIGURE 71. *Myrtaceae. Inflorescence diagrams.—I.* Metrosideros albiflora.—*II.* M. carminea.—*III.* M. diffusa.—*IV.* M. perforata.—*V.* M. kermadecensis.—*VI, VII.* M. umbellata.—*VIII.* Rhodomyrtus tomentosa.—*IX.* Acca sellowiana. *(I–VII from Dawson (1968) with some graphical alterations; bracts were ommited by Dawson.)*

one or the other mode, even closely related species can be different in this respect. Thus in many species of sect. *Adnataria* of subg. *Symphyomyrtus* (Pryor & Johnson, 1971), the main axes of the inflorescences were found to have terminal flowers (*E. melliodora* A. Cunn., *E. paniculata* Sm. (Fig. 76 I), *E. polycarpa* F. Muell., *E. polyanthemos* Schau., *E. populnea* F. Muell., *E. pruinosa* Schau. (Fig. 76 II), while others (e.g., *E. sideroxylon* A. Cunn.) have a proliferating main axis. In still others (e.g., *E. intertexta* R. T. Baker) inflorescences with terminal flowers and proliferating inflorescences were even found on the same herbarium sheet (Penfold & Willis, 1961, pl. 38, fig. 6). According to Johnson (1972: 23, fig. 5) this form "has adaptive significance" and is derived from forms without a terminal flower (the reverse seems more probable).

The partial inflorescences are condensed cymes (Fig. 75 III, IV), which often are described as umbels but more correctly should be called umbellasters (Johnson, 1972; Briggs

FIGURE 72. *Myrtaceae. I, II.* Melaleuca decora; *inflorescence before (left) and after (center) proliferation.—Right.* Callistemon rigidus; *proliferating shoot after anthesis, with fruits of preceding flowering phase. (From Troll.)*

& Johnson, 1979) or sciadioids (Troll, 1964: 53).

The number of flowers in such umbellasters can be seven or more, but often their number is reduced, and they are not rarely uniflorous (*Eucalyptus globulus* Labill., *E. tetraptera* Turcz.). They can show significant characters, such as concrescence of their gynoecia in *E. lehmannii* (Schau.) Benth. or broadening of the hypopods, especially in *E. platypus* Hook. (Fig. 77). In *E. cinerea* F. Muell. (Fig. 73), *E. macrorhyncha* F. Muell., and other species with proliferating inflorescences, a strong delay of anthesis as already noted for *Beaufortia decussata* takes place. As a consequence the top of the inflorescence axis may produce vegetative branches while the partial inflorescences at its base are still in flower. The connection of these conditions with the formation of cataleptic (Müller-Doblies & Weberling, 1984) flower-bearing short shoots and with cauliflory seems to be obvious here.

Frequently the flower-bearing branches are reduced to botryoids, as in *Myrciaria floribunda* (Willd.) Berg (Cremers, 1983/1986, fig. 42/7) or *Eugenia guatemalensis* Cogn. In species of *Blepharocalyx* (*B. tweedii* Hook. & Arn., *B. gigantea* Lillo, cf. Cabrera, 1978, fig. 143; Digilio & Legname, 1966, fig. 82) or *Backhousia myrtifolia* Hook. & Harvey, the paracladia are long-stalked and loosely branched, seven- to five-flowered cymes. This reduction of the paracladia goes even further to form long-stalked, loosely branched triads, as in *Myrcianthes cisplatensis* (Camb.) Berg, *Myrceugenella apiculata* (DC.) Kausel, or *Eugenia pseudo-mato* Legr. (Digilio & Legname, 1966, figs. 84, 87) or to long-stalked, biflorous or uniflorous (monadic or dyadic) paracladia still with prophylls (*Eugenia pungens* Berg; Digilio &

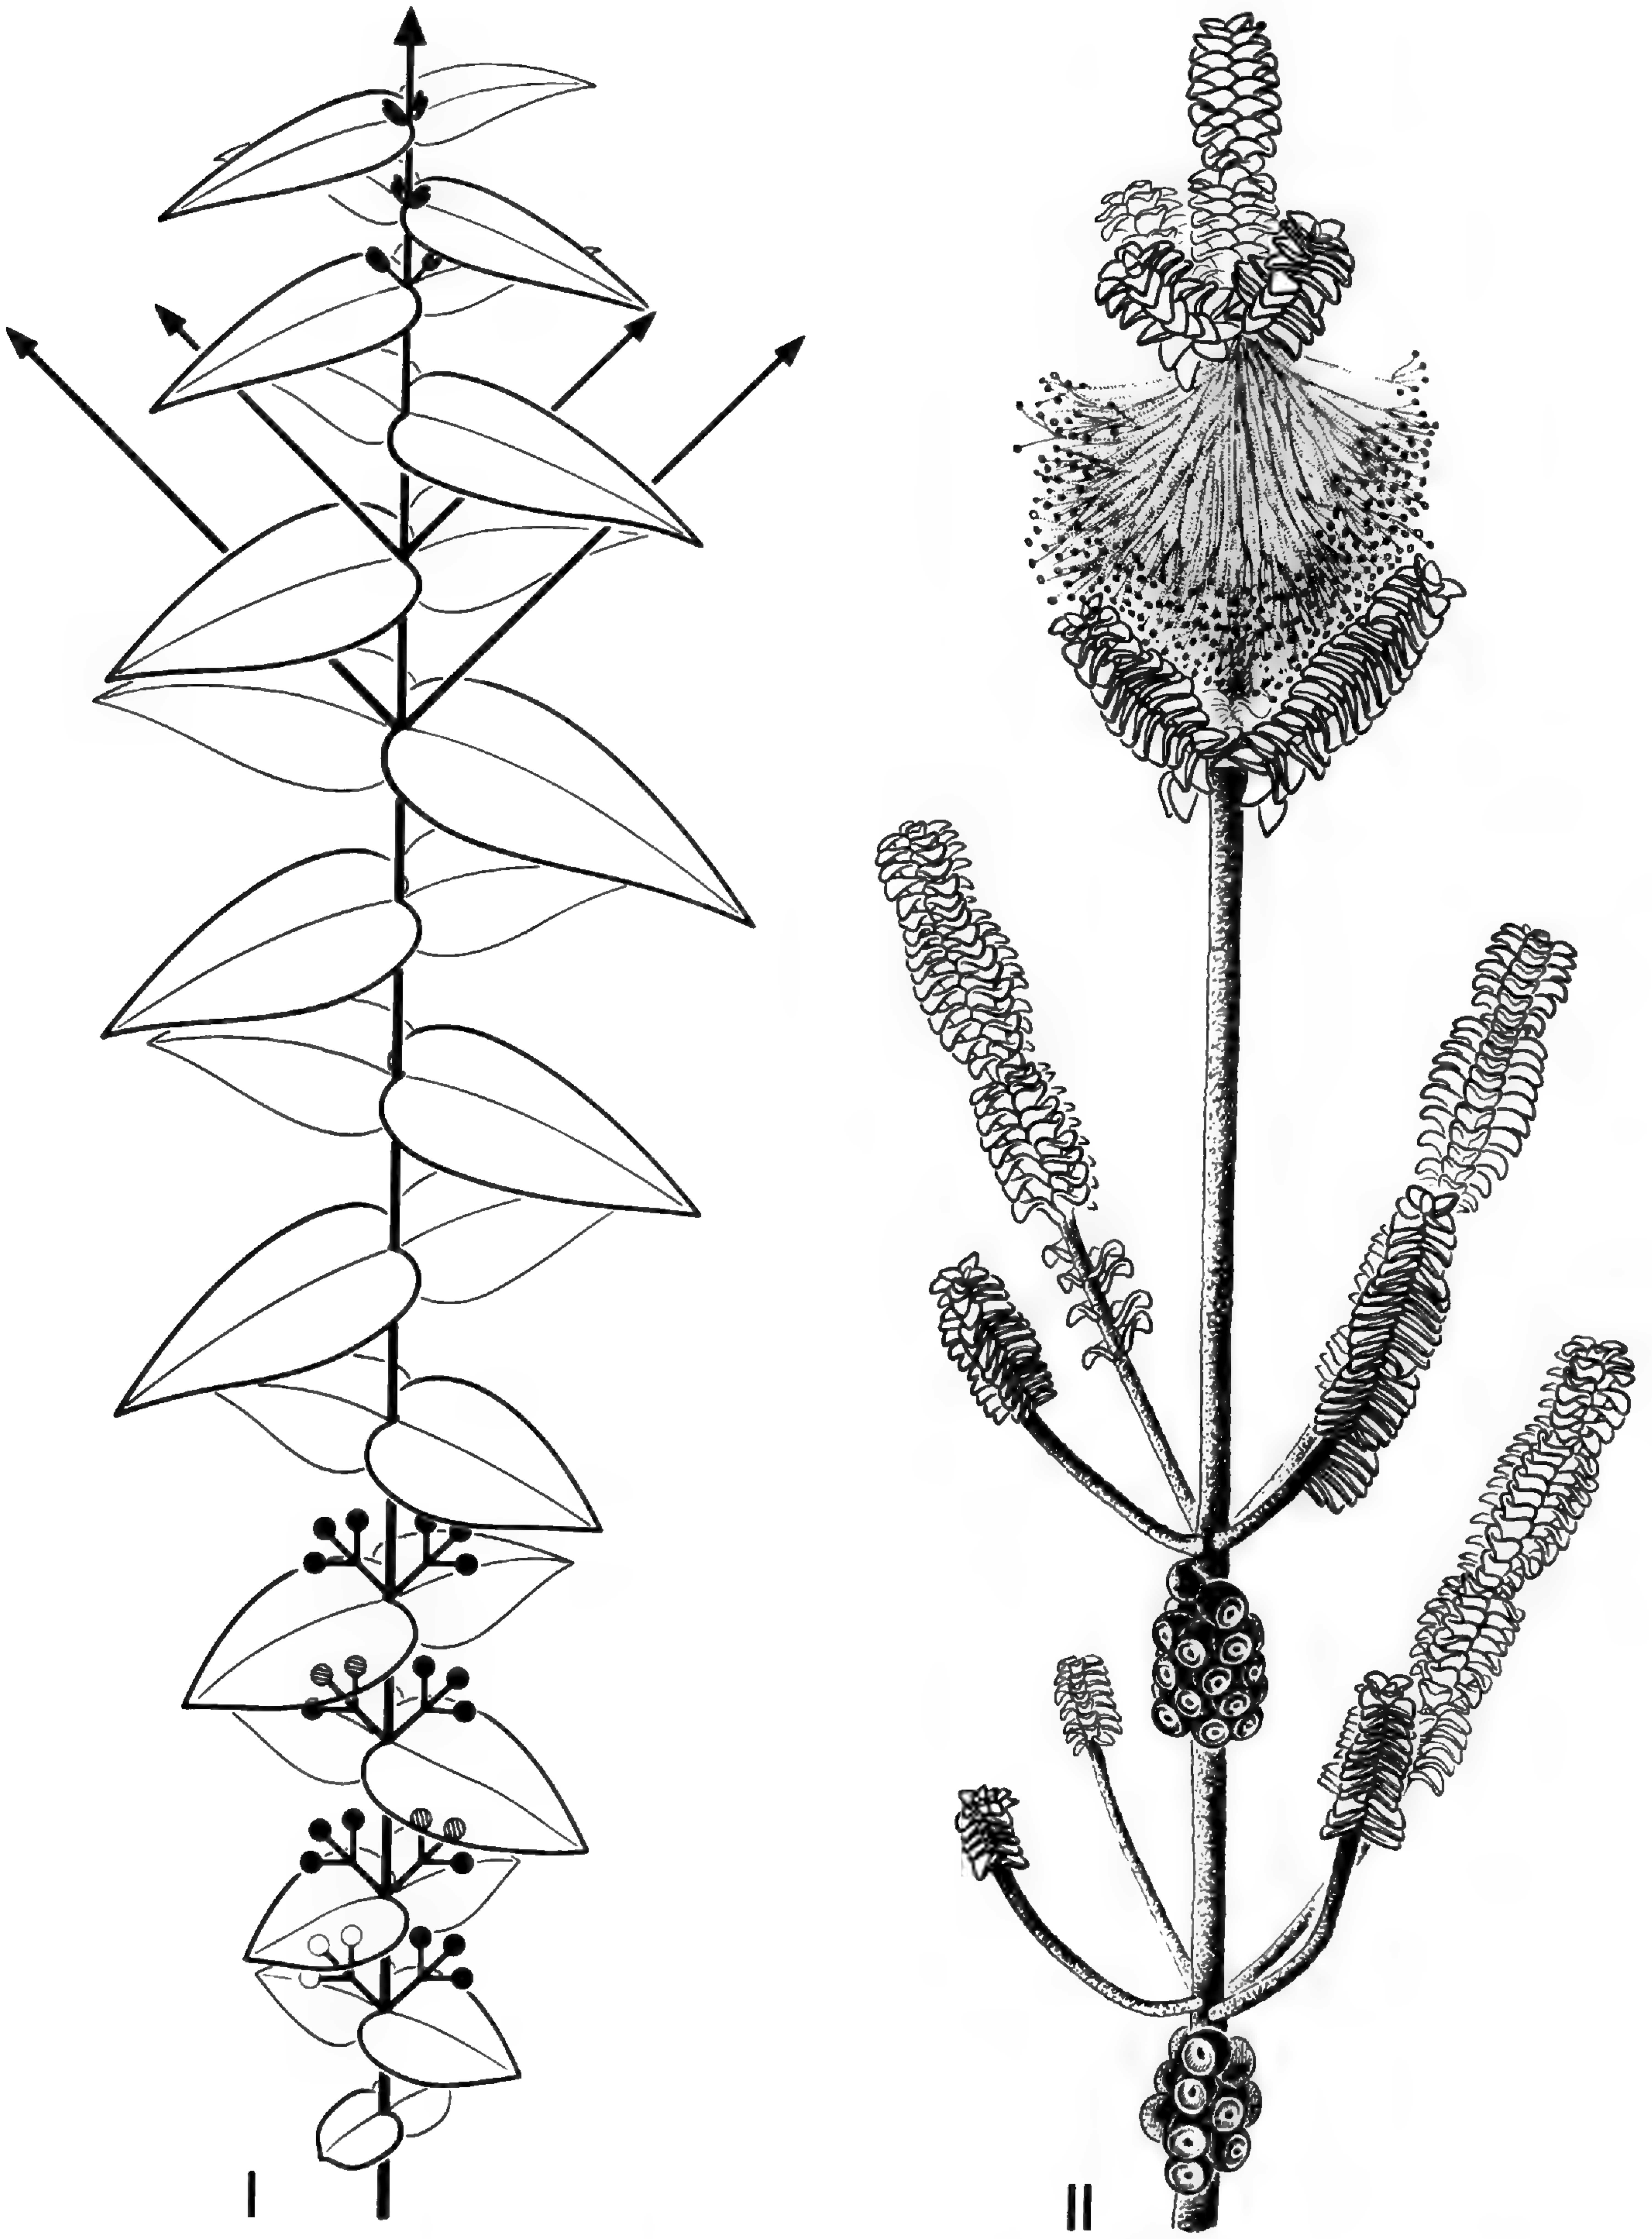

FIGURE 73. *Myrtaceae.—I.* Eucalyptus cinerea; *diagram of a flowering shoot. The proliferating inflorescence axis already had developed branches when anthesis had started (*Weberling 7413*).—II.* Beaufortia decussata; *flowering shoot with fruits of preceding flowering phases.*

FIGURE 74. *Myrtaceae.* Pimenta dioica; *inflorescences.—Left. Proliferation has taken place already.—Right. The inflorescence axis still ends in a bud. (From Troll.)*

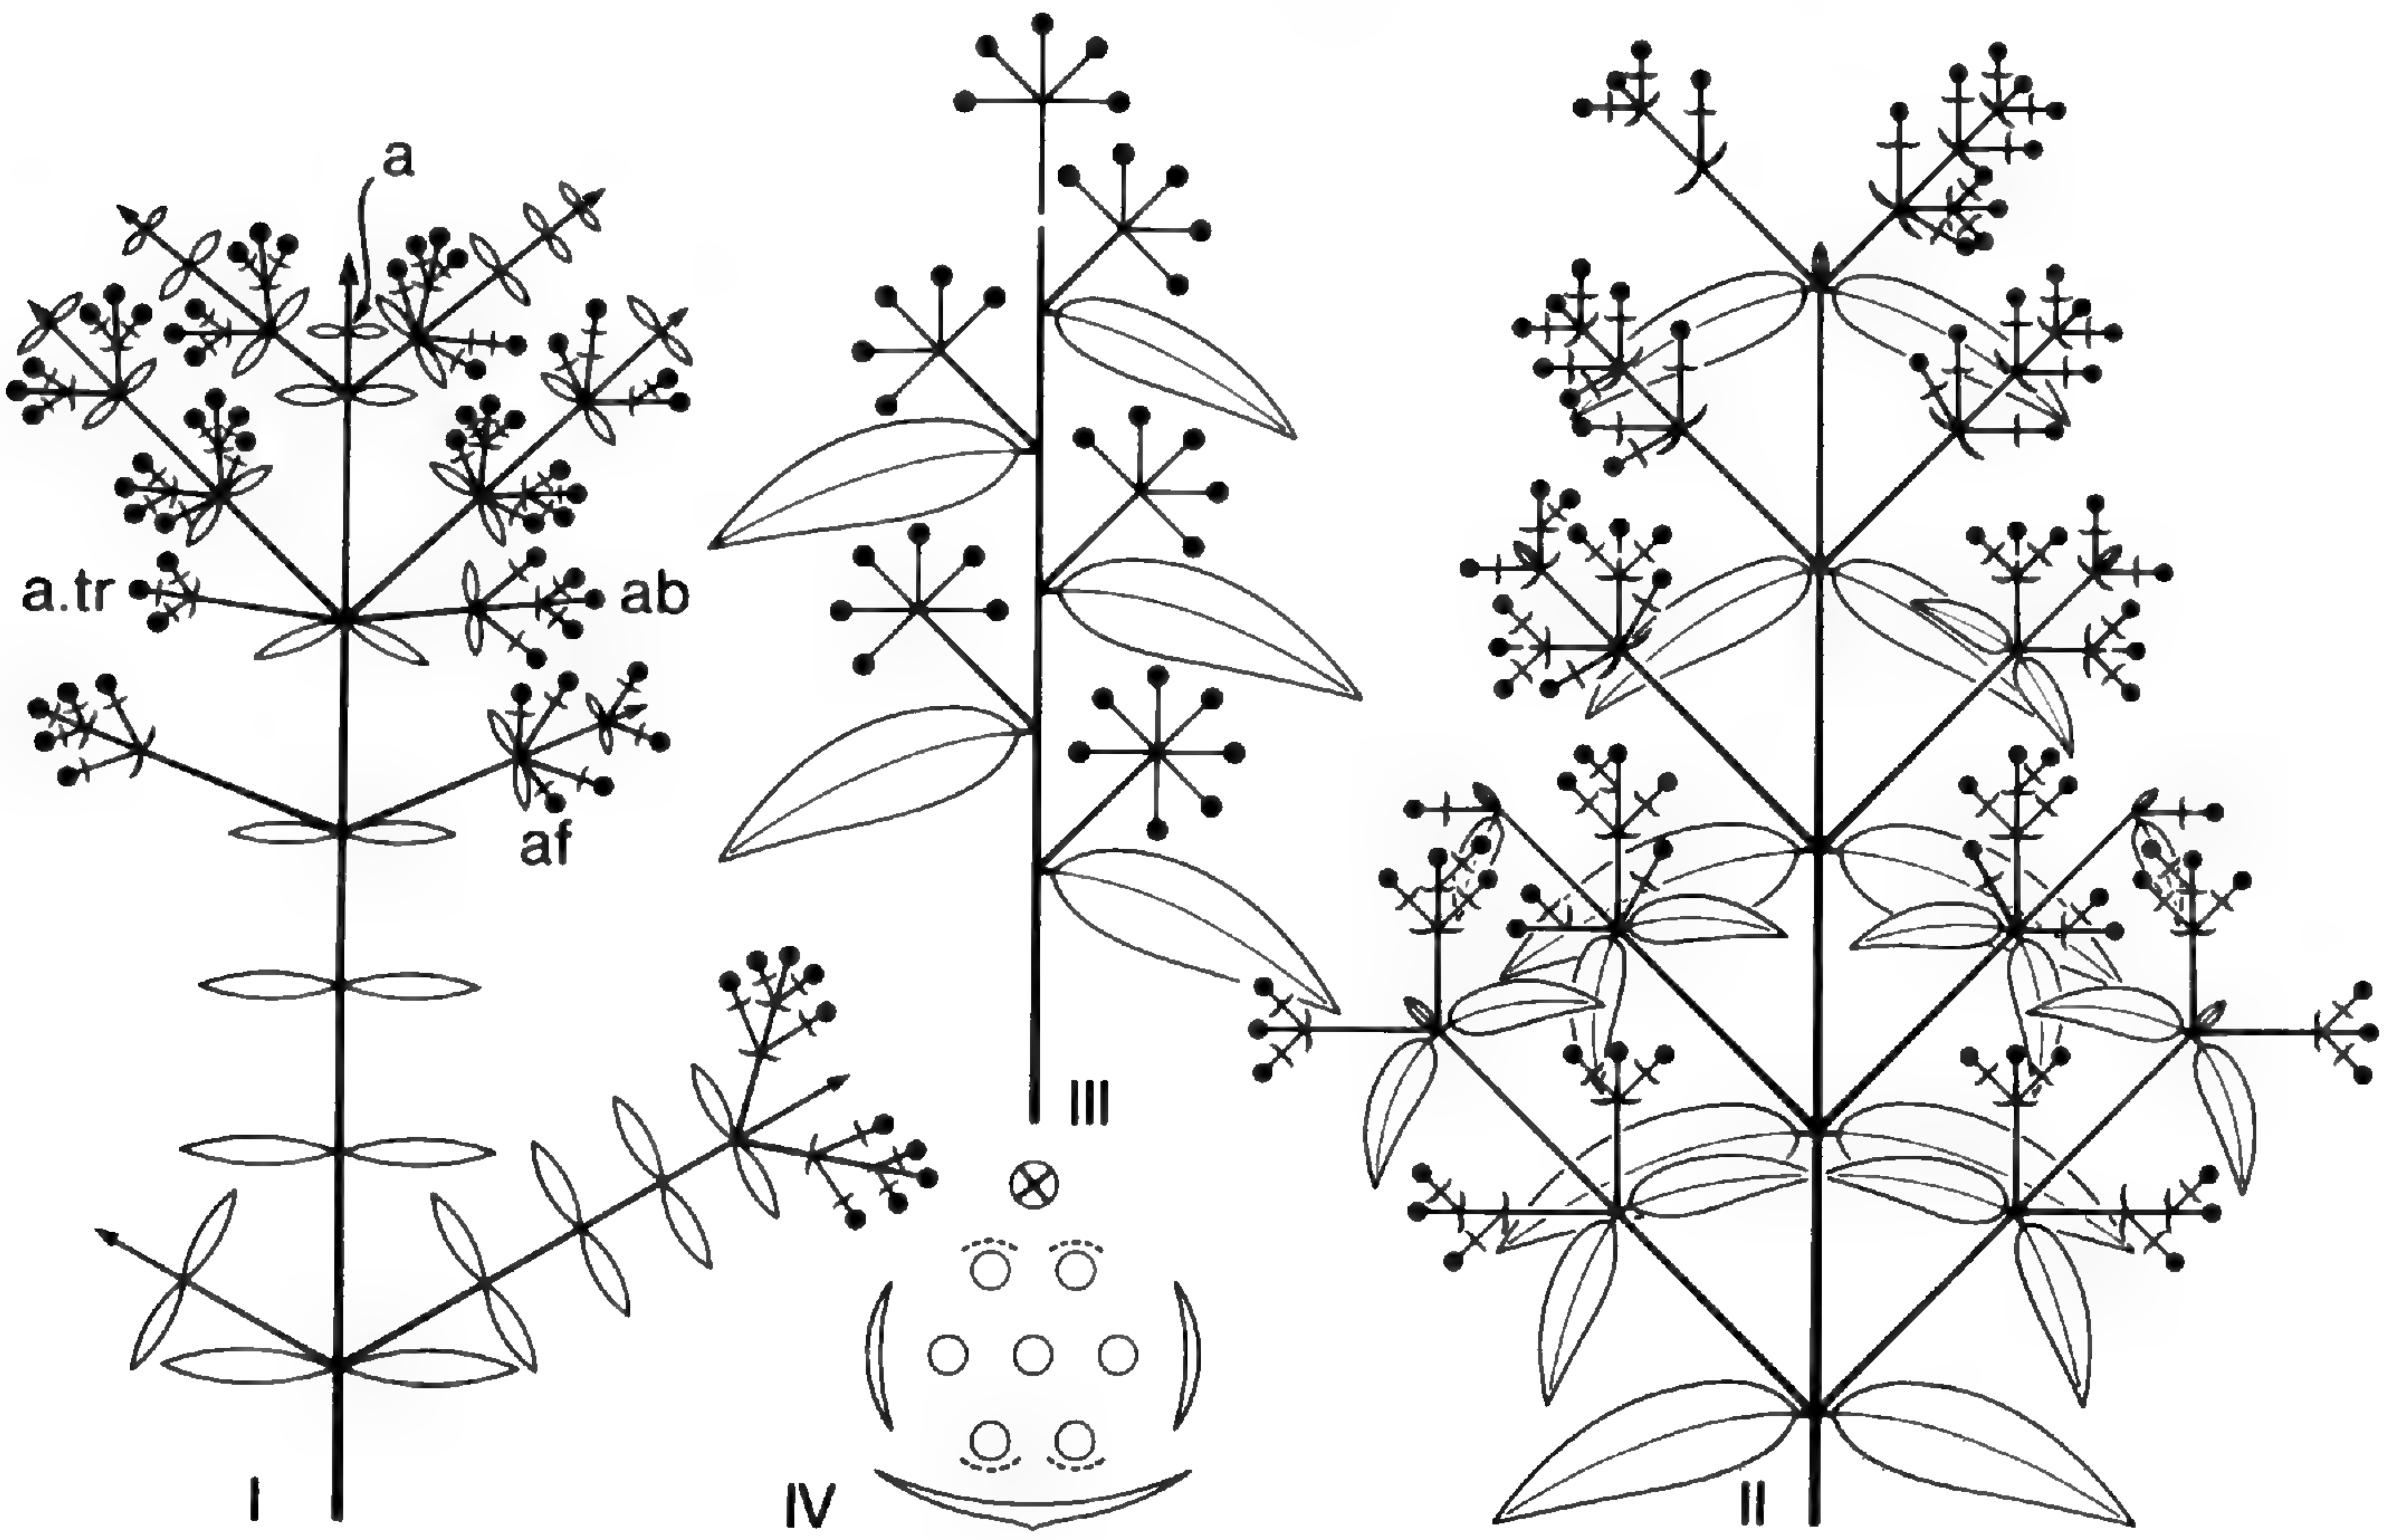

FIGURE 76. *Myrtaceae.—I.* Eucalyptus paniculata.*—II.* E. pruinosa; *flowering branches. (From F. Mueller.)*

Legname, 1966, fig. 85). Condensed and sessile triadic or uniflorous paracladia compose the spikelike proliferating inflorescences so characteristic of many species of *Calothamnus, Callistemon* (triadic pc in *C. suberosum* only; Dawson, 1978a, fig. 3), *Melaleuca* (Fig. 72), and *Beaufortia* (Fig. 73 II).

Leafy proliferating botrya are characteristic for all or many species of the myrtoid genera *Ugni, Myrtus, Fenzlia, Psidium, Myrceugenia, Luma, Acca* (Fig. 71 IX), and others and of the leptospermoid genera *Eremaea, Baeckea, Balaustion, Calythrix, Wehlia, Pileanthus, Thryptomene, Micromyrtus* (Fig. 78 III, IV), *Verticordia* (Fig. 78 I, II), *Regelia* (also triadic pc?, cf. Briggs & Johnson, 1979), and others.

In many species of *Kunzea* (e.g., *K. capitata* Reichb. and *K. ericifolia* Reichb., Fig. 79 I), the botrytic or spikelike inflorescences are capitate, as in species of *Agonis* (Fig. 80 II) and *Sinoga.*

The agglomeration of flowers into showy heads decidedly supports the attraction of pollinators. This is especially true for the pseudanthial inflorescences of *Darwinia* and *Actinodium.* In both, the dense heads are botrya that can proliferate after flowering (especially in *Darwinia,* Fig. 81). In *Darwinia* the subtending leaves of the flowers are inconspic-

uous, but the adjacent leaves are often greatly enlarged, petaloid, and colored, giving the capitate inflorescence a flowerlike shape (Fig. 82). For the western Australian species, Briggs & Johnson (1979: 201) found "a sequence from (for example) the little-modified *D. thymoides* Benth., through *D. virescens* (Meissn.) Benth., where the petaloid leaves are about as long as the perigynia ('floral tubes'), to the pendulous 'bells' . . . of *D. meeboldii* C. A. Gardn. ('Mondurup Bell') or *D. speciosa* (Meissn.) Benth., in which individual flowers are hidden by several series of long petaloid leaves," and the inflorescence axis "is anauxotelic" (Figs. 80 IV, 82). In *Actinodium cunninghamii* Schau. ex Lindley, the "daisy-like" flower heads have several rows of "rays" formed by modified sterile flowers (Figs. 80 V, 82). The axis of the capitulum "is somewhat swollen but not flat, and variation in the length of the peduncles of the monads brings the flowers to approximately the same level, although the outermost arise c. 2–5 mm below the innermost" (Briggs & Johnson, 1979: 202).

It is not rare that the development of triadic to uniflorous paracladia and the arrangement in leafy thyrsic, botrytic or spikelike proliferating inflorescences is limited to branches of more or less long main shoots

that remain vegetative themselves. This applies to *Baeckea astartoides* Benth., *B. behrii* F. Muell., and others. The next step in this differentiation of a system of vegetative long shoots and flower-bearing short shoots may be that the short shoots develop and flower in the season that follows the development of the long shoot. This was observed in *Campomanesia xanthocarpa* Berg, in which the flower-producing short shoots bear cataphylls at their bases (also seen in *Myricariopsis baporetii* (Legrand) Kausel?; see Kausel, 1955–1957: 508, fig. 10). This characteristic "cauliflorous" position of the thyrsoid bracteose inflorescences in *Myrrhinium* species may be explained by an extreme delay of the development and flowering of such short shoots (cf. Fig. 83).

A remarkable reduction of flower-bearing lateral shoots can be observed in some species of *Chamelaucium* and *Hypocalymma.* In *C. uncinatum* Schau. (Fig. 79 II) leafy axes bear pairs of flowering branches that after the production of only two flowers terminate in a bud. This means that only the prophylls of the flowering branches are fertile. Sometimes, however, we can find the flowering branches producing two pairs of flowers before ending in a terminal bud (Fig. 80 VIII). By this observation we are justified to interpret the flower pairs as reduced (commonly anauxotelic) botrytic paracladia, especially as there are species of *Chamelaucium* with botrytic though bracteose flowering shoots (e.g., *C. gracile,* Fig. 80 VI). Whereas in the flowering shoots of *C. uncinatum* the hypopods of first

FIGURE 82. *Myrtaceae.—Left.* Darwinia meissneri (Meebold 1361 *(M)).—Right.* Actinodium cunninghamii *Schau.* (Meebold 1313 *(M)).*

and second order are well developed, they are completely reduced in the species of *Hypocalymma* (Fig. 80 VII). Thus the inflorescences of this genus consist of axillary sessile flower pairs including between the flowers a terminal bud that sometimes may become auxotelic. The same inflorescence structure was seen in *Myrceugenia campestris* (DC.) Legrand & Kausel. According to Briggs & Johnson (1979), even the uniflorous elements composing the spikelike inflorescences of *Melaleuca exarata* are lateral flowers of reduced lateral spikes. Except this single lateral flower, which according to Briggs & Johnson must be regarded as terminating a lateral axis of second order, we could only detect a series of about six bracts interpretable as the last remnant of the reduced spikes. In *N. nesophila* F. Muell. the dense spikelike inflorescence, which often proliferates, is composed of three-flowered cymes (Leins, 1965). A case similar to *Chamaelaucium* can be found in *Rhodomyrtus tomentosa* (Ait.) Wight (Fig. 71 VIII) and *R. parviflora* Alston, and in *Octamyrtus*. Here the prophylls of the flowering branches bear single flowers or triads, and the terminal bud at least produces one pair of small leaves.

Considering the indefinite character of the thyrsic or botrytic inflorescence axes and their main branches, which can be observed in some inflorescences, the question arises whether all of these inflorescences still may be classified as variants of the monotelic type. In many cases the answer is not simple, because the proliferation of various axes within the inflorescence may obscure the true morphological character.

In the thyrsoid paniculate inflorescences of *Syzygium* and many others mentioned above, there is no doubt about their monotelic character, even if the main axis of these inflorescences terminates in an anauxotelic or auxotelic bud. The same applies to the inflorescence of *Syzygium paniculatum*, which normally is a botryoid (Fig. 68 II) terminating a leafy shoot. The inflorescence of *S. jambos* (L.) Alston differs from these by the abortion of the terminal flower (Fig. 67). Troll (1969: 259) classified this inflorescence as a truncate monotelic synflorescence. Keeping in mind the flexibility in the formation of terminal flowers closing thyrsoid-paniculate inflorescences, which was demonstrated for several taxa of Myrtaceae, this view seems to be acceptable. Commonly the thyrsoid- or paniclelike flower-bearing branches—the paracladia—of such truncate monotelic systems are still provided with terminal flowers, revealing the monotelic character of the flowering system. Within *Eugenia*, one species with terminal flowers, *E. apiculata* DC. (Fig. 84 VI) was found by Sell (1982), but most of the species seem to have indeterminate flowering systems. The inflorescence structure depicted in Figure 84 I and II is not uncommon: the inflorescence axis terminates in an indefinite botrytic flowering system, and the branches inserted below this terminal botrys repeat this structure. Thus in all essential features this flowering system is in accordance with inflorescences of the polytelic type (Fig. 3 II) as characterized by Troll. According to Troll (1964–1969) and Weberling (1961, 1964, 1965, 1981, 1982, 1983a, b; Troll & Weberling, 1966), the polytelic type probably has been derived repeatedly from the monotelic during the evolution of the different groups of angiosperms by reduction of the terminal flower(s) and specialization of the paracladia of the monotelic system. As a result of this specialization the distal elements of the series of flower-bearing branches are reduced to single lateral flowers or lateral cymes (partial florescences, pf), which constitute elements of an apical system composed of lateral flowers only to which the term "florescence" is referred. The lower lateral branches repeat the structure of the main stem by producing (indefinite) florescences themselves, co-florescences, and thus are termed paracladia (pc) of the polytelic system (not to be mixed up with the paracladia of the monotelic systems).

FIGURE 83. *Myrtaceae.* Myrrhinium loranthoides; *flowering branch (I), flower (II), and fruit (III). (From Digilio & Legname.)*

Referring this typology to the inflorescences of *Eugenia polystachya* Rich. and *E. muricata* DC. (Fig. 84 I, II), we can regard the terminal botrys as the main florescence and the lateral axes with botrya as paracladia with co-florescences. In the same way the inflorescences of *E. patens* Poir. and several other species can be interpreted; rarely the single lateral flowers are replaced by triadic partial florescences (e.g., *E. muricata*, and according to Briggs & Johnson, 1979: 200, *E. dichotoma* DC.).

These polytelic forms of inflorescences can be derived from monotelic forms as repre-

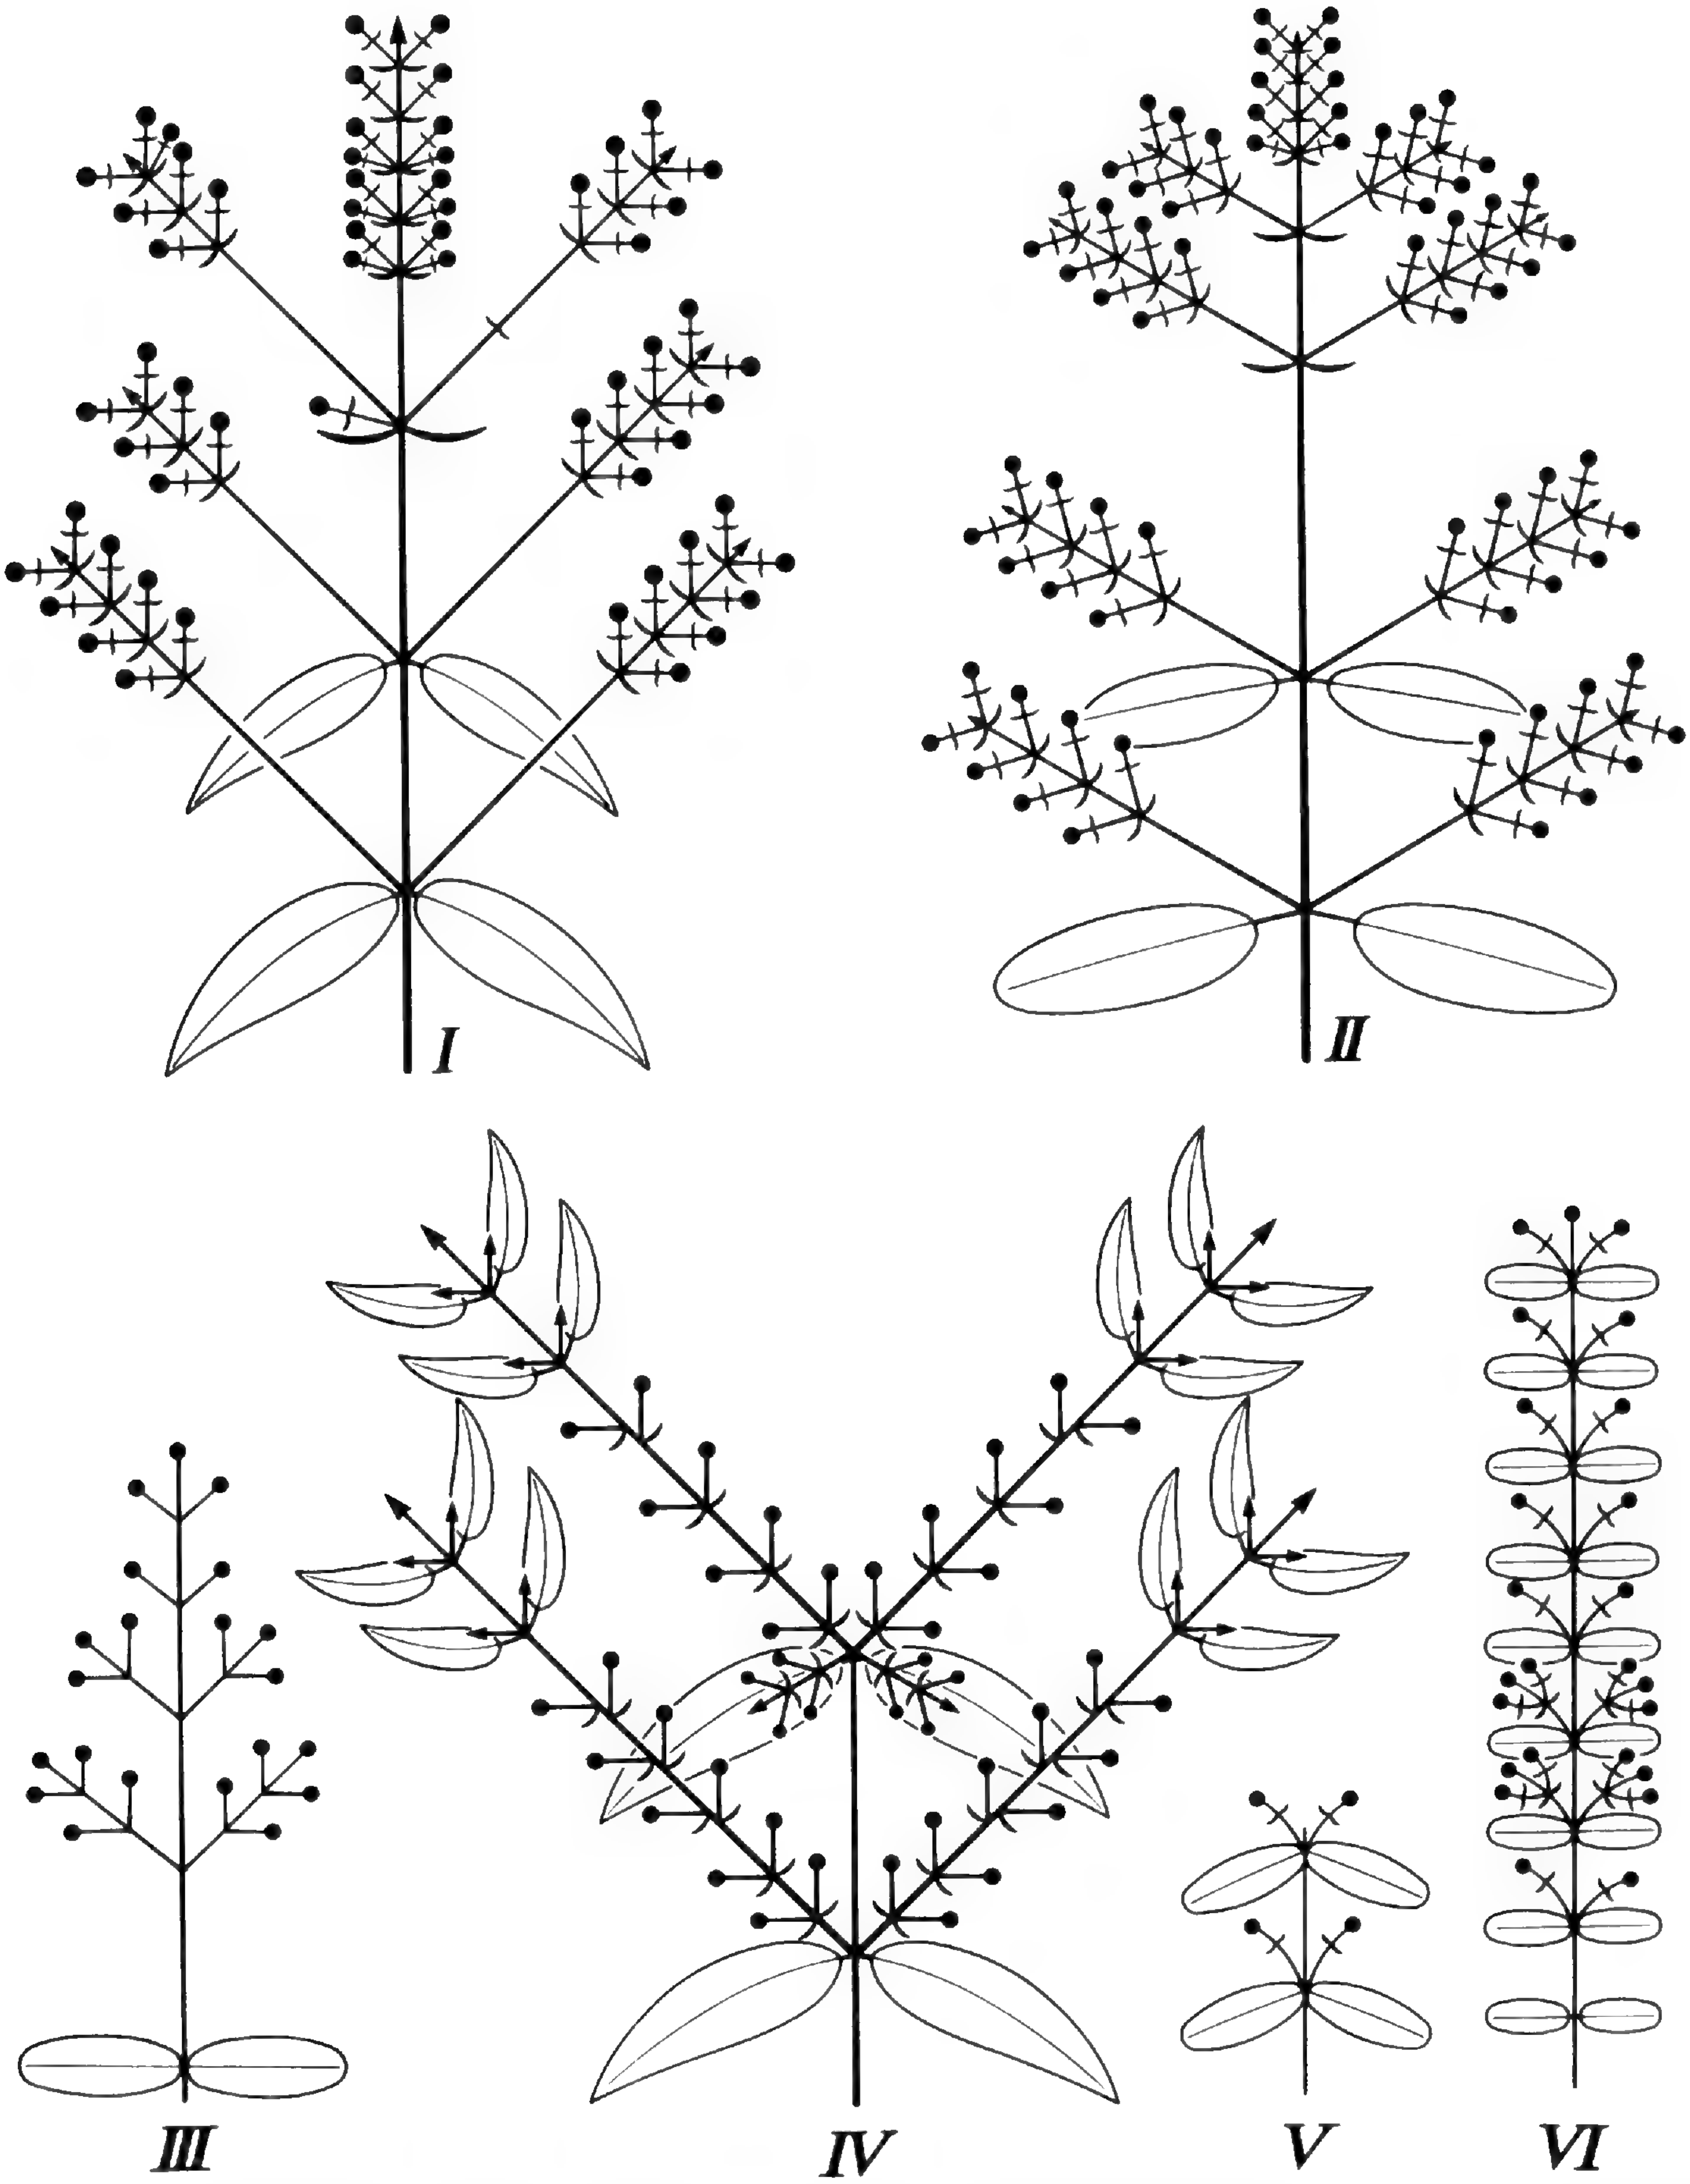

FIGURE 84. *Myrtaceae. Diagrams of flowering branches.—I.* Eugenia polystachya *(*J. M. Pires et al. 50523 *(M)).—II.* Eugenia muricata *(*Oldeman 2539*).—III.* Syzygium aromaticum *(*Oldemann B. 1096*).—IV.* Eugenia *cf.* uruguayensis *(*Weberling 5577*).—V.* E. sancta *(redrawn from Fl. Mart. XIV, 2: 26).—VI.* E. apiculata. *(II, III, V from Cremers, 1983/1986; VI from Sell, 1982.)*

sented even within *Eugenia* by species like *E. apiculata*. As mentioned before, this species has a thyrsoid-botryoid inflorescence that is still closed by a terminal flower. On the other hand, the pherophylls in this inflorescence are somewhat foliaceous. The same applies to *E. sancta* DC. (Fig. 84 V), with indefinite inflorescences.

In *Eugenia polystachya* the botrytic flowering systems end in a seemingly abortive bud. In others, however, such as *E.* cf. *uruguayensis* Cambess., they are auxotelic and produce a vegetative continuation of the bracteose botrytic axis (Fig. 84 IV). Proliferation also takes place in the botrytic leafy inflorescences of *E. parviflora* DC. (Sell, 1982) similar to the botrytic leafy proliferating inflorescences of many myrtoid and leptospermoid taxa mentioned above.

In general, a clear tendency towards the polytelic inflorescence structure can be confirmed for the Myrtaceae. In some transitional cases, however, and especially in cases of proliferating inflorescences, it can be difficult to decide whether the inflorescence of a certain taxon should be regarded as a (truncate) monotelic or a polytelic system.

The inflorescences of the Oliniaceae are monotelic throughout and follow the pattern of Myrtaceae with (thrysoid-)paniculate inflorescences, which we regard to be the central type within the whole order. The panicles are usually conical, caused by shortening of the internodes, but they can be contracted to somewhat globose heads, e.g., in *Olinia rochetiana* A. Juss. The ramification of the branches sometimes tends to be botryoidlike. In some species terminal as well as axillary panicles can be observed. This may be due to the considerably extended and sometimes irregular flowering season (Phillips, 1926): the lowermost paniclelike branches develop separately from the terminal panicle in a somewhat later stage of the flowering season, forming separate flowering systems.

FLORA OF THE VENEZUELAN GUAYANA—IV

Julian A. Steyermark[1,2]

ABSTRACT

Recent expeditions in the Venezuelan Guayana to Cerro Yutajé, Murisipán-tepui, Camarcaibarai-tepui, and Cerro de la Neblina, have resulted in additional new taxa, especially in the Aquifoliaceae and Rubiaceae, of which the following are described: Paepalanthus holstii *(Eriocaulaceae)*; Rapatea chimantensis, Stegolepis minor *(Rapateaceae)*; Rauia subtruncata, Raveniopsis liesneri *(Rutaceae)*; Ochthocosmus micranthus *(Linaceae)*; Ilex abscondita, I. acutidenticulata, I. altiplana, I. attenuata, I. brevipedicellata, I. cardonae, I. ciliolata, I. davidsei, I. glabella, I. gransabanensis, I. guaiquinimae, I. holstii, I. ignicola, I. jauaensis, I. longipilosa, I. magnifructa *var.* minor, I. marahuacae, I. paujiensis, I. polita, I. spathulata, I. summa, I. wurdackiana *(Aquifoliaceae)*; Allophylus parimensis *(Sapindaceae)*; Coussarea evoluta, Faramea boomii, F. morilloi, F. paludicola, F. yavitensis, F. yutajensis, Ferdinandusa boomii, Morinda longipedunculata, Psychotria anartiothrix, P. edaphothrix, P. pectinata, P. steinii, P. thesceloantha, P. yutajensis, Rudgea corocoroensis, *and* Sabicea bariensis *(Rubiaceae)*.

ERIOCAULACEAE

PAEPALANTHUS

Paepalanthus holstii Steyermark, sp. nov. TYPE: Venezuela. Bolívar: Dist. Piar, Murisipán-tepui, summit, 5°53'N, 62°3'W, 2,300 m, 22 Mar. 1987, *Bruce Holst 3523* (holotype, MO; isotype, VEN). Figure 1.

Herba perennis caulescens; caulibus elongatis 10–30 cm longis, parte foliacea 10–20 cm longa, dense foliosis; foliis supra argentiis, eis supremis supra sericeo-pubescentibus nitidis late lanceolatis apice prolongatis, acumine ligulato 1 mm longo, 4–5 cm longis 1–1.4 cm latis; pedunculo pubescenti; capitulis 8–10 mm diam.; bracteolis involucri atrobrunneo-nigris late triangulari-ovatis acuminatis 2–2.5 mm longis, basi 1.5 mm latis extus sericeo-pubescentibus marginibus ciliolatis intus glabris; bracteis receptaculi subligulatis apice abrupte acutis extus dense pilosis aliter glabris 2.5–2.7 mm longis 0.6–1 mm latis; bracteolis masculinis oblanceolatis obtusis dorsaliter carinatis 2.5 × 0.7 mm parte apicali extus dense pilosis; sepalis masculinis spathulatis apice rotundatis 2 mm longis 0.5 mm latis extus praeter apicem dense pilosum glabris intus glabris; corollae masculinae tubo anguste infundibuliformi 2.2 mm longo ad medium 0.7 mm lato basi 0.1 mm lato.

Perennial caulescent herb with elongated stems 10–30 cm long, the foliose portion 10–20 cm long, densely foliose. Leaves, especially the uppermost, densely silvery, sericeous and shining above, older ones glabrous both sides, many (11–17) nerved, broadly lanceolate, acute, the apex prolonged into a short, narrowly ligulate, obtuse acumen 1 mm long, 4–5 cm long, 1–1.4 cm wide, the margins densely ciliate on youngest leaves, eciliate or nearly so. Peduncles several, 10–16 cm long, 1 mm diam., several-costate, sparsely pilosulous or glabrescent except beneath the head where densely antrorsely pilose with ascending, subappressed hairs. Heads semihemispheric, 8–10 mm broad, 5 mm high. Involucral bractlets brownish black, with dark brown lower margins, the remainder black, broadly triangular-ovate, acuminate, 2–2.5 mm long, 1.5 mm broad at base, sericeous pubescent along exterior length of black middle portion, glabrous throughout within. Receptacular bracts subligulate most of length,

---

[1] *This work was supported by a grant from the National Science Foundation. I am greatly indebted to the curators of F, NY, US, and VEN for the loan of critical material of Rapateaceae and Aquifoliaceae.*

[2] *Missouri Botanical Garden, P.O. Box 299, St. Louis, Missouri 63166-0299, U.S.A.*

ANN. MISSOURI BOT. GARD. 75: 311–351. 1988.

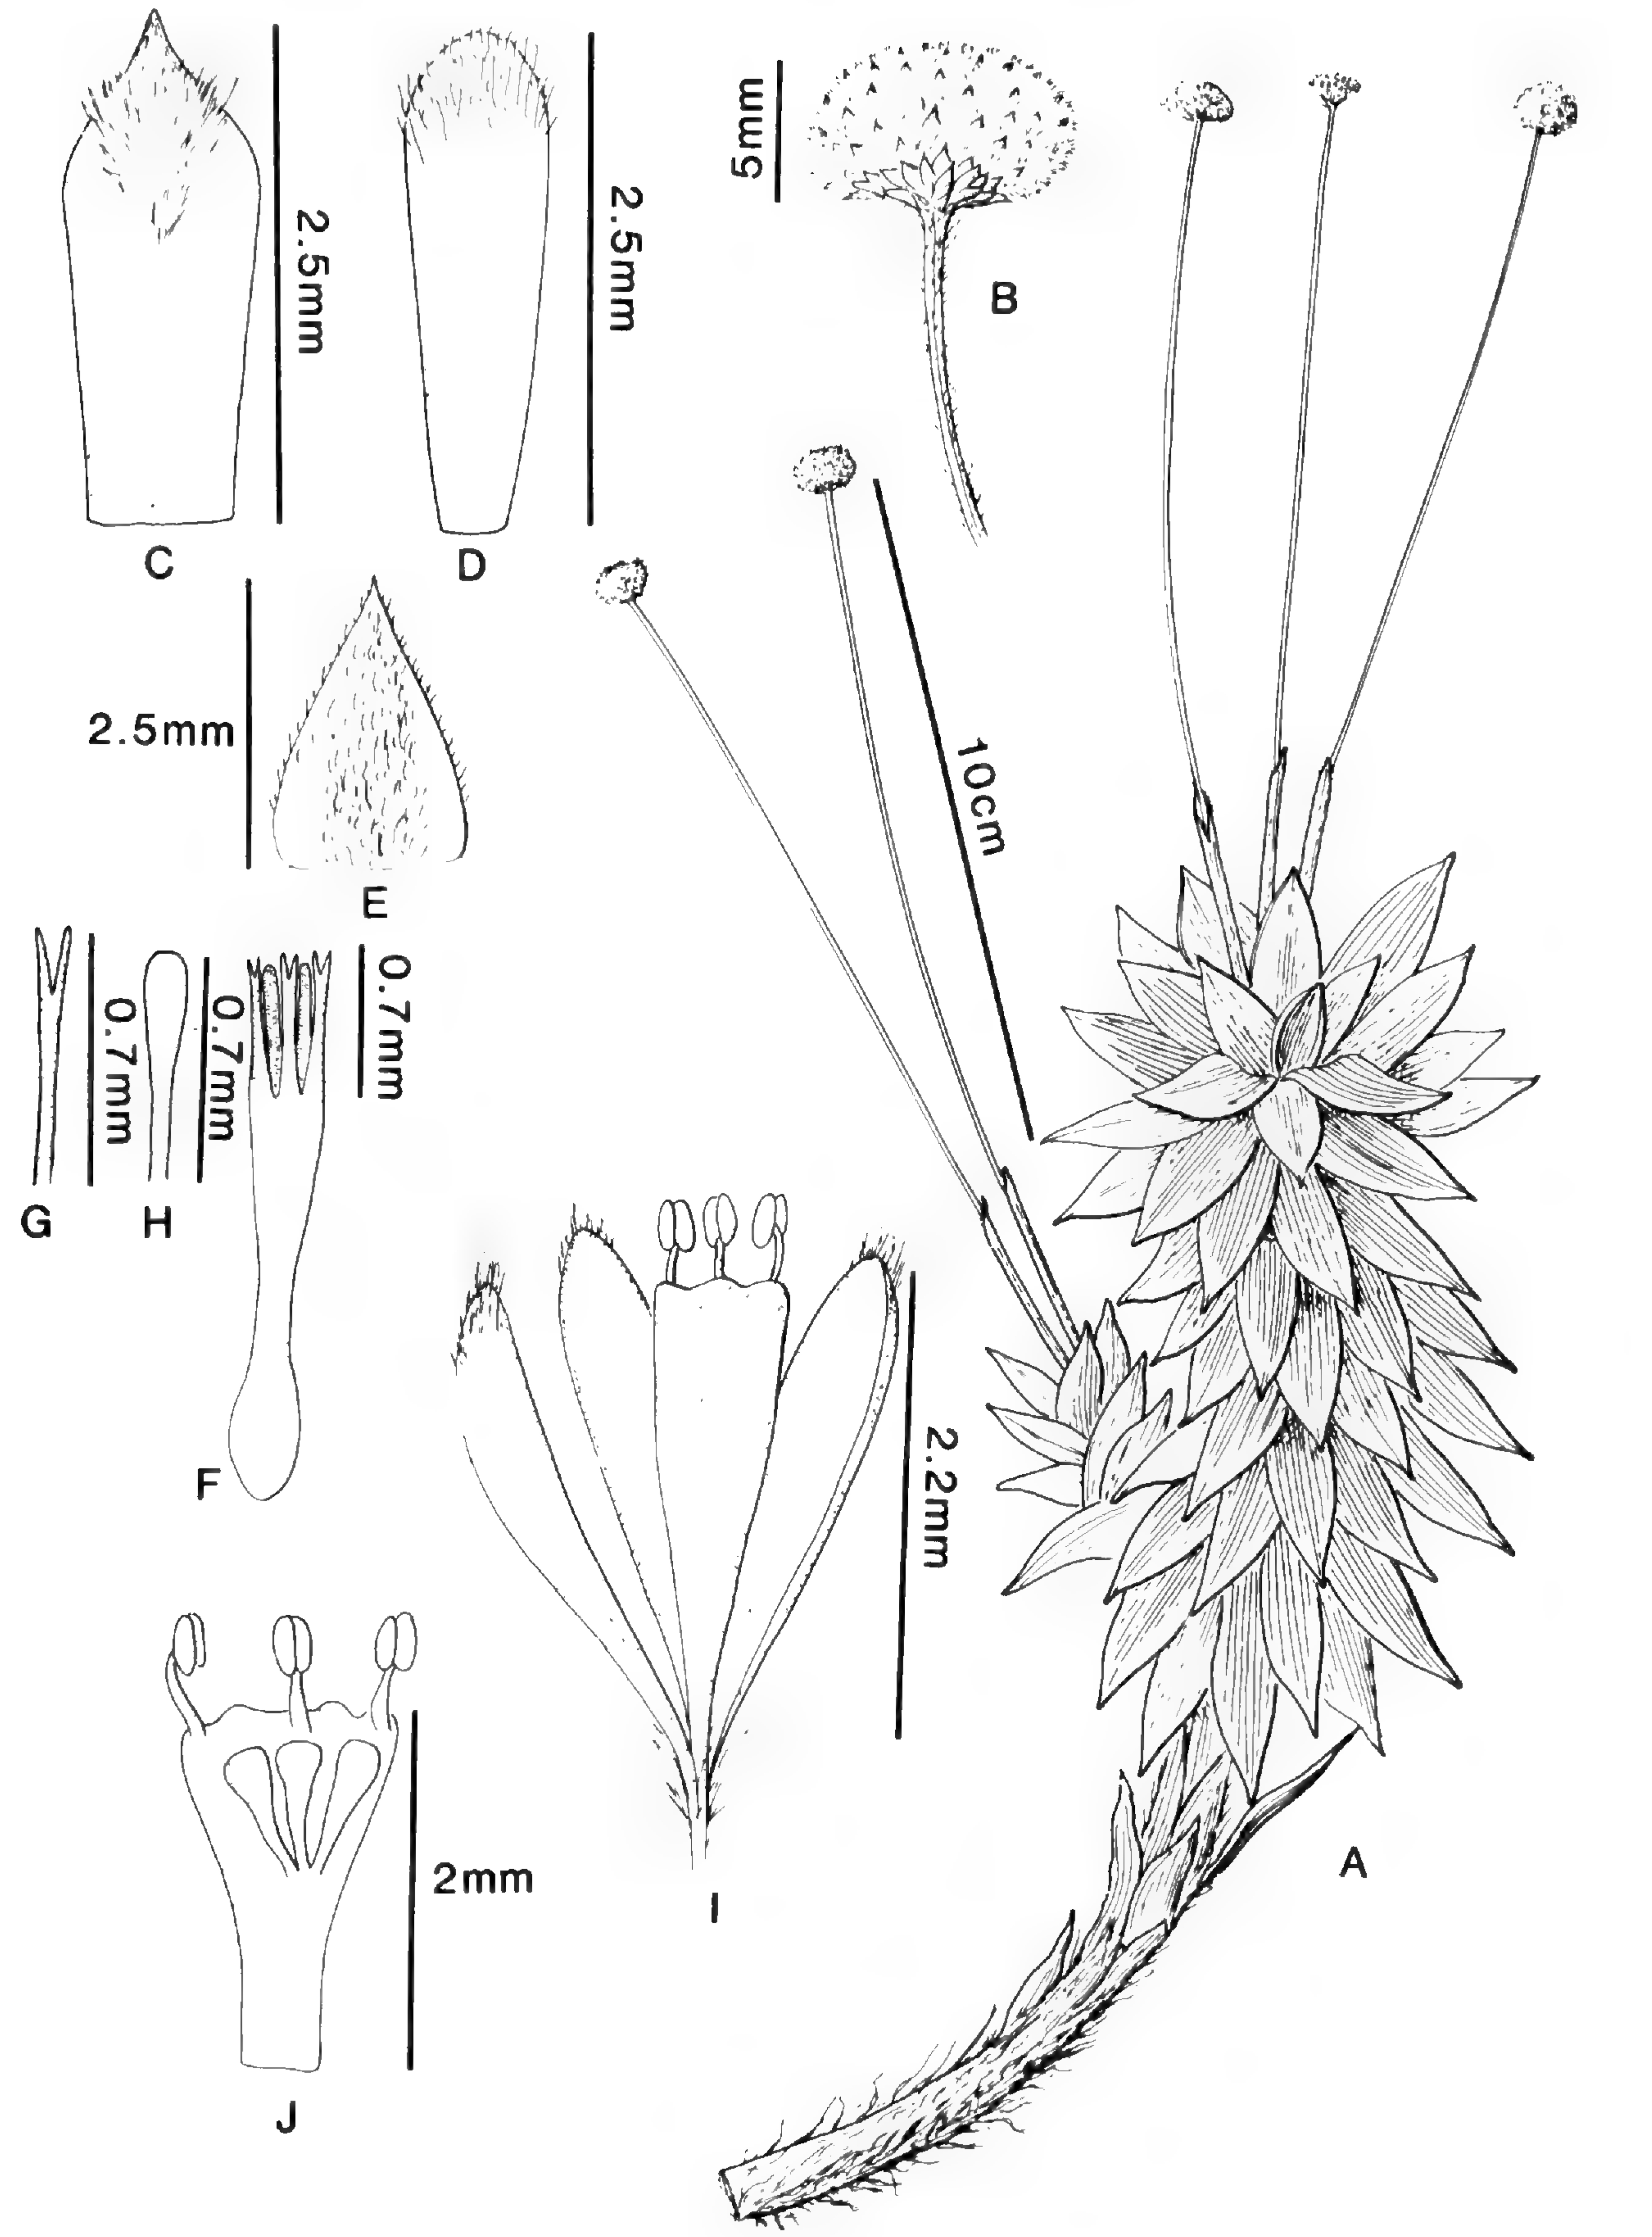

FIGURE 1. Paepalanthus holstii.—*A. Habit.—B. Inflorescence.—C. Receptacular bract.—D. Bractlet subtending pistillate flower.—E. Outer involucral bract.—F. Pistillate flower, corolla.—G. Outer segments of pistillate corolla.—H. Inner segments of pistillate corolla.—I. Staminate flower.—J. Interior of staminate corolla.*

abruptly ampliate above into a dark, acute apex, this densely pilose without, glabrous within, as is the rest of the bract, 2.5–2.7 mm long, 0.6–1 mm wide most of length.

Staminate florets: bractlet subtending flowers oblanceolate, obtuse, dorsally keeled, 2.5 mm long, 0.7 mm wide, densely villous without with erect villous hairs in apical portion, glabrous within. Staminate sepals separate, spathulate, rounded at apex, 2 mm long, 0.5 mm wide, densely villous within with long, erect hairs, glabrous on most of outer surface without except for long hairs around apex. Staminate corolla narrowly infundibuliform, gradually widened upward, 2.2 mm long, 0.7 mm wide above, 0.1 mm wide at base; stamens 3; anthers 0.2 mm long; filaments 0.2 mm long. Pistillate florets: corolla narrowly cylindric, 2.8 mm long, tubular, upper part 1.8 mm long, constricted to the ovary, 0.2 mm wide, outer segments linear, bifid at apex, 0.7 mm long, 0.1 mm wide, inner ones spathulate, truncate, 0.8 mm long.

This beautiful species with silvery foliage is well marked by its short, ovate-lanceolate leaves with a prolonged obtuse apex. From *Paepalanthus macrocaulon* Mold. var. *venamoensis* Mold. it differs in the densely sericeous median outer portion of the involucral bracts and shorter, silvery-sericeous upper surface of the younger leaves, while from *P. roraimensis* Mold. it is distinguished by the pubescent peduncle, involucral bracts pubescent throughout their median length outside, and the densely sericeous-silvery upper surface of the uppermost leaves.

It is a pleasure to name this species after Bruce K. Holst, who succeeded in collecting plants from the previously unexplored Murisipán-tepui and Aparamán-tepui.

RAPATEACEAE

RAPATEA

Rapatea chimantensis Steyermark, sp. nov. TYPE: Venezuela. Bolívar: Chimantá Massif, lower southwestern slopes of Chimantá-tepui (Torono-tepui), 1,000 m, 24 May 1953, *Julian A. Steyermark 75584* (holotype, VEN; isotypes, MO, NY). Figure 2.

Planta herbacea terrestris ca. 1-metralis; vaginis 22–25 cm longis late alatis, parte superiore 7 cm anguste alata utroque latere 2–3 mm lato, basim versus una latere 20–30 mm lato; laminis basi abrupte constrictis late lineari-ligulatis apice tenuiter acuminatis basi abrupte cordatis 1.3 mm longis, 9–11.5 cm latis supra valde plicatis nervis primariis 35–45 elevatis acutis papillato-puberulentibus, subtus cristis rotundatis 1–1.5 mm latis dense papillato-puberulentibus; costa valde conspicua basim versus 3–4 mm lata; pedunculo 43 cm longo infra apicem 20 mm lato alibi 6 mm lato parte suprema 15 cm anguste alato 1–2 mm lato; capitulo subreniformi subcompresso semisphaerico 7 cm lato; spiculis numerosis 17–18 mm longis brevipedicellatis; bracteis involucralibus duobus anguste lanceolatis longiacuminatis basi late expansis 25 cm longis in dimidio superiore 15–17 mm latis basi 70 mm latis; bracteolis vix gradatis apice abrupte apiculatis 18 mm longis.

Terrestrial herbaceous plant ca. 1 m tall; leaf sheaths 22–25 cm long, broadly winged, upper 7 cm narrowly winged 2–3 mm wide on each margin, the wing widening below to 20–30 mm wide on one side; leaf blades erect-ascending, subcoriaceous, dull green above, silvery green below, abruptly constricted at the base, broadly ligulate-linear, slenderly acuminate at the apex, abruptly cordate at the base, 1.3 mm long, 9–11.5 cm wide, conspicuously plicate on upper surface with 35–45 elevated acute nerves on either side of the midrib separated by broad depressions 1–2 mm wide, papillate-puberulent, the lower surface with 42–49 rounded, shallowly convex ridges 1–1.5 mm wide, densely papillate-puberulent; midrib 3–4 mm wide below. Peduncle 43 cm long, 6 mm wide except at the expanded summit where 20 mm wide, finely costate, narrowly winged 1–2 mm wide in the uppermost 15 cm. Flowering head subcompressed, subhemispheric, 7 cm wide. Involucral bracts narrowly lanceolate, slenderly acuminate at the apex, broadly expanded at base, 25 cm long, 15–17 mm wide in upper half, 70 mm wide at base, three times longer than wide. Bracteoles submembranous, scarcely or not graduate, lanceolate, 18 mm long, the outer ones 18 × 3 mm, about equaling the spikelets, abruptly acuminate-pungent at the 3-nerved apex, the apiculate portion 1–2 mm long; other bracteoles subequal, ligulate-lanceolate, 12–14 × 4 mm with a cusp 1 mm long. Spikelets numerous, shortly pedicellate, 17–18 mm long. Sepals lanceolate, cuspidate, 9 × 2.5–3 mm. Anthers linear, bilobed at base, the connective triangular-lanceolate, acuminate, 2 mm long, the thecae

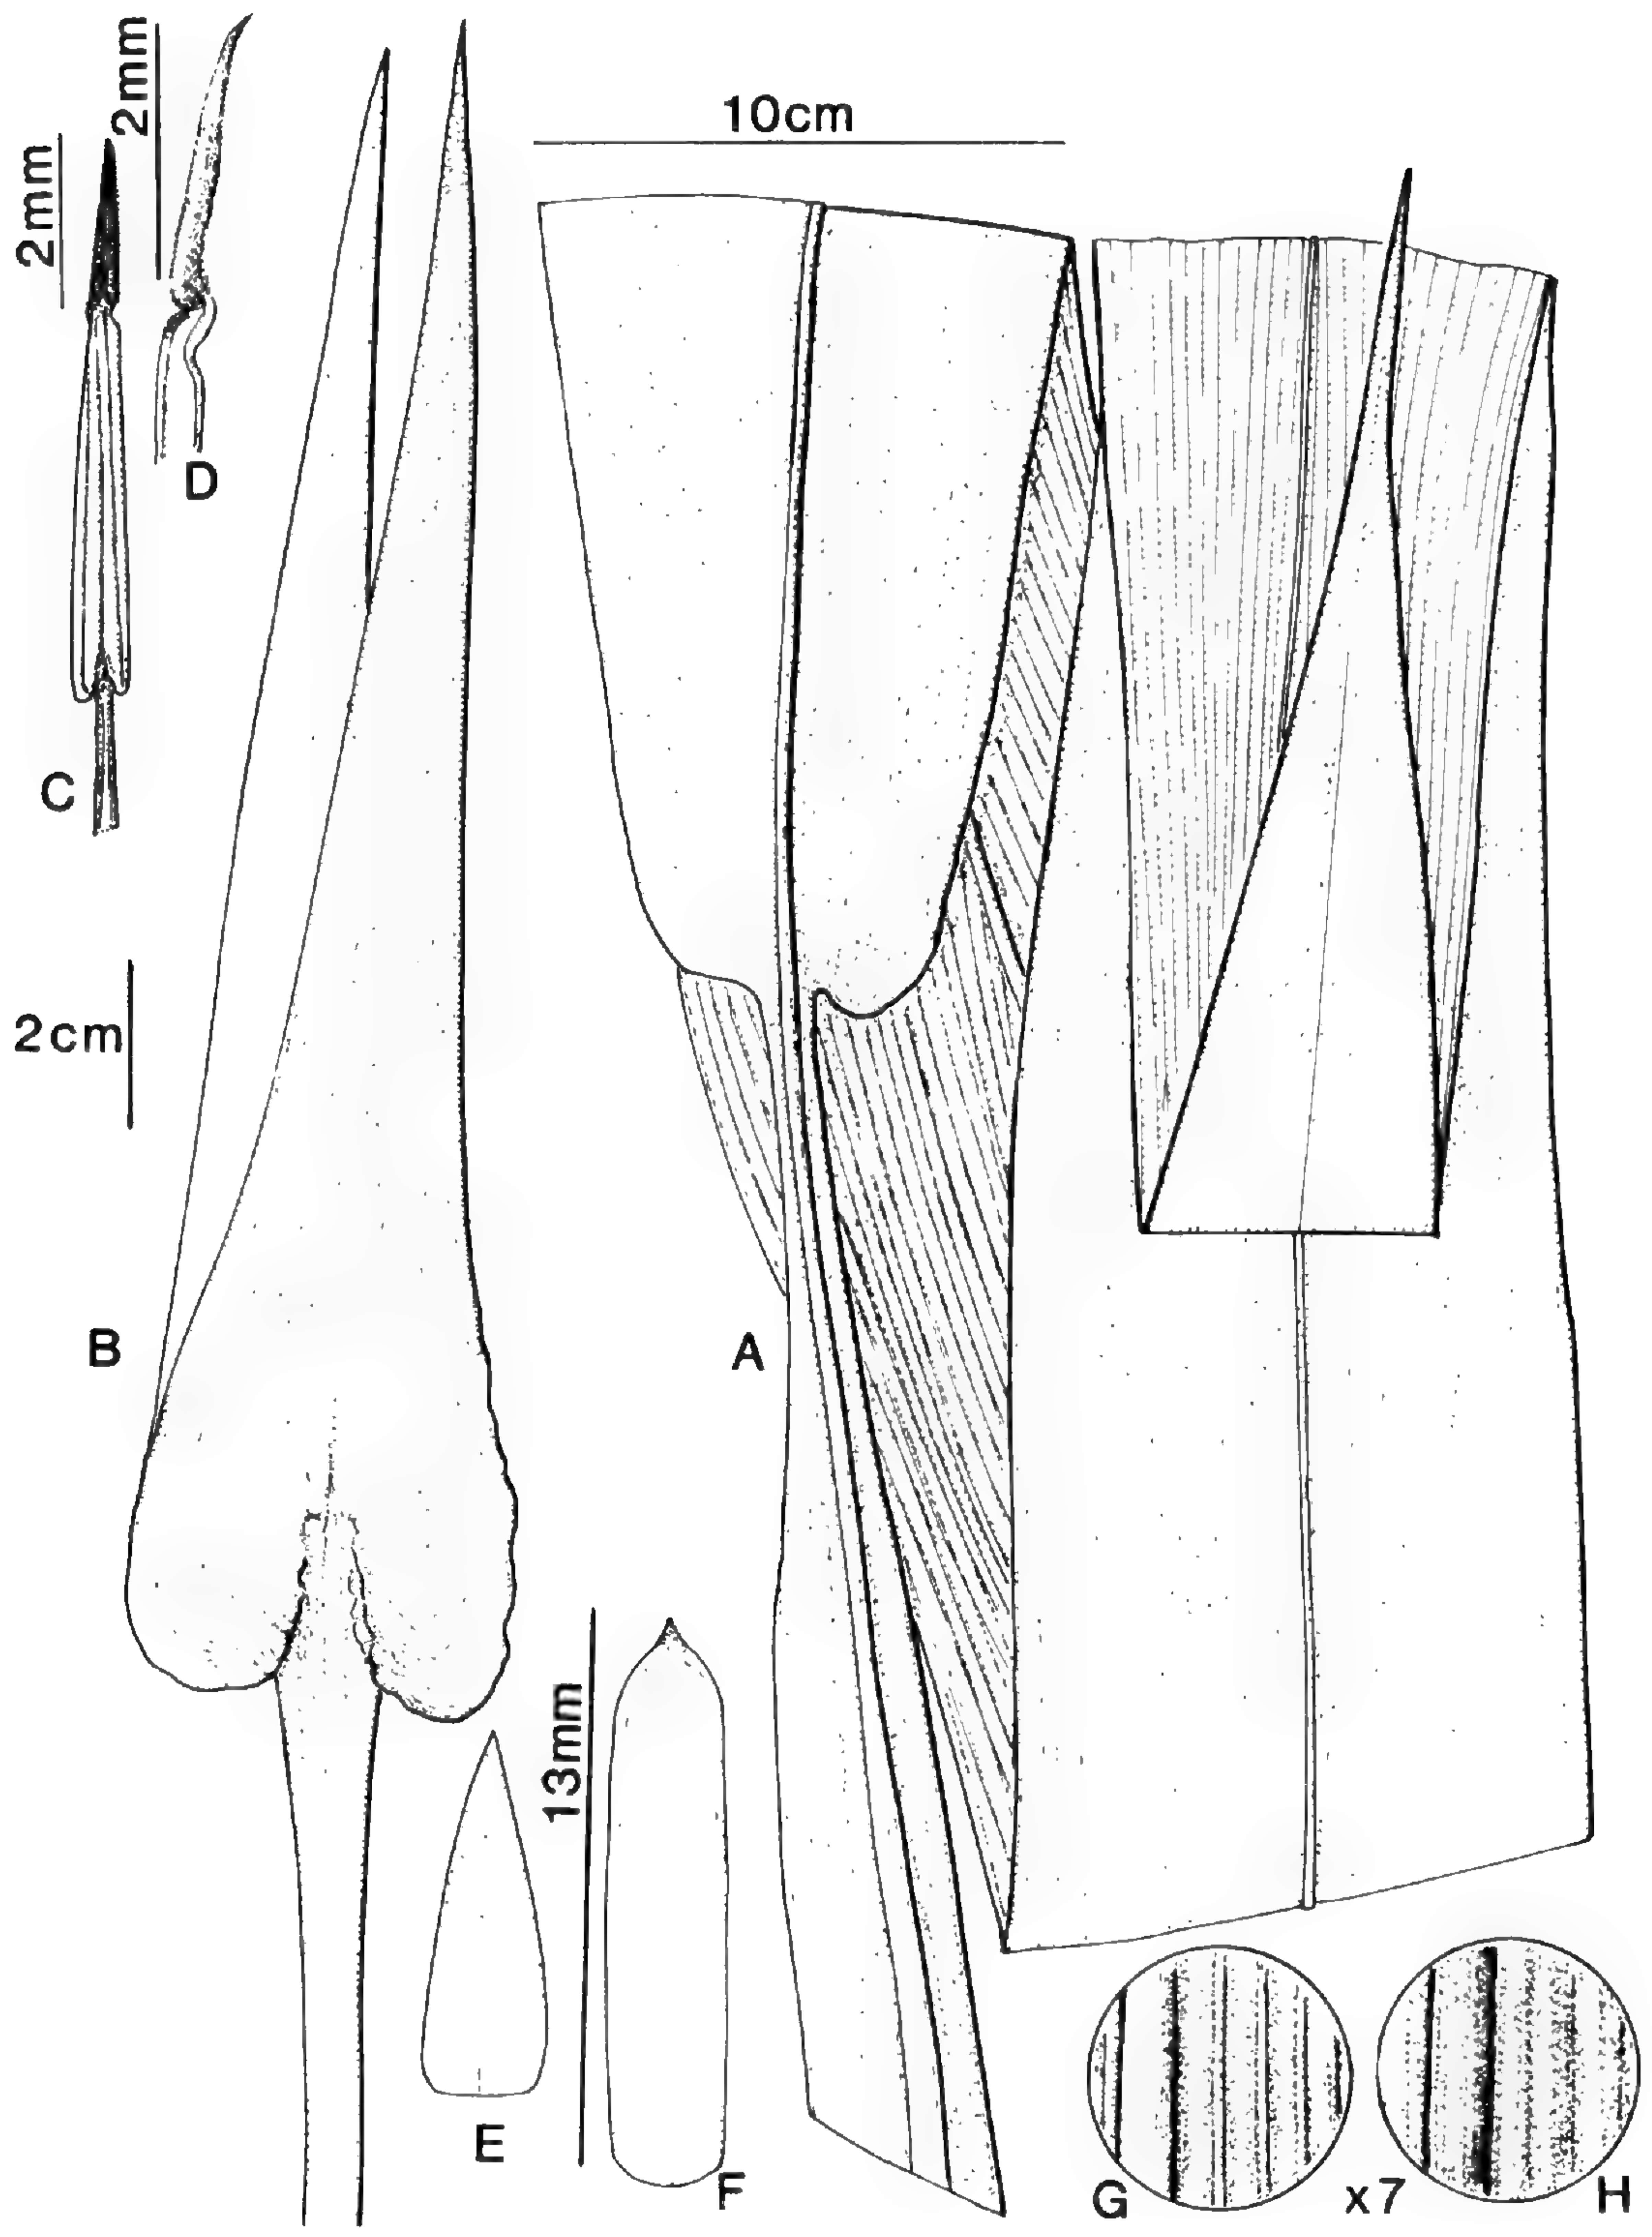

FIGURE 2. Rapatea chimantensis.—*A. Leaf blade and sheath.—B. Habit of cephalar bract with upper portion of peduncle.—C. Stamen, abaxial view.—D. Upper part of anther with connective, lateral view.—E. Sepal.—F. Outer bracteole.—G. Detail of upper leaf surface.—H. Detail of lower leaf surface.*

4.5–5 mm long, 0.7 mm wide toward the apex, 1 mm wide at base; filaments 2 mm long.

This taxon resembles *Rapatea fanshawei* Maguire but differs in having much longer involucral bracts which are more prominently narrowed above the base, longer, more narrowly winged peduncles, and outer bracteoles about equaling the spikelets. There are further differences in the leaf surfaces. In *R. fanshawei* the lower leaf surface has acutely elevated lines of nerves, whereas those of *R. chimantensis* have the nerves shallowly convex with rounded ridges. Moreover, the upper leaf surface of *R. chimantensis* has nerves more strongly elevated and more widely spaced than those in *R. fanshawei*. The leaf blades are longer and wider in *R. chimantensis*. Although related to *R. fanshawei*, the relatively equal length of the bractlets would ally the new taxon to *R. steyermarkii* Maguire.

STEGOLEPIS

Stegolepis minor Steyermark, sp. nov. TYPE: Venezuela. Bolívar: Sierra de Lema, cabeceras del Río Chicanán, 80 km (en linea recta) al suroeste de El Dorado, 6°5′N, 62°W, 500 m, on banks and bluffs at base of uppermost waterfall of headwaters of Río Chicanán at base of high NE-facing sandstone bluffs, 28 Aug. 1961, *Julian A. Steyermark 89577* (holotype, VEN; isotype, NY).

Herbae perennes 0.5–0.6-metralis; vaginis subinduratis valde nervatis 14–25 cm longis 7 cm latis, valde scarioso-marginatis auriculus rotundatis; laminis ubique viridibus late linearibus apice subfalcate acutis 60 cm longis 6.5 cm latis tenuiter nervatis, costa subtus supra elevato; pedunculo apice subcompresso 1.5–2.5 mm lato sub apice 2.5–4 mm dilatato; capitulis compressis 13–14-floris 1.5 cm altis 2.3–3 cm latis; spiculis 13–14, lanceolato-ellipticis, sepalis inclusis 11–12 mm longis 3–5 mm latis; bracteolis castaneis subfructu laxe patentibus inferioribus late triangularibus acutis vel acuminatis carinatis 2–3.5 mm longis 1.5–2.5 mm latis medianis superioribusque lineari-lanceolatis acuminatis ecarinatis 5–8 mm longis 1.5–2.5 mm latis; sepalis sub fructu erectis haud deflexis anguste lanceolatis acutis 9–10 mm longis 2.5 mm latis.

Perennial herbs 0.5–0.6 m tall. Leaf sheaths subindurated, strongly nerved, 14–25 cm long, 7 cm wide, the margins broadly scarious, the auricles rounded. Leaf blades deep green both sides, broadly linear, subfalcately acute at apex, 60 cm long, 6.5 cm wide, finely nerved; midrib elevated above. Peduncle 0.5–0.6 mm long, subcompressed, 1.5–2.5 mm wide, 2.5–4 mm wide below the dilated apex. Heads compressed, 13–14-flowered, 1.5 cm high, 2.3–3 cm broad. Spikelets 13–14, lance-elliptic, 11–12 mm long including the sepals, 3–5 mm wide. Bracteoles castaneous-brown, spreading loosely in fruit, the lower ones broadly triangular, acute to acuminate, carinate, 2–3.5 mm long, 1.5–2.5 mm wide, the middle and upper bracteoles linear-lanceolate, acuminate, ecarinate, 5–8 mm long, 1.5–2.5 mm wide. Fruiting sepals erect, not deflexed, narrowly lanceolate, acute, 9–10 mm long, 2.5 mm wide.

The type specimen was previously identified by Maguire as "probably *Stegolepis ferruginea*." That taxon and the related *S. steyermarkii* Maguire, however, have essentially globose, noncompressed heads. *Stegolepis minor* is related to *S. ptaritepuiensis* Steyerm. and *S. celiae* Maguire. From *S. ptaritepuiensis* the new taxon differs in having much smaller heads and spikelets, and much broader leaves with a conspicuous elevated midrib on the upper surface. It is distinguished from *S. celiae* by the smaller heads with fewer, shorter spikelets, slenderer peduncles, conspicuous upper midrib, and conspicuously nerved, subindurate leaf sheath.

RUTACEAE

RAUIA

Rauia subtruncata Steyermark, sp. nov. TYPE: Venezuela. Bolívar: 20–25 km SW of Manteco, on road to San Pedro de las Dos Bocas, 7°10′N, 62°55′W, 200 m, 1–3 Aug. 1978, *Ronald Liesner & Angel González 5991* (holotype, VEN; isotype, MO). Figure 3.

Arbor 6-metralis, foliorum laminis elliptico-ovatis vel oblongo-ellipticis abrupte longiacuminatis 10.5–23 cm longis 4–9.5 cm latis, nervis lateralibus utroque latere 9–10 subtus elevatis supra sulcatis, venulis tertiariis supra inconspicuis; calyce campanulato 4.5 mm longo summo 3 mm lato basi 1.8 mm lato truncato; corolla alba cylindrica 18 mm longa, tubo 8–9 mm longo basi 2 mm lato extus dense brevistrigilloso sub anthesi sine glandulis negris, lobis 7–8 mm longis 1–1.5 mm latis; staminodiis tribus subulatis 9 mm longis; antherae fertilis connectivo late lanceolato attenuato 1.5 mm longo 0.4 mm lato minute pulverulento.

Tree 6 m tall; stems glabrous or with sparingly evanescent, minutely appressed, scattered pubescence. Leaves alternate or rarely opposite, 1-foliolate; leaf blades elliptic-ovate or oblong-elliptic, abruptly long-acuminate, the acumen 2 cm long, acute at base with 2 thickened glands at junction with petiole, 10.5–23 cm long, 4–9.5 cm wide, glabrous both sides; lateral nerves 9–10 each side, ascending at a 45° angle, elevated below, inconspicuous and slightly impressed above; tertiary venation conspicuous below, reticulate and slightly elevated, above slightly less manifest. Inflorescences terminal, corymbose-paniculate, many-flowered, 4–7.5 cm long, 4–8.5 cm wide, long pedunculate, with

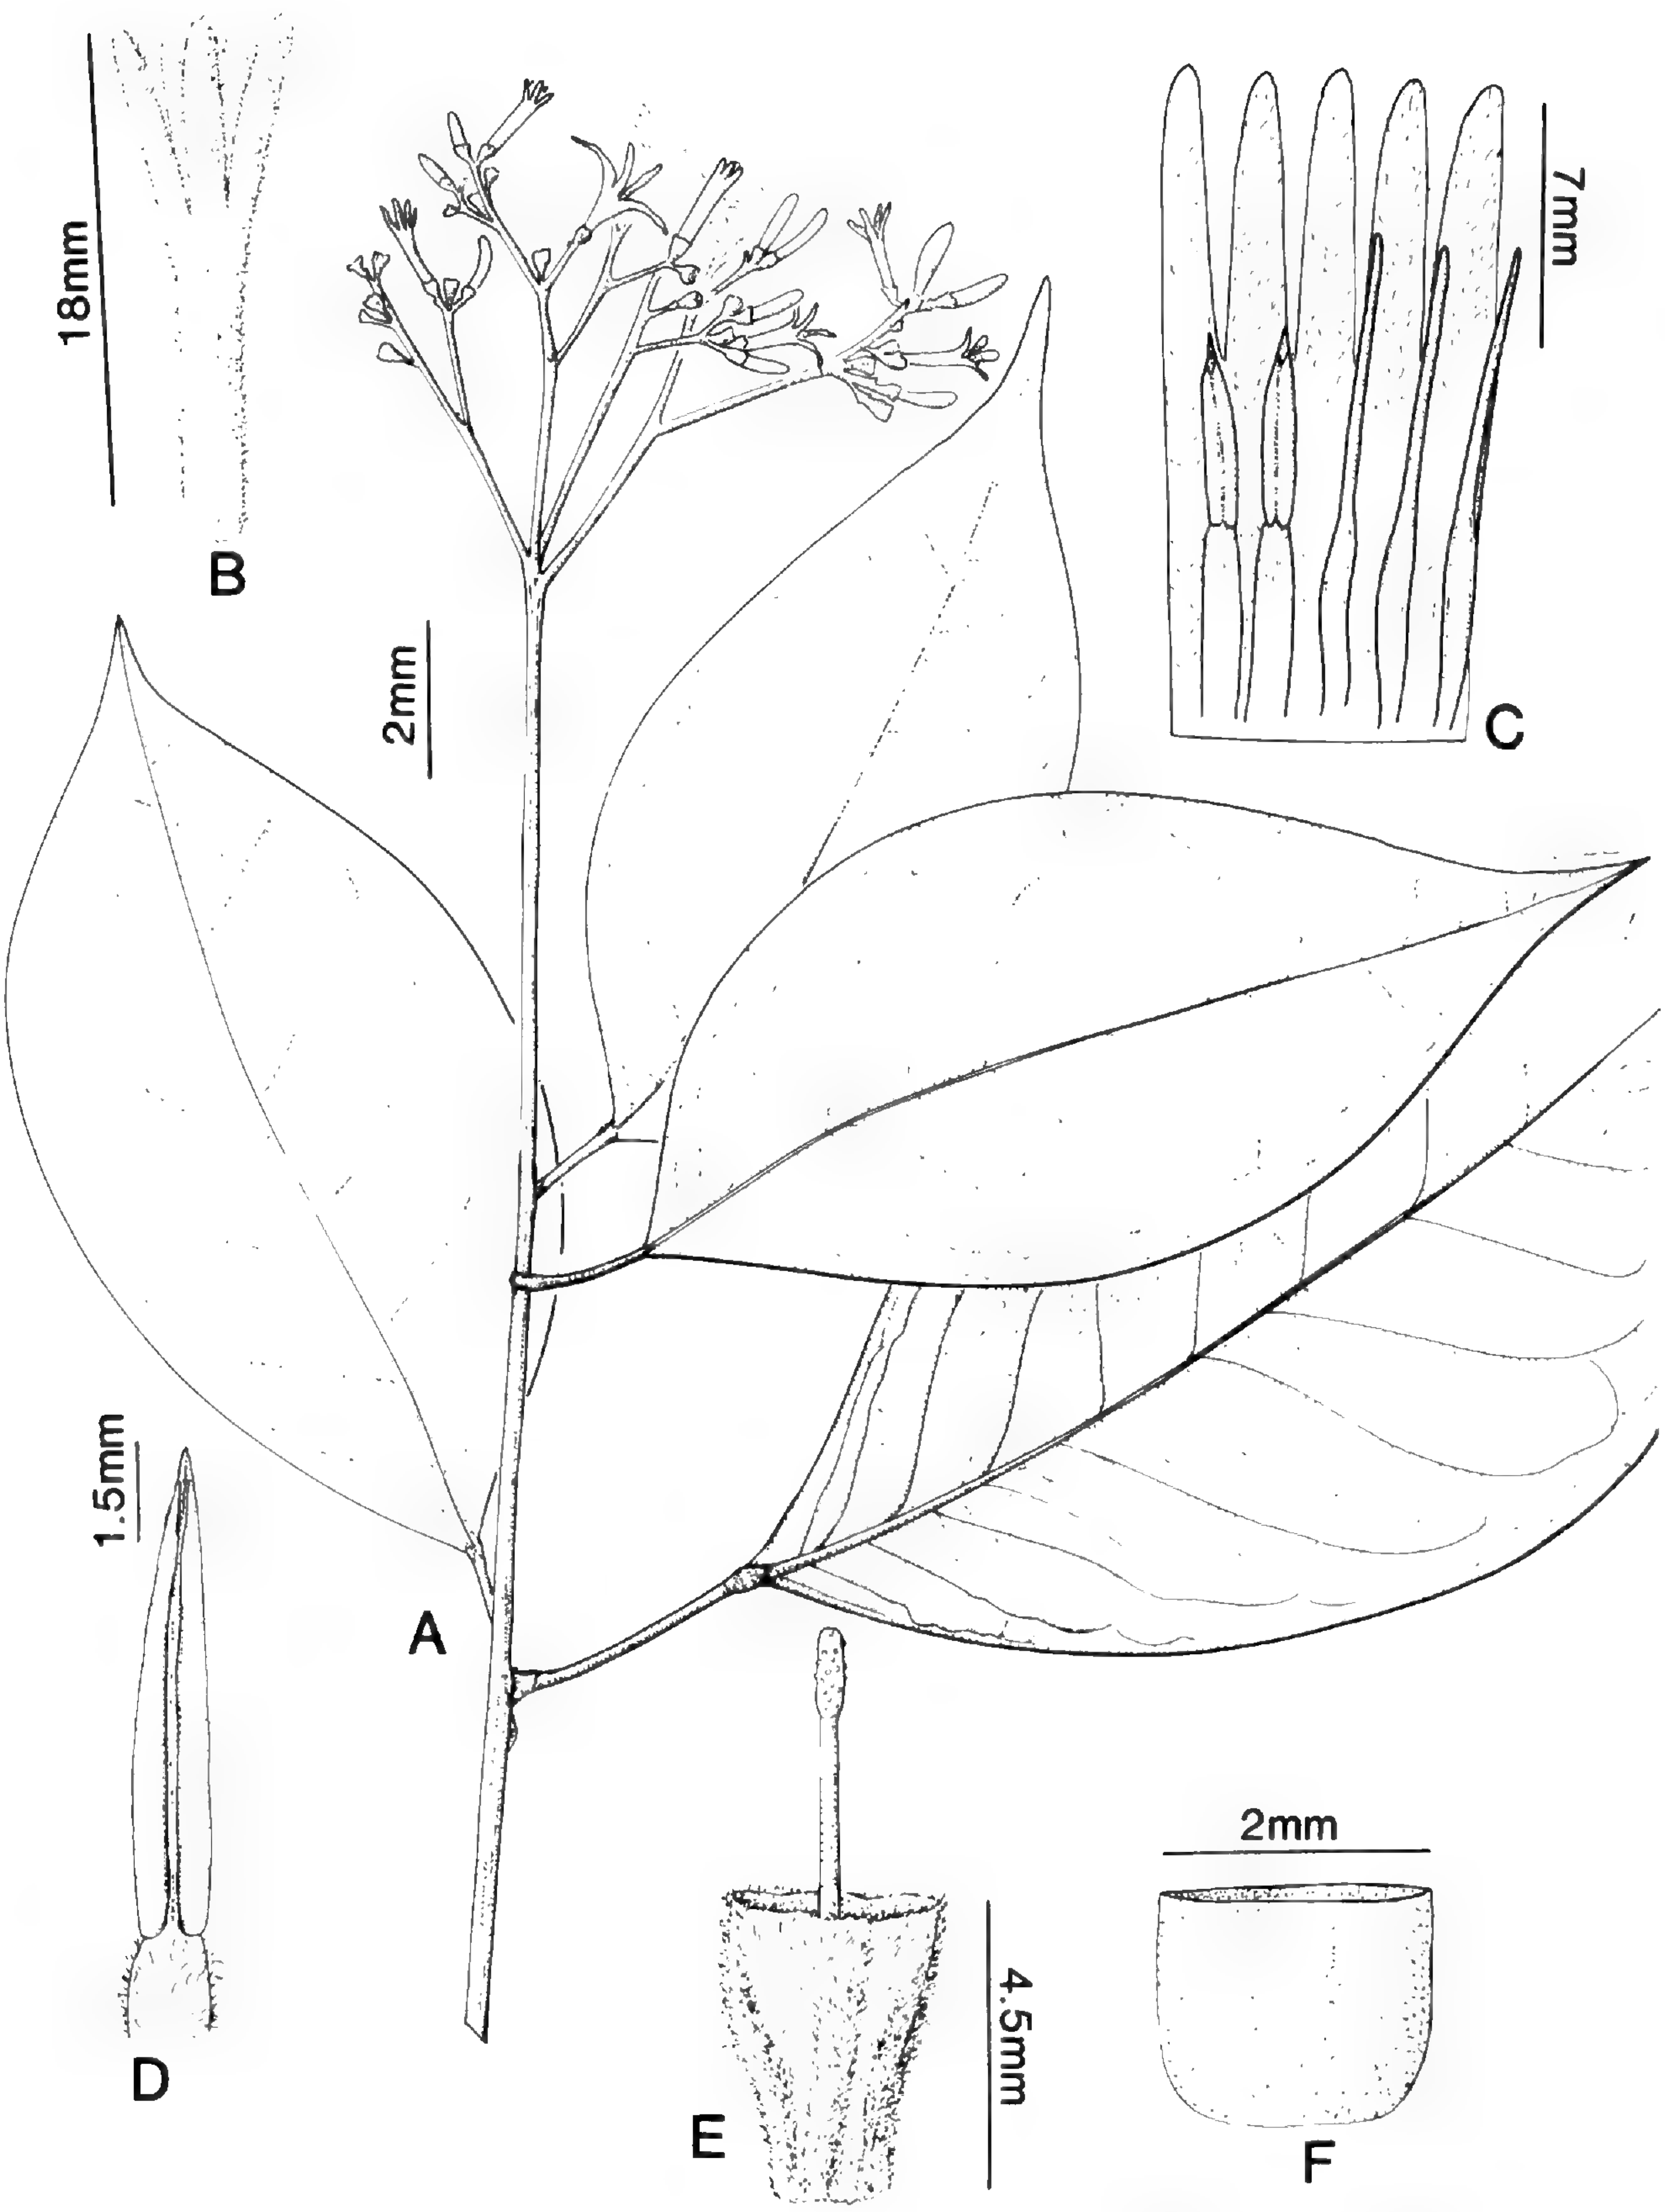

FIGURE 3. Rauia subtruncata.—*A. Habit of flowering branch.—B. Corolla, before anthesis.—C. Interior of corolla, showing two fertile anthers and three staminodia.—D. Anther with upper portion of filament.—E. Calyx.—F. Disk.*

2–4 unequal, main dichasially branched axes; each dichasium cymosely flowered; peduncle elongated, 7–11 cm long, 2–3 mm diam., glabrous to shortly appressed-pubescent below the axes of the inflorescence; each main axis 1.5–4 cm long in unbranched portion, 1–1.5 mm wide, longitudinally striate, densely appressed-pubescent with buff hairs; calyx thick textured, obtusely 5-angulate, campanulate, 4–5 mm long, 3 mm wide at summit where subtruncate or barely subundulately toothed, constricted 1.5 mm above base, 1.8 mm wide at base, densely appressed without with congested buff pubescence, glabrous within, with scattered black, resinous glands; corolla white, cylindric, 18 mm long, 2 mm wide at base, densely short-strigillose without, in anthesis lacking black resinous glands, the tube 8–9 mm long, densely pilosulous within for 4 mm between the filaments and staminodia, glabrous in the basal 2 mm; lobes 5, thickish, linear-ligulate, subobtuse, 7–8 mm long, 1–1.5 mm wide, minutely pilosulous within; fertile anthers 2, curved, 4.8 mm long, 0.6–0.7 mm wide including the connective; connective lanceolate, attenuate, 1.5 mm long, 0.4 mm wide; filaments united to the tube 4 mm above its base, free for 1–2 mm, glabrous in lowest 3 mm, densely pubescent in upper half; staminodia 3, subulate, free for 9 mm, attached to tube 6 mm from base, pilosulous but glabrous in uppermost 4 mm, glabrous ventrally, pilosulous dorsally; disk cupular, 1.8 mm long, 2 mm wide, slightly undulate at the truncate summit; ovary 1.2 mm high, 1.5 mm broad, glabrous.

This species differs from *Rauia resinosa* Nees & C. Martius in having a longer, broader calyx which is subtruncate at the summit, longer and broader corolla lobes and corolla tube, three instead of five staminodia, lance-attenuate prolonged connective of the fertile anthers, proportionately broader leaf blades, less elevated lateral nerves on the lower surface and less sulcate on the upper surface, and more evident tertiary venation of the upper surface.

RAVENIOPSIS

Raveniopsis liesneri Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Depto. Río Negro, Cerro de la Neblina, Camp 4, 15 km NNE of Pico Phelps, N branch of river in canyon, 0°51′N, 65°57′W, 780 m, 15–18 Nov. 1984, *Ronald Liesner 16605* (holotype, MO; isotype, VEN). Figure 4.

Caules stellato-pubescentes, foliis trifoliatis; calycis lobis ovato-oblongis apice late rotundatis 2–3 mm longis 1–1.5 mm latis stellato-pubescentibus; corolla cylindrico-infundibuliformi 17–19 mm longa summo 4.5–5 mm lata basi 2–2.5 mm lata stellato-pubescenti; staminodiis tribus subulatis 1.8 mm longis 0.1 mm latis inaequalibus; stylo 8–12 mm longo glabro.

Shrub 1 m tall, stems stellate-pubescent with the branched stellate hairs closely aggregated in the lower part of the main axis. Leaves trifoliate, the terminal leaflet the largest, symmetric, subacute to obtuse at apex, 2.5–6.5(–8) cm long, 1.2–2.5 cm wide, glabrous above except for the stellate midrib and lateral nerves, densely white stellate beneath, the pubescence concealing the surface; lateral nerves sulcate above, slightly elevated below, 7–9 each side, ending at the margins; petiolule of terminal leaflet 5–15 mm long, stellate; lateral leaflets mainly asymmetric, oblique at base, oblanceolate to oblong, subacute to obtuse at apex, 2.5–5.5 cm long, 1–2 cm wide, the lower side rounded at base, the upper side acute; lateral nerves 5–7 each side; petiolule of lateral leaflets 1–3 mm long or subsessile; petiole 0.5–3 cm long, densely stellate-pubescent. Inflorescence axillary or terminal, dichasial, the axes unilaterally racemose, 1.5–6 cm long, densely stellate-pubescent; peduncle 4–4.5 cm long, densely stellate-pubescent; terminal flower present or absent at apex of peduncle. Calyx 5 mm long, the tube 3 mm long, 1.5 mm wide at base, 3.5 mm wide at junction with calyx lobes; calyx lobes 5, slightly unequal, ovate-oblong, broadly rounded at apex, 2–3 mm long, 1–1.5 mm wide, the larger lobe 1.5 mm wide, the others 1 mm wide. Corolla straight or nearly so, or very slightly curved in bud, cylindric-infundibuliform, 17–19 mm long, 2–2.5 mm wide at base, 4.5–5 mm wide at summit, stellate-pubescent externally, within minutely pubescent in lines in the lower ⅓ below the staminodia; longer corolla lobes ovate-oblong, rounded at apex, 3.5–4 mm long, 2–2.5 mm wide; 3 shorter lobes ovate-oblong, rounded at apex, 2 mm long, 1.2 mm wide; 3 staminodia subulate, 1.8 mm long, 0.1 mm wide, one of them shorter than the other two. Fertile anther narrowly oblong,

minutely mucronate at apex, 2.5 mm long, glabrous; basal appendages suborbicular, rounded, venose, 1 mm long, 1 mm wide. Style 8–12 mm long, glabrous; ovary pilose; disk cupular, 0.75 mm high, 1.5 mm diam.

This species is related to *Raveniopsis stelligera* Cowan of Cerro Duida and Yutajé. It differs in the small corollas, more narrowly oblong, rounded calyx lobes, shorter staminodia, and shorter style. Five species and one variety of the genus are now recorded from Cerro de la Neblina.

LINACEAE

OCHTHOCOSMUS

Ochthocosmus micranthus Steyermark, sp. nov. TYPE: Venezuela. Bolívar: Ayavaparú, 10 km southwest of Wadacapiap, 5°18′N, 60°58′W, 1,100 m, 13 Nov. 1986, *Lionel Hernández 348* (holotype, MO; isotype, VEN). Figure 5.

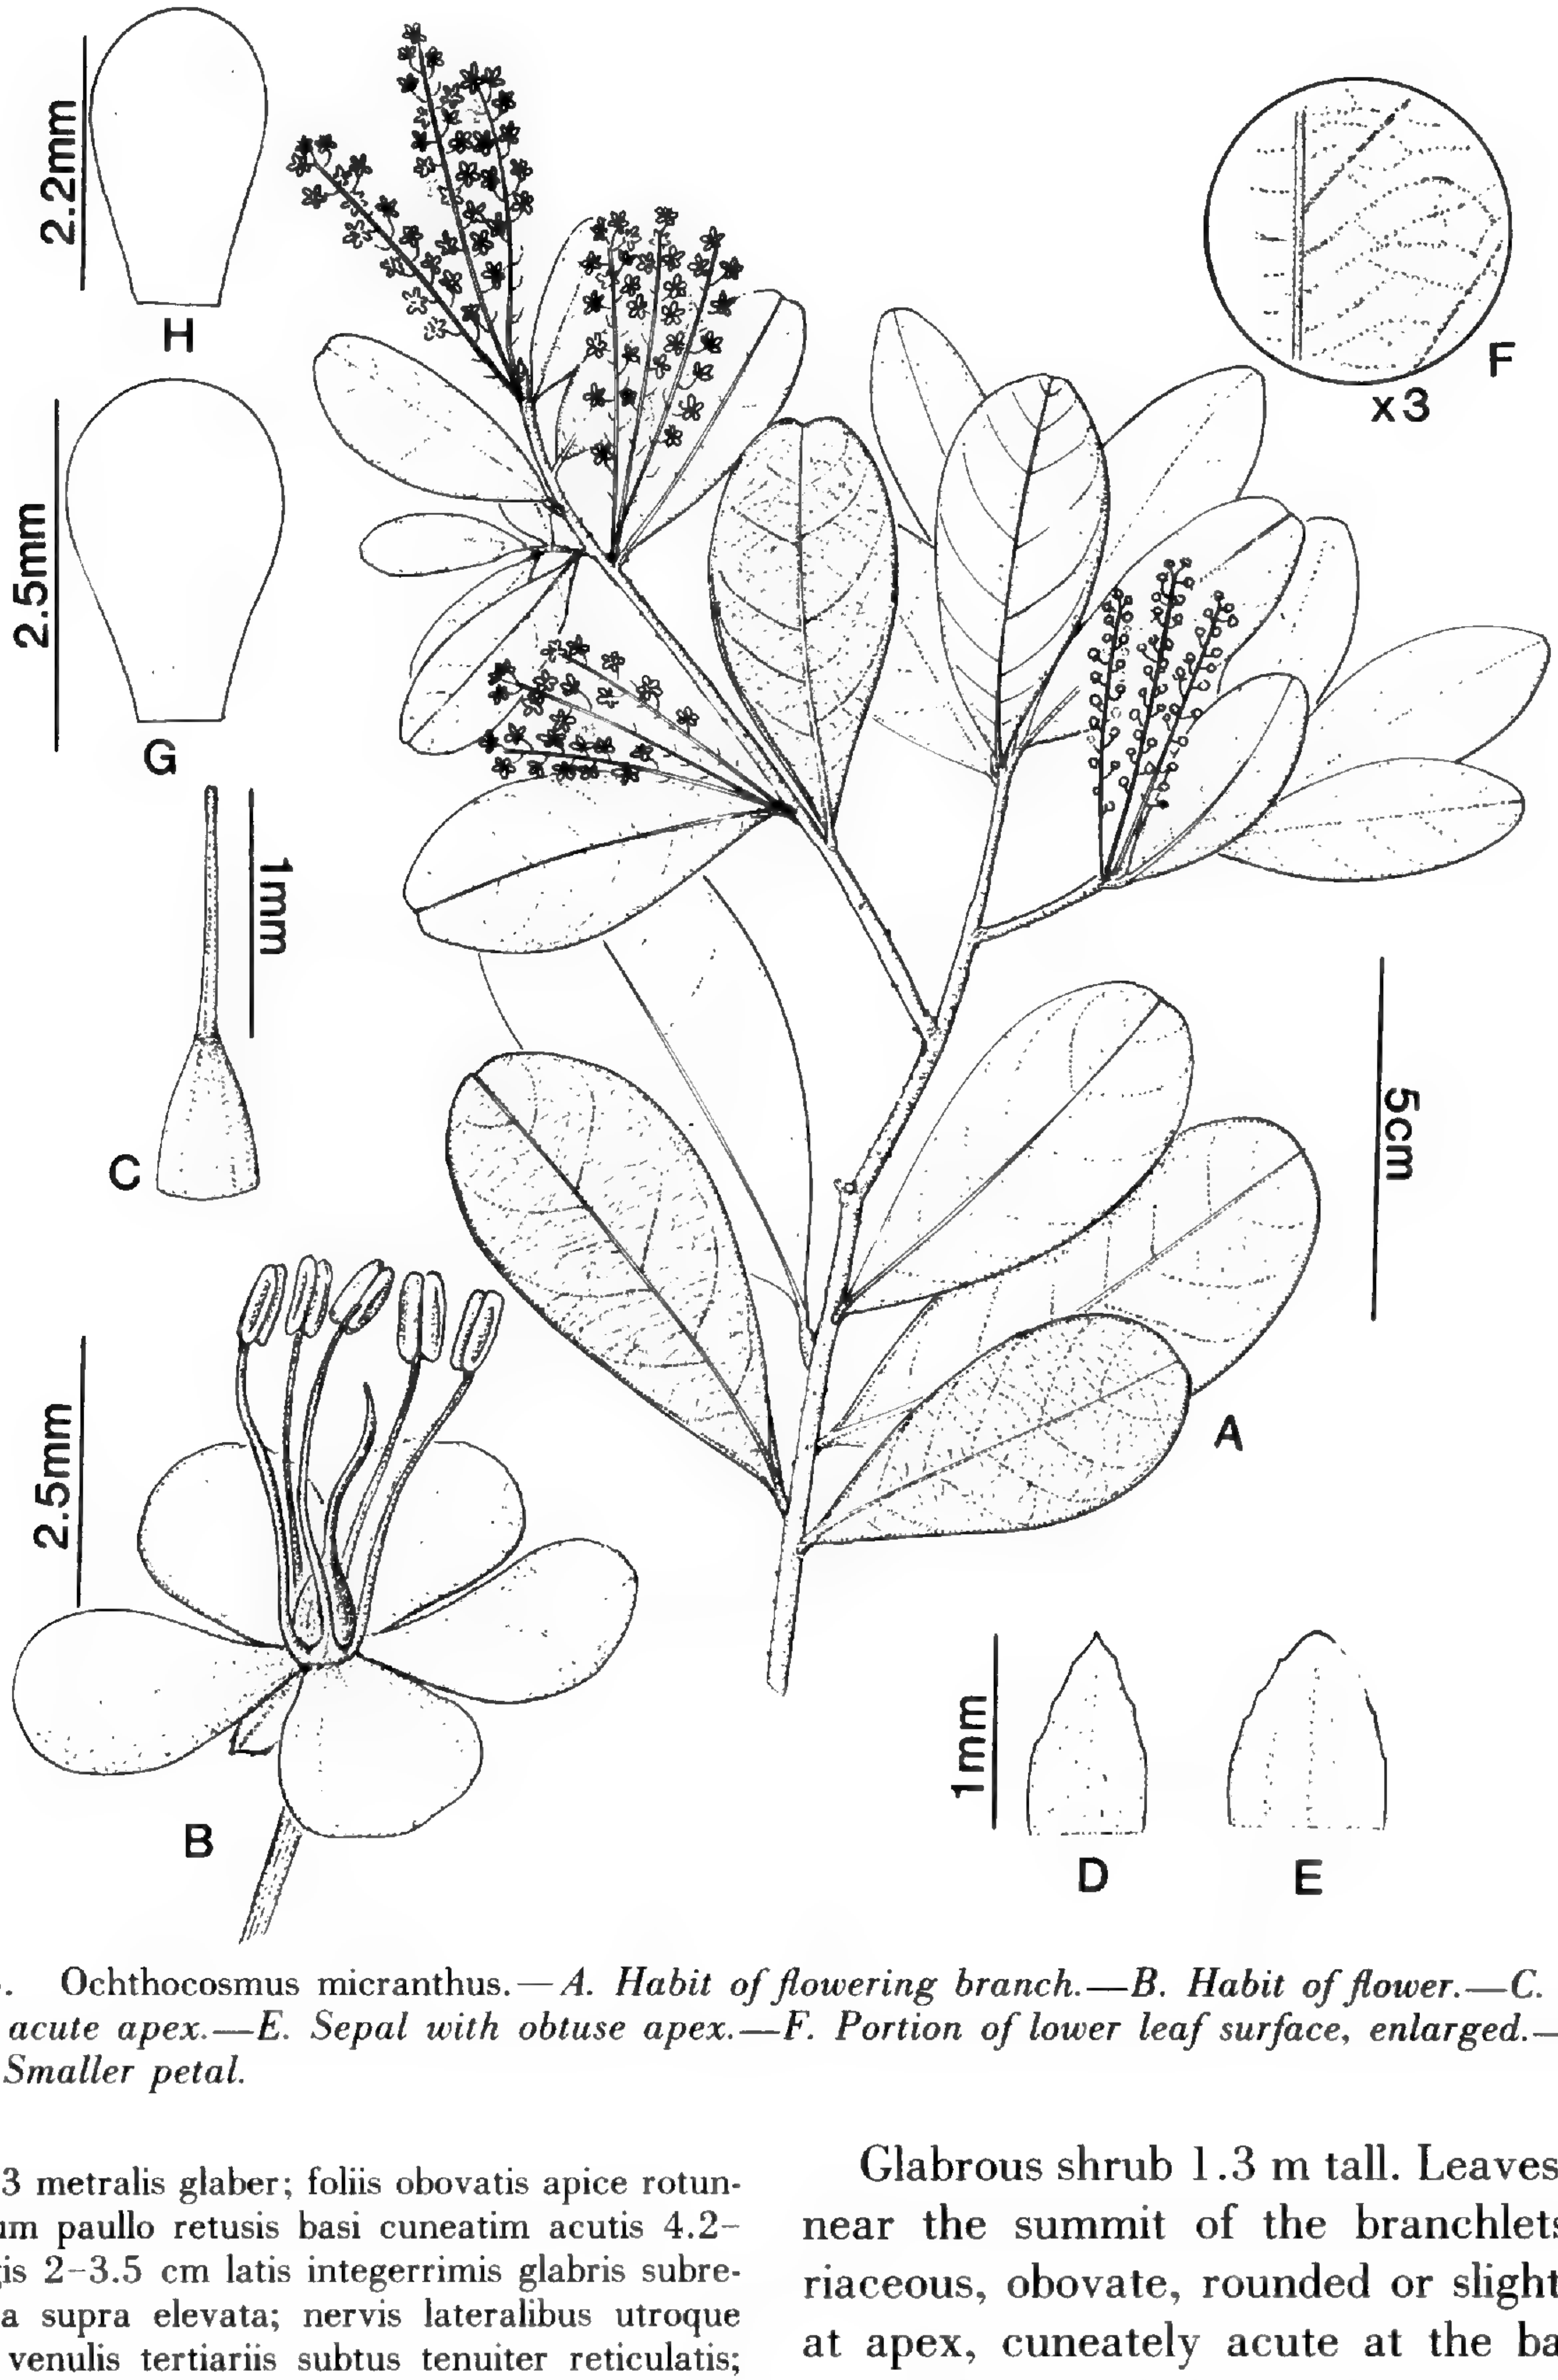

FIGURE 5. Ochthocosmus micranthus.—*A. Habit of flowering branch.—B. Habit of flower.—C. Pistil.—D. Sepal with acute apex.—E. Sepal with obtuse apex.—F. Portion of lower leaf surface, enlarged.—G. Larger petal.—H. Smaller petal.*

Frutex 1.3 metralis glaber; foliis obovatis apice rotundatis interdum paullo retusis basi cuneatim acutis 4.2–7.5 cm longis 2–3.5 cm latis integerrimis glabris subrevolutis; costa supra elevata; nervis lateralibus utroque latere 4–8; venulis tertiariis subtus tenuiter reticulatis; petiolis 2–5 mm longis; inflorescentia fasciculatis axillaribus racemosis 3.5–5.5 cm longis 7–9 mm latis; pedicellis filiformibus 3–3.5 mm longis; bracteis sub pedicellis lanceolato-subulatis vel lanceolatis 1 mm longis apice appendice fuscata praeditis deciduis; floribus parvis, sepalis quinque parum inaequalibus oblongo-ovatis apice subobtusis raro subacutis 1–1.5 mm longis 0.7 mm latis plerumque integris praeter aliquot apicem versus 1–2 prominentibus; petalis leviter inaequalibus majoribus late obovatis rotundatis 2.5 × 1.7 mm, minoribus oblongo-obovatis rotundatis 2.2 × 1.3 mm; antheris oblongis 0.8 mm longis, filamentis 3 mm longis; ovario ovoideo-conico 0.7 × 0.7 mm, stylo 1 mm longo.

Glabrous shrub 1.3 m tall. Leaves crowded near the summit of the branchlets, subcoriaceous, obovate, rounded or slightly retuse at apex, cuneately acute at the base, 4.2–7.5 cm long, 2–3.5 cm wide, entire, glabrous, subrevolute; midnerve elevated above and below; lateral nerves 4–8 each side, arcuate-ascending at a 30–45° angle, anastomosing near the margins, impressed above, slightly elevated below; tertiary venation finely reticulate and elevated below, impressed above. Inflorescence fasciculate, axillary in the upper leaf axils with usually 3 peduncles, racemose, 3.5–5.5 cm long, 7–9 mm wide; pedicels filiform, 3–3.5 mm long. Bracts subtending pedicels lance-subulate or lanceolate, 1 mm long with a darkened attenuate apical projection. Flowers small for the genus. Sepals 5, slightly unequal, hyaline, oblong-ovate, subobtuse or one of them sometimes acute or subacute at the apex, 1–1.5 mm long, 0.7 mm wide, mainly entire, but with one or two of them with minute projections toward the apex. Petals slightly unequal, the larger broadly obovate and rounded at apex, 2.5 × 1.7 mm, the smaller ones oblong-obovate, rounded, 2.2 × 1.3 mm. Stamens 5; anthers oblong, 0.8 × 0.3 mm; filaments 3 mm long. Ovary ovoid-conic, 0.7 × 0.7 mm, style erect for 1 mm, then spreading upwardly 0.5–0.8 mm long. Fruit not seen.

Paratype. VENEZUELA. BOLÍVAR: same locality as type, 15 Nov. 1986, *Hernández 359* (VEN).

This species is distinguished from the other known members of the genus by its smaller petals and sepals. The entire leaves with non-thickened, eglandular margins of the sepals are additional distinguishing characters. In the key to species previously published (Steyermark & Luteyn, 1980), *Ochthocosmus micranthus* would fall into the group including *O. multiflorus* and *O. longipedicellatus*.

LITERATURE CITED

STEYERMARK, J. & J. LUTEYN. 1980. Revision of the genus *Ochthocosmus* (Linaceae). Brittonia 32(2): 128–143.

AQUIFOLIACEAE

Since the treatment of *Ilex* by Edwin (1965) for *Botany of the Guayana Highland*, in which 55 taxa were treated, including 22 new species and seven varieties, many additional collections resulting from expeditions into this region have accumulated. A study of these new collections of *Ilex* have yielded a large number of new taxa. For the examination of types and other critical material, the author wishes to thank the curators of the herbaria of F, NY, and US for their courtesy in making these loans and gifts available.

One of the difficulties in studying the genus has been that a fair number of new taxa are based on either fruiting material or on staminate or pistillate specimens only. Furthermore, some of the descriptions by Edwin included references to so-called black pubescence on various parts of the plant. However, a careful examination of the type material of these "pubescent" specimens reveals that the so-called black trichomes are only artifacts consisting of fungal hyphal threads. This has been verified by Dr. Richard Harris of the New York Botanical Garden (pers. comm.). Added to the difficulties are differences in the position and type of inflorescence of the staminate and pistillate plants, the latter often having axillary solitary inflorescences only, whereas the staminate plants may bear either axillary fasciculate, or axillary solitary and lateral inflorescences. The terminology used in the present description for the inflorescences is that employed and illustrated by Edwin (1965, fig. 26). Another difficulty in the examination of herbarium material is the interpretation of the punctate or epunctate lower leaf surface. It is possible to misinterpret a leaf surface that appears dotted with dark punctations only to discover that such dots represent merely artifacts of lichens or fungi. This difficulty is well exemplified in the interpretation by Loesener (1901) of the lower surface of the leaf of *Ilex vacciniifolia* Klotzsch (p. 22, loc. cit.). In this case, Loesener intepreted the black dots as fungi, but an examination of conspecific material collected at the type locality and elsewhere indicates that the dots represent actual punctations.

ILEX

Ilex abscondita Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Cerro de la Neblina, Camp 7, south slopes of Cañon Grande, 0°55′N, 66°0′W, 1,900 m, 30 Nov. 1984, *Croat 59478* (holotype, MO; isotypes, NY, VEN).

Frutex vel arbor 3–5 metralis; foliis late obovatis apice rotundatis basi cuneatis 5.5–9 cm longis 4–6 cm latis integerrimis glabris subtus punctatis, costa leviter sulcata intus minute puberulenti; nervis lateralibus utroque latere 5–7 supra sulcatis intus minute puberulentibus; venatione tertiaria subtus obsoleta; petiolis 7–13 mm longis glabris; inflorescentiis masculinis axillaribus lateralibusque, foemineis axillaribus solitariis; pedunculis minute puberulis, fructiferis 6.5–11 mm longis; baccis immaturis 7–9 mm longis 6 mm diam.

Shrub or tree 3–5 m tall. Leaves subcoriaceous, broadly obovate, broadly rounded at apex, cuneate at the base, 5.5–9 cm long, 4–6 cm wide, entire, glabrous, revolute, entire, glabrous, dark punctate beneath; midnerve shallowly sulcate above with a minute puberulence within; lateral nerves 5–7 on each side, sulcate above with a minute puberulence within. Petioles 7–13 mm long, glabrous. Staminate inflorescence axillary and lateral, 3-flowered. Pistillate inflorescence axillary, solitary. Peduncle and pedicels minutely puberulent, the fruiting peduncle 6.5–11 mm long. Immature fruit ovoid, 7–9 mm long, 6 mm diam.

Paratype. VENEZUELA. Same locality and date as type, *Croat 59500* (MO, VEN).

This species differs from *Ilex sipapoana* Edwin in the broader obovate leaves rounded and broadest at summit and in the absence of tertiary venation on the lower surface. The new taxon differs from *I. magnifructa* Edwin in the longer petioles, sulcate puberulent interior of the lateral nerves of the upper leaf surface, and the shorter fruiting pedicels.

Ilex acutidenticulata Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Dept. Atabapo, Cerro Marahuaca, below Salto Los Monos on tributary of headwaters of Río Iguapo, 3°35′N, 65°23′W, 1,500–1,650 m, 12 Mar. 1985, *Ronald Liesner 18595* (holotype, MO; isotype, VEN). Figure 6B.

Arbor 3–8-metralis; foliis lanceolato-ellipticis vel elliptico-oblanceolatis apice acutis vel abrupte acuminatis basi acutis 5–8.5 cm longis 1.5–3 cm latis, marginibus superioribus 1–3-denticulatis, glabris subtus minute punctatis, nervis lateralibus utroque latere 5–7 paullo adscendentibus; petiolis 8–10 mm longis glabris; infructescentiis axillaribus lateralibusque solitariis fasciculatisque; pedicellis 3–5 mm longis; baccis globosis 5 × 5 mm; pyrenis dorsaliter unicanaliculatis.

Tree 3–8 m tall. Leaves lance-elliptic or elliptic-oblanceolate, acute to abruptly acuminate at apex, acutely narrowed at base, 5–8.5 cm long, 1.5–3 cm wide, upper ¼–⅓ part of the margins with 1–3 slender, acute teeth, glabrous, minutely punctate beneath; lateral nerves 5–7 each side, slightly ascending at 25–30° angle, slightly elevated below; tertiary venation slightly manifest below. Infructescence axillary and lateral, solitary and fasciculate, fruiting pedicels 3–5 mm long, minutely puberulent. Fruit globose, 5 × 5 mm. Immature pyrenes dorsally 1-canaliculate.

Paratype. VENEZUELA. TERRITORIO FEDERAL AMAZONAS: Cerro de la Neblina, Camp 7, south slopes of Cañon Grande, along river below camp, 0°55′N, 66°0′W, 1,800 m, 29 Nov. 1984, *Croat 59450* (MO, VEN).

From *Ilex microdonta* Reissek of southern Brazil the new taxon differs in having fewer and smaller teeth confined to the upper leaf margins, punctate lower leaf surface, less ascending lateral nerves, and shorter pedicels. It is distinguished from *I. karuaiana* Edwin by the fewer, sharper teeth, less prominently reticulate upper leaf surface, and shorter pedicels.

Ilex altiplana Steyermark, sp. nov. TYPE: Venezuela. Bolívar: between San Ignacio de Yuruani and San Francisco de Yuruani, bordering small stream between km 251.5 and 253 south of El Dorado on road to Santa Elena, 1,200 m, 4 Jan. 1975, *Julian A. Steyermark 111402* (holotype, VEN).

Arbor 3–20-metralis, ramulis superne minute puberulis glabrescentibus; foliorum laminis elliptico-ovatis vel oblongo-ellipticis apice abrupte acutis vel acuminatis utrinque glabris, costa media subtus interdum minute sparsimque puberulenti excepta; petiolis 3–7 mm longis minute puberulentibus vel glabris; inflorescentia foeminea solitaria axillari lateralique, pedicellis 4.5–9 mm longis subanthesi minute puberulis sub fructu glabris; stigmate elongato late tholiformi 1 mm longo; fructu subgloboso 4–5 × 4–5 mm, pyrenes quattuor dorsaliter unisulcatis.

Tree 3–20 m tall, upper part of stems minutely pubescent or glabrescent in age. Leaves subcoriaceous or firmly membranous, ovate- or oblong-elliptic, abruptly acute or acuminate at apex, acute at base, 4–6.5 cm long, 2–2.5 cm wide, epunctate, glabrous both sides except minutely and sparsely puberulent on the lower midrib of younger leaves; lateral nerves 4–8 on each side, inconspicuous, slightly ascending, not sulcate on upper side; midrib sulcate above, slightly elevated below. Petioles 3–7 mm long, minutely puberulent or glabrous. Pistillate inflorescence solitary, axillary and lateral, 1–4-flowered; pedicels 4.5–9 mm long, minutely puberulent in anthesis, glabrous in fruit. Stigma broadly dome-shaped, elongated, conspicuous, 1 mm long. Fruit subglobose, 4–5 × 4–5 mm, glabrous. Pyrenes 4, brown, trigonous, 3.5 mm long, 2 mm wide, dorsally unisulcate.

Paratypes. VENEZUELA. BOLÍVAR: Gran Sabana, 152 km south of El Dorado, 1,350–1,400 m, 20 Dec. 1970, *J. Steyermark, G. C. K. & E. Dunsterville 104090* (VEN); km 119 south of El Dorado, 1,030 m, *Steyermark et al. 93037* (VEN).

This species shows a close affinity to *I. macarenensis* Cuatrec. of Colombia, but differs in the larger stigma and shorter petioles. Additionally, the leaf apex is shortly and obtusely acute to acuminate rather than narrowly cuspidate, the combined pistillate peduncle and pedicel is longer, and the lateral nerves are not prominently sulcate as in *I. macarenensis*.

Ilex attenuata Steyermark, sp. nov. TYPE: Brazil. Amazonas: Sierra Pirapucú, Comissão de Limites BR-1, 1,250 m, 24 Jan. 1966, *Nilo T. Silva & Umbelino Brazão 60873* (holotype, MO; isotypes, INPA, G, VEN, NY).

Arbor, 12-metralis, foliis oblongo-ellipticis vel late elliptico-lanceolatis apice longiattenuatis obtuse acuminatis, acumine 1–2 cm longo, 3–5 mm lato, basi obtusis vel subacutis 7–13.7 cm longis 2.5–4.7 cm latis, utroque margine remote 7–10-crenulatis glabris subtus punctatis; nervis lateralibus utroque latere 6–7 superne impressis inconspicuis; nervulis tertiariis subtus reticulatis elevatis; petiolis 7–14 mm longis glabris; infructescentiis solitariis axillaribus lateralibusque; pedunculis pedicellisque minute puberulis; bracteis sub pedicellis lanceolatis acuminatis usque 0.5–1 mm longis; florum foemineorum calyce 2–3 mm lato dense puberulo, lobis late rotundatis vel subtruncatis 1.5–2 mm latis dense puberulis ciliatisque tubo longiore; bacca globoso 5–6 × 5–6 mm; pyrenes trigonis 4 mm longis dorsaliter 3–4-costatis.

Tree 12 m tall. Leaves subcoriaceous, oblong-elliptic or broadly elliptic-lanceolate, narrowed to a long-attenuate, obtusely acuminate apex, the acumen 1–2 cm long, 3–5 mm wide, obtuse to subacute at base, 7–13.5 cm long, 2.5–4.7 cm wide, each margin with 7–10 crenulations 3–8 mm distant, glabrous, dark punctate beneath; midnerve sulcate above; lateral nerves 6–7 each side, inconspicuously impressed above, irregularly anastomosing; tertiary venation reticulately elevated below. Petiole 7–14 mm long, glabrous. Infructescence near apex of branchlets, solitary, axillary and terminal. Pistillate flowers either on simple pedicels 6–7 mm long, or, if these in 3s at the end of a peduncle, 3–4 mm long. Peduncle and pedicels minutely puberulous, the puberulence in vertical lines. Bracts subtending pedicels lanceolate, acuminate, 0.5–1 mm long. Pistillate calyx 2–3 mm wide, densely puberulous, the lobes broadly rounded or subtruncate, 1.5–2 mm wide, densely puberulous and ciliate, longer than the tube. Fruit globose, 5–6 × 5–6 mm; pyrenes trigonous, 4 mm long, 3–4-dorsally costate.

In leaf shape this taxon resembles *Ilex symplociformis* Loes. of Brazil, but is distinguished by having a solitary, axillary and lateral pistillate inflorescence, longer peduncles and pedicels, the latter subtended by acuminate bracts, leaf blades with fewer and more distant crenulations, and suborbicular, rounded calyx lobes.

Ilex brevipedicellata Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Dept. Atabapo, Cerro Marahuaca, "Sima Camp," south-central portion, forested slopes along eastern branch on Caño Negro, 3°43′N, 65°31′W, 1,140 m, 21–22, 24 Feb. 1985, *Julian A. Steyermark & Bruce Holst 130531* (holotype, MO; isotype, VEN). Figure 6D.

Arbor 15-metralis, foliis oblongo-obovatis apice rotundatis saepe emarginatis basi acutis 4–7 cm longis 2.5–3.5 cm latis integerrimis glabris subtus valde negro-punctatis; nervis lateralibus utroque latere 5–6; nervulis tertiariis obsoletis; petiolis 4–8 mm longis glabris; inflorescentiis solitariis axillaribus lateralibusque, pedicellis 1–1.5 mm longis glabris; calyce sub fructu 2.5 mm lato, lobis suborbicularibus 1.5 mm latis minute ciliolatis.

Tree 15 m tall. Leaves firmly membranous or chartaceous, revolute, oblong-obovate, rounded and often emarginate at apex, acute at base, 4–7 cm long, 2.5–3.5 cm wide, entire, glabrous, strongly black punctate beneath; midnerve sulcate above; lateral nerves 5–6 each side, faint beneath; tertiary venation obsolete. Inflorescence solitary, axillary and lateral. Pedicels 1–1.5 mm long, 0.8 mm wide, glabrous. Calyx lobes in fruit suborbicular, rounded, 1.5 mm wide, 0.5 mm long, minutely ciliolate; calyx tube puberulent to glabrescent.

This species differs from *Ilex sessilifructa* Edwin of Cerro de la Neblina in the shorter pedicels and more manifest lateral nerves on both leaf surfaces. It differs from *I. culmenicola* Steyerm. of Cerro Duida in the very short pedicels and rounded leaf apex and from *I. gleasoniana* Steyerm. of Cerro Duida in the larger, nonmucronate leaf apex, shorter pedicels, more abundantly punctate leaves, and the more conspicuous lateral nerves on the lower leaf surface.

Ilex cardonae Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: orillas del Río Castanho, afluente del Padauiri que cae del Río Negro y éste último al Amazonas, 100–140 m, 16–24 Feb. 1946, *Felix Cardona 1480* (holotype, VEN).

Arbor, ramulis glabris; foliis oblongo-ellipticis apice acutis basi acutis 11–13 cm longis 3.5–4.5 cm latis obscure repando-crenulatis epunctatis glabris; petiolis 6–8 mm longis glabris; inflorescentia masculina fasciculata axillari lateralique; pedunculis 3–5-floris 3–4 mm longis puberulis; pedicellis 1–2 mm longis puberulis; floribus 4-meris, calycis lobis suborbicularibus rotundatis extus puberulis.

Tree with glabrous stems. Leaves submembranous or chartaceous, oblong-elliptic, acute at apex and base, 11–13 cm long, 3.5–4.5 cm wide, obscurely repand-crenulate, epunctate, glabrous; main lateral nerves 7–8 each side, ascending at an angle of 45–60°, impressed above, slightly elevated below; upper midrib shallowly sulcate, lower midrib elevated; tertiary venation grossly reticulate below. Petioles 6–8 mm long, glabrous. Inflorescence staminate, fasciculate, axillary and lateral. Peduncles 3–5-flowered, 3–4 mm long, puberulous. Pedicels 1–2 mm long, puberulous. Flowers 4-merous. Calyx lobes suborbicular, rounded, puberulous without.

This species is related to *I. tateana* Steyerm. of Cerro Duida and Marahuaca, but differs in the thinner, smaller, epunctate leaf blades, puberulous peduncles, pedicels, and calyx lobes.

Ilex ciliolata Steyermark, sp. nov. TYPE: Venezuela. Bolívar: 0.4 km north of El Pauji on trail to Uaiparú, 4°30'N, 61°35'W, 800–900 m, 4 Nov. 1985, *Ronald Liesner 19479* (holotype, MO; isotype, VEN).

Arbor 5-metralis, ramulis superioribus juvenilibusque minute puberulis; foliis elliptico-ovatis vel oblongo-ovatis apice acutis obtusis vel rotundatis basi acutis vel subacutis 4.5–6.5 cm longis 2–3.3 cm latis integerrimis subtus obscure minuteque pallide punctatis, subtus costa nervis lateralibusque minute puberulis superne costa sulcata et prope margines puberulis, marginibus revolutis ciliolatis aliter glabris; nervis lateralibus utroque latere plerumque 5; petiolis 4–7 mm longis minute puberulis glabrescentibus; inflorescentiis masculinis solitariis axillaribus lateralibus; pedunculo 2.5–3 mm longo; pedicellis 2.5–6 mm longis; pedunculis pedicellisque minute puberulis; calycis lobis suborbicularibus 1 mm latis; fructu globoso 4 × 4 mm.

Tree 5 m tall; young stems and uppermost branches minutely puberulent. Leaves elliptic-ovate to oblong-ovate, acute, obtuse, or rounded at the apex, acute to subacute at base, 4.5–6.5 cm long, 2–3.3 cm wide, entire, obscurely and minutely pale punctate beneath, the lower midrib and lateral nerves minutely puberulent, the midrib above and marginal upper surface puberulent, the margins revolute, minutely ciliolate; lateral nerves mainly 5 each side. Staminate inflorescence solitary, axillary and lateral, cymosely flowered with a peduncle 2.5–3 mm long or epunctate, pedicels 2.5–6 mm long; peduncle and pedicels minutely puberulent. Calyx lobes suborbicular, 0.5 mm long, 1 mm wide, erose-ciliolate; petals 3 mm long, 1 mm wide. Fruit globose, 4 × 4 mm.

This taxon is characterized by the abundance of minute pubescence near the margins of the upper surface of the leaf blades, on the lower midrib and lateral nerves, peduncles, pedicels, as well as the upper portions of the stems. It is related to *Ilex sulcata* Edwin and *I. steyermarkii* Edwin of higher altitudes in Estado Bolívar, which differ in their glabrous vegetative parts. From *Ilex steyermarkii* it differs further in having both axillary and lateral inflorescences. In his description of *I. steyermarkii*, Edwin (1965) mistook small, black hairlike fungal structures occurring upon the leaf margins as true trichomes. Descriptions of such artifacts are frequently encountered in a number of species described in the above mentioned publication.

Ilex davidsei Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Dept. Río Negro, lower part of the Río Baria, 1°27′–1°10′N, 66°32′–66°25′W, inundated forest along river, 80 m, 22–23 July 1984, *Gerrit Davidse 27719* (holotype, MO; isotype, VEN).

Arbor 8-metralis, ramulis juvenilibus minute puberulentibus glabrescentibus; foliis elliptico-oblongis vel anguste ellipticis apice in acumen obtusum 5–12 mm longum 3–5 mm latum productis basi acutis vel subacutis, 4–7.5 cm longis 1.5–3 cm latis, marginibus 2–4 remote crenulatis glabris subtus punctatis; nervis lateralibus utroque latere 5–6; nervulis tertiariis subtus vix manifestis; petiolis 5–8 mm longis glabris; inflorescentiis masculinis solitariis axillaribus racemose denseque ca. 25-floris 1.3–1.7 cm longis 7 mm latis, rhachidi minute puberulenti; floribus 4-meris, pedicellis 0.5–1 mm longis minute puberulentibus; calycis lobis suborbicularibus rotundatis 1 mm latis valde ciliolatis aliter glabris; petalis oblongo-obovatis 1.5 mm longis; inflorescentiis foemineis solitariis axillaribus densifloris racemosis 1.2–1.5 cm longis 0.6–0.7 mm latis; pedicellis 1 mm longis puberulentibus; calycis lobis suborbicularibus rotundatis ciliolatis 1.2 mm latis ciliolatis.

Tree 8 m tall. Young stems minutely puberulent, glabrescent. Leaves elliptic-oblong or narrowly elliptic, the apex prolonged into an obtuse acumen 5–12 mm long, 3–5 mm wide, acute to subacute at base, 4–7.5 cm long, 1.5–3 cm wide, the margins with 2–4 remote crenulations, glabrous, punctate below; lateral nerves 5–6 each side, slightly manifest below; tertiary venation scarcely apparent below, obsolete above. Petioles 5–8 mm long, glabrous. Staminate inflorescences solitary, axillary, racemose, densely ca. 25-flowered, 1.3–1.7 cm long, 7 mm wide, rachis minutely puberulent; flowers 4-merous; pedicels 0.5–1 mm long, minutely puberulent. Calyx tube 1.5 mm wide, glabrous; calyx lobes suborbicular, rounded, 1 mm wide, conspicuously ciliolate, glabrous elsewhere. Petals oblong-obovate, broadly rounded at apex, 1.5 mm long, 1 mm wide, ciliolate on upper margins. Pistillate inflorescence solitary, axillary, elongated, simply racemose, 1.2–1.5 cm long, 0.6–0.7 mm wide; pedicels 1 mm long, puberulent. Rachis puberulent. Calyx 2.5 mm wide, lobes suborbicular, rounded, 1.2 mm wide, ciliolate.

Paratype. VENEZUELA. BOLÍVAR: Río Pacimoni between Caño Arapacua and Caño Boridahari, 110 m, *Maguire & Wurdack 34905* (NY).

This taxon is characterized by the short, densely flowered, racemose, solitary, axillary inflorescence and leaves with a pronounced, elongated, obtuse acumen and remotely few crenate margins. It shows affinities with members of section 3 (*Thyrsiflorae*), section 4 (*Symplociformes*), and section 5 (*Brachythyrsae*) of Loesener (1901). From *Ilex conocarpa* Reissek and *I. symplociformis* Reissek it differs in the more remotely, fewer-crenate leaf margins, smaller leaves with a more pronounced elongated apex, and a shorter, narrower inflorescence. It is distinguished from *I. casiquiarensis* Loes. by the smaller leaves with fewer lateral nerves and by more congested inflorescences with shorter staminate lateral axes and shorter pedicels.

Ilex glabella Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Dept. Río Negro, Cerro de la Neblina, Camp 4, 15 km NNE of Pico Phelps, north branch of river in canyon, 0°51′N, 65°57′W, 780 m, 15–18 Mar. 1984, *Ronald Liesner 16688* (holotype, MO; isotype, VEN).

Arbor, ramulis glabris; foliis oblongo-lanceolatis apice obtuse vel acute subacuminatis basi rotundatis 10–15 cm longis 4.5–6 cm latis integerrimis glabris subtus punctatis; nervis lateralibus principalibus utroque latere 11–13; venulis tertiariis subtus manifeste reticulatis; petiolis 10–11 mm longis glabris; inflorescentiis masculinis subterminalibus vel terminalibus axillaribus fasciculatisque, pedunculis quattuor 5–8 mm longis unusquisque 5-floris umbellatis; pedicellis 3–4.5 mm longis; floribus 4-meris, calyce glabri 2.5 mm lato, lobis suborbiculari-ovatis apice subacutis vel apiculatis 0.8 × 0.8 mm.

Tree with glabrous branchlets. Leaves subcoriaceous, oblong-lanceolate, obtusely to acutely subacuminate at apex, rounded at base, 10–15 cm long, 4.5–6 cm wide, entire, glabrous, subrevolute; midnerve shallowly sulcate above; principal lateral nerves 11–13 on each side, slightly ascending at 10–20° angle, impressed above, somewhat manifest beneath; tertiary venation manifestly reticulate below. Petiole 10–11 mm long, glabrous. Staminate inflorescence subterminal in the uppermost leaf axils or terminal, axillary, fasciculate with 4 peduncles 5–8 mm long, each bearing 5 umbellately arranged pedicellate flowers; pedicels 3–4.5 mm long, glabrous. Flowers 4-merous; calyx 2.5 mm wide, glabrous; lobes suborbicular-ovate, narrowed to a subacute or apiculate apex, 0.8 × 0.8 mm, glabrous. Petals ligulate-oblong, rounded at apex, 1.5 mm long, 1 mm wide.

In Loesener's monograph (1901) this species would fall in subsection A, *Punctatae* Loes., section 9 *Micranthae* Loes. of series *Paltoria* (Ruiz & Pavon) Maxim. From *Ilex tarapotina* Loes. of Peru it differs in the glabrous stems and inflorescences, shorter peduncles with longer pedicels, glabrous calyx, and larger leaf blades with rounded bases. *Ilex glabella* differs from *I. andarensis* Loes. of Peru by having glabrous peduncles, pedicels, calyx, and branchlets and by having more numerous, less ascending lateral nerves of the leaf blades.

Ilex gransabanensis Steyermark, sp. nov. TYPE: Venezuela. Bolívar: road from Ikabarú to Santa Elena, 16 km north of Ikabarú, 4°20'N, 61°45'W, 750 m, 26 July 1982, *Croat 54158-A* (holotype, MO; isotype, VEN).

Frutex 1.5-metralis, ramulis glabris; foliis obovato-oblongis vel oblongo-ovatis apice rotundatis obtusis vel subobtusis basi obtusis vel subacutis 5–9.5 cm longis, 3.5–5 cm latis integerrimis glabris subtus punctatis; costa supra subelevata vel subimpressa 1 mm lata; nervis lateralibus supra obsoletis vel impressis utroque latere 6–11; petiolis 9–13 mm longis glabris; inflorescentia foeminea axillari lateralique solitaria vel fasciculata; pedunculo fructifero 1 mm longo fructifero puberulo, pedicellis sub fructu 2–5 mm longis puberulis; calycis lobis sub fructu suborbicularibus rotundatis 2 mm latis ciliolatis aliter glabris; bacca globoso 6 × 6 mm; pyrenis trigonis 4 mm longis dorsaliter laevibus.

Shrub 1.5 m tall. Branchlets glabrous. Leaves coriaceous, shining above, obovate-oblong or oblong-ovate, rounded, obtuse or subobtuse at apex, obtuse to subacute at base, 5–9.5 cm long, 3.5–5 cm wide, entire, glabrous, punctate below, slightly recurved on margins; midrib subelevated, subimpressed above, 1 mm wide; lateral nerves obsolete or impressed above, 6–11 each side, forking before reaching margins, not manifestly anastomosing. Petioles 9–13 mm long, glabrous. Pistillate inflorescence axillary and lateral, solitary or fasciculate, fruiting peduncle 1 mm long, puberulent; fruiting pedicels 1–2 on a peduncle, 2–5 mm long, puberulent. Calyx minutely puberulent, the lobes in fruit suborbicular, rounded, 1–1.5 mm long, 2 mm wide, ciliolate. Fruit globose, 6 × 6 mm. Pyrenes trigonous, 4 mm long, dorsally smooth above, without ridges.

This taxon resembles *Ilex tepuiana* Edwin in leaf shape but differs in the dorsally smooth pyrenes and much longer petioles. From *I. solida* Edwin it is differentiated by the much shorter fruiting pedicels and much longer petioles, while from *I. fanshawei* Edwin it may be distinguished by the dorsally smooth achenes and rounded leaf apex.

Ilex guaiquinimae Steyermark, sp. nov. TYPE: Venezuela. Bolívar: Cerro Guaiquinima, southeast-central part of the summit, 5°44'4"N, 63°41'8"W, 730–900 m, 24 May 1978, *Julian A. Steyermark, Paul Berry, G. C. K. & E. Dunsterville 117276* (holotype, VEN; isotype, MO).

Arbor, ramulis glabris; foliis late oblongis apice late rotundatis basi acutis vel subacutis 10–16 cm longis 6.5–8 cm latis integerrimis glabris subtus punctatis; costa superne leviter lateque sulcata subtus manifeste elevata; nervis lateralibus utroque latere 6–7 angulo 30–45° adscendentibus 1.5 1.7 cm remotis; petiolis 10–18 mm longis glabris; inflorescentia foeminea solitaria axillari lateralique pedunculo sub fructu 3–5 mm longo glabro; pedicellis 3 mm longis glabris; calyce glabro, lobis leviter suborbicularibus rotundatis; bacca globosa 5 mm longa 5.5 mm diam.; pyrenis 5 mm longis dorsaliter late unisulcata.

Tree with glabrous branchlets. Leaves broadly oblong, broadly rounded at apex, acute to subacute at base, 10–16 cm long, 6.5–8 cm wide, entire, glabrous, punctate below; midrib 2 mm wide, shallowly and widely sulcate above, conspicuously elevated below; lateral nerves slender, 6–7 each side, ascending at an angle of 30–45°, 1.5–1.7 cm apart, impressed or slightly elevated above, slightly elevated below, branching before reaching margin; tertiary venation slightly evident above, obscure below. Petioles 10–18 mm long, glabrous. Pistillate inflorescence solitary, axillary, lateral. Fruiting peduncle 3–5 mm long, glabrous; pedicels 3 mm long, glabrous. Calyx glabrous, the lobes shallowly suborbicular, rounded. Fruit globose, 5 mm long, 5.5 mm diam. Pyrenes 5 mm long, 3 mm wide, dorsally broadly 1-sulcate.

Closely related to *Ilex jenmanii* Loes., from which it differs in the fewer lateral nerves more distantly separated (15–17 mm vs. 4–10 mm in *I. jenmanii*), broadly oblong leaves rounded at the apex, punctate lower leaf surface, shallowly and widely sulcate upper midrib, and solitary, axillary, and lateral inflorescence. From *I. marginata* Edwin it is distinguished by the ascending lateral nerves of the leaf blades.

Ilex holstii Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Dept. Atabapo: Cerro Marahuaca, "Sima Camp," south-central portion of forested slopes along east branch of Caño Negro, 3°43'N, 65°31'W, 1,140 m, 21–22, 24 Feb. 1985, *Julian A. Steyermark & Bruce Holst 130481* (holotype, MO; isotype, VEN).

Arbor 4-metralis, ramulis glabris; foliis lanceolatis apice acuminatis basi acutis vel subacutis 5.5–8 cm longis 1.3–2.5 cm latis integerrimis glabris subtus ut videtur epunctatis; nervis lateralibus angulo 5–20°; petiolis 6–10 mm longis glabris; inflorescentia foeminea solitaria axillari lateralique, pedunculo 2–7 mm longo glabro vel absenti; pedicellis tenuibus solitariis vel duobus 4–7 mm longis 0.3–0.5 mm latis; calyce glabro 2.5 mm lato, lobis vix manifestis truncatis; bacca 4–6 × 4–6 mm; pyrenis 4, trigonis 4 mm longis dorsaliter late 1-sulcatis.

Tree 4 m tall with glabrous branchlets. Leaves subcoriaceous, lanceolate, acuminate at apex, with an attenuate mucro 0.5 mm long, acute or subacute at base, 5.5–8 cm long, 1.3–2.5 cm wide, 2.7–4 times longer than broad, entire, glabrous, the midnerve shallowly sulcate above, slightly elevated below; lateral nerves obsolete above, manifestly impressed below, subhorizontally spreading at an angle of 5–20°, tertiary venation faintly reticulate below. Petioles 6–10 mm long, glabrous. Pistillate inflorescence solitary, axillary, lateral. Fruiting peduncle when present 2–7 mm long, glabrous; fruiting pedicels solitary or 2 together, slender, 4–7 mm long, glabrous. Calyx in fruit glabrous, 2.5 mm diam., the lobes scarcely evident, truncate. Fruit globose, 4–6 × 4–6 mm. Pyrenes 4, trigonous, 4 mm long, 2–2.5 mm wide, broadly unisulcate dorsally.

This species is similar to *Ilex oliveriana* Loes. in unisulcate pyrenes, leaf shape and mucronate apex, and the size of the fruit; but it differs in the longer petioles, more prominently impressed, subhorizontal lateral nerves, and longer mucros of the leaf blades. From *I. macarenensis* it differs principally in the dorsally unisulcate achenes.

Ilex ignicola Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Dept. Río Negro, Cerro Aratitiyope, 70 km south-southwest of Ocamo, 2°10'N, 65°34'W, 990–1,100 m, 24–28 Feb. 1984, *Julian A. Steyermark, Paul Berry & Francisco Delascio 130112* (holotype, MO; isotype, VEN).

Arbor 6-metralis, ramulis novellis minute puberulis vel glabris; foliis elliptico-oblongis apice anguste obtusis vel subacutis basi acutis vel subacutis 5.5–8 cm longis 2.5–

3.5(–4) cm latis integerrimis glabris; costa superne subelevata vel leviter sulcata plerumque puberula subtus impressa vel elevata plerumque puberula; nervis lateralibus utroque latere 7–9; petiolis 5–9 mm longis minute puberulis glabrescentibus; inflorescentia foeminea solitaria axillari lateralique, pedicellis 3–4 mm longis minute puberulis; calyce sub fructu puberulo, lobis leviter suborbicularibus rotundatis 1 mm latis puberulis; bacca subobovoidea 7–8 mm longo 5 mm lato; pyrenis quattuor trigonis 4–5 mm longis dorsaliter late 1-sulcatis.

Tree 6 m tall; young stems minutely puberulent, glabrescent. Leaves subcoriaceous, elliptic-oblong, narrowly obtuse or subacute at apex, acute to subacute at base, 5.5–8 cm long, 2.5–3.5(–4) cm wide, entire, glabrous, subrevolute; midnerve subelevated or shallowly sulcate above, puberulous, impressed or elevated below, mainly puberulous; lateral nerves 7–9 each side, inconspicuous, scarcely evident below, impressed above, ascending at a 45° angle; tertiary venation obsolete above, scarcely evident beneath. Petioles 5–9 mm long, minutely puberulous or glabrescent. Pistillate inflorescence solitary, axillary, lateral. Pedicels 3–4 mm long, minutely puberulent. Calyx puberulous in fruit, the lobes shallowly suborbicular, rounded, 1 mm wide, puberulent. Fruit subobovoid, 7–8 mm long, 5 mm broad. Pyrenes 4, trigonous, 4–5 mm long, 2 mm wide, dorsally broadly unisulcate, the sulcation sharply angled.

This species is marked by the usually minutely puberulent upper and lower midnerves, the puberulent pedicels and calyx, and the slightly longer than broad subobovoid fruits with unisulcate pyrenes.

Ilex jauaensis Steyermark, sp. nov. TYPE: Venezuela. Bolívar: Meseta de Jaua, Cerro Jaua, southwest summit, 4°48′50″N, 64°34′10″W, gallery forest along tributary of Río Marajano, 1,750–1,800 m, 22–28 Feb. 1974, *J. A. Steyermark, V. C. Espinoza & C. Brewer-Carías 109294* (holotype, VEN; isotype, MO).

Arbor 4-metralis, ramulis glabris; foliis oblongo-obovatis apice rotundatis retusis basi acutis vel obtusis 4–5.5 cm longis 2–3 cm latis integerrimis glabris subtus punctatis; nervis lateralibus utroque latere 5; venulis tertiariis obsoletis; petiolis 5 mm longis glabris; inflorescentia foeminea solitaria axillari lateralique; pedicellis sub fructu 13–14 mm longis glabris; calyce sub fructu glabro, lobis leviter suborbicularibus 2 mm latis; bacca in sicco 7 mm longo, 8 mm diam., in vivo 9 mm longo 10 mm diam.; pyrenis trigonis 4.5–6 mm longis dorsaliter late unisulcatis, cristis marginalibus prominentibus.

Tree 4 m tall with glabrous branchlets. Leaves coriaceous, oblong-obovate, mainly rounded at the retuse apex, acute to obtuse at base, 4–5.5 cm long, 2–3 cm wide, entire, glabrous, punctate below; lateral nerves 5 each side, narrowly sulcate above, slightly manifest and subelevated below; tertiary venation not evident. Petioles 5 mm long, glabrous. Pistillate inflorescence solitary, 1-flowered, axillary, lateral. Fruiting pedicels 13–14 mm long, glabrous. Calyx glabrous in fruit, the lobes shallowly suborbicular, 2 mm wide. Fruit 7 mm long, 8 mm wide (dried state), 9 mm long, 10 mm wide (living state). Pyrenes trigonous, 4.5–6 mm long, 3–4 mm wide, with prominent marginal ridges.

Paratype. VENEZUELA. BOLÍVAR: Cerro Marutani, 1,420 m, *Steyermark et al. 124032* (VEN).

The retuse, mainly rounded leaf apex distinguishes this taxon from *Ilex sulcata* Edwin and *I. tiricae* Edwin; the longer petioles, shorter leaves, and oblong-obovate leaf shape differentiate it from *I. lasseri* Edwin; the longer petioles, shorter pistillate pedicels, and obtuse to acute leaf base distinguish it from *I. solida*; and the longer and less thickened petioles differentiate the new species from *I. tepuiana* Edwin.

Ilex longipilosa Steyermark, sp. nov. TYPE: Venezuela. Bolívar: 3 km south of El Pauji, non-forested south slope and summit of El Abismo, 4°30′N, 61°35′W, 800–1,050 m, 11 Nov. 1985, *Ronald Liesner 19878* (holotype, MO; isotype, VEN). Figure 6A.

Frutex 1.5-metralis, ramulis dense hirtellis pilis usque 0.5 mm longis instructis; foliis cuneiformi-obovatis vel suborbiculari-ovatis apice rotundatis abrupte apiculatis basi cuneatis 4–7 cm longis 2.5–5.5 cm latis plerumque integris vel raro 1–2-denticulatis subtus costa valde pilosa pilis 0.3–0.9 mm munitis; nervis lateralibus subtus pilosulis pilis divaricatis instructis alibi subtus sparse pilosulis vel glabratis, subtus minute punctatis; nervis lateralibus utroque latere 6–8 angulo 10–20° divaricatis; venulis tertiariis subtus grosse reticulatis; petiolis 3–7 mm longis dense hirtellis pilis patentibus; inflorescentia foeminea solitaria axillari lateralique 10–20 mm longo ramosa 5–6 axibus 4–10 mm longis praedita; pedunculo 4–9 mm longo puberulo; pedicellis 1.5–2 mm longis puberulis; bracteis deltoideo-lanceolatis acutis vel acuminatis 1.2 mm longis 0.5 mm latis glabris vel extus basi paucipilosis; floribus 4-meris, calycis lobis suborbicularibus rotundalis vel paullo subacutis 1.3 mm latis leviter irregulariterque erosis; petalis obovato-oblongis rotundatis 3 mm longis 2 mm latis.

Shrub 1.5 m tall, the branchlets densely hirtellous with spreading hairs up to 0.5 mm long. Leaves cuneiform-obovate or suborbicular-ovate, abruptly apiculate at the rounded apex, cuneate at base, 4–7 cm long, 2.5–5.5 cm wide, mainly entire or rarely with 1–2 minute toothlike projections, subrevolute, the lower midrib strongly pilose with spreading hairs 0.3–0.9 mm long, the lateral nerves beneath with spreading hairs, the lower surface pilosulous to glabrate, the upper surface glabrous except for the minutely puberulent sulcate midrib, minutely punctate on lower surface; midnerve sulcate above, elevated below; lateral nerves 6–8 each side, divaricately spreading at a 10–20° angle, slightly manifest below, inconspicuous and faintly sulcate above. Petioles 3–7 mm long, densely hirtellous with spreading hairs. Pistillate inflorescence solitary, axillary, lateral, 10–20 mm long, cymosely or paniculately branched with 5–6 lateral axes 4–10 mm long; peduncle 4–9 mm long, shortly puberulous; pedicels 1.5–2 mm long, shortly puberulous. Bracts deltoid-lanceolate, acute to acuminate, 1.2 mm long, 0.5 mm wide, mainly glabrous or with a few hairs at the outer base. Flowers 4-merous; calyx lobes suborbicular, rounded or slightly subacute, 1.3 mm wide, the margins slightly irregularly erose. Petals obovate-oblong, rounded, 3 mm long, 2 mm wide.

From the taxa placed by Loesener (1901) in his section 7 *Megalae*, subsection *Pedicellata* Loes., especially *Ilex villosula* Martius, *I. velutina* C. Martius, *I. brasiliensis* (Sprengel) Loes., and *I. theezans* var. *riedelii* Loes., the new species differs in its solitary, axillary, and lateral (vs. fasciculate) inflorescences, punctate lower leaf surface, and differently shaped leaves. The longer pubescence of the new species is somewhat reminiscent of *I. maguirei* Wurdack of Cerro de la Neblina, which differs in its rounded leaf bases, differently shaped leaves, shorter petioles, pubescent, elongated fruit, and only 1–3-flowered inflorescences.

Ilex magnifructa Edwin, var. **minor** Steyermark, var. nov. TYPE: Venezuela. Territorio Federal Amazonas: Cerro Ualipano, orillas del Río Parucito, 6°N, 65°43′W, 1,760 m, Feb. 1962, *Felix Cardona 2943* (holotype, US; isotype, MO).

A var. *magnifructa* pedicellis fructiferis 5–10 mm longis recedit.

Leaf blades broadly oblong-obovate, rounded at apex, broadly rounded or obtuse at base, 7.5–10.5 cm long, 4–8 cm wide. Petioles 2–3 mm long. Calyx lobes 4, deltoid, acute. Fruiting pedicels 5–10 mm long.

This variety differs from var. *magnifructa* in the shorter fruiting pedicels.

Ilex marahuacae Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Cerro Marahuaca, "Sima Camp," south-central portion, forested slopes along E branch of Caño Negro, 3°43′N, 65°31′W, 1,140 m, 21–22, 24 Feb. 1985, *J. A. Steyermark & B. K. Holst 130425* (holotype, MO; isotype, VEN).

Arbor 4-metralis, ramulis glabris; foliorum laminis ovatis vel oblongo-ovatis apice obtuse vel argute acuminatis, acumine 8–10 mm longo, basi rotundatis vel subobtusis 6.5–11 cm longis 2.5–4.5 cm latis punctatis glabris, marginibus remote obscureque crenulato-serrulatis; venulis tertiariis supra reticulatis aliquantum impressis; petiolis 6–8 mm longis; infructescentia solitari axillari; floribus 4-meris; pedunculo 5–6 mm longo glabro 2–3-flora; calycis lobis suborbicularibus rotundatis minute erosis sparsim ciliatis; pyrenis 4 trigonis dorsaliter laevibus vel sublaevibus.

Tree 4 m tall, the stems glabrous. Leaf blades subcoriaceous, ovate or oblong-ovate, obtusely to acutely acuminate at apex, the acumen 8–10 mm long, rounded to subobtuse

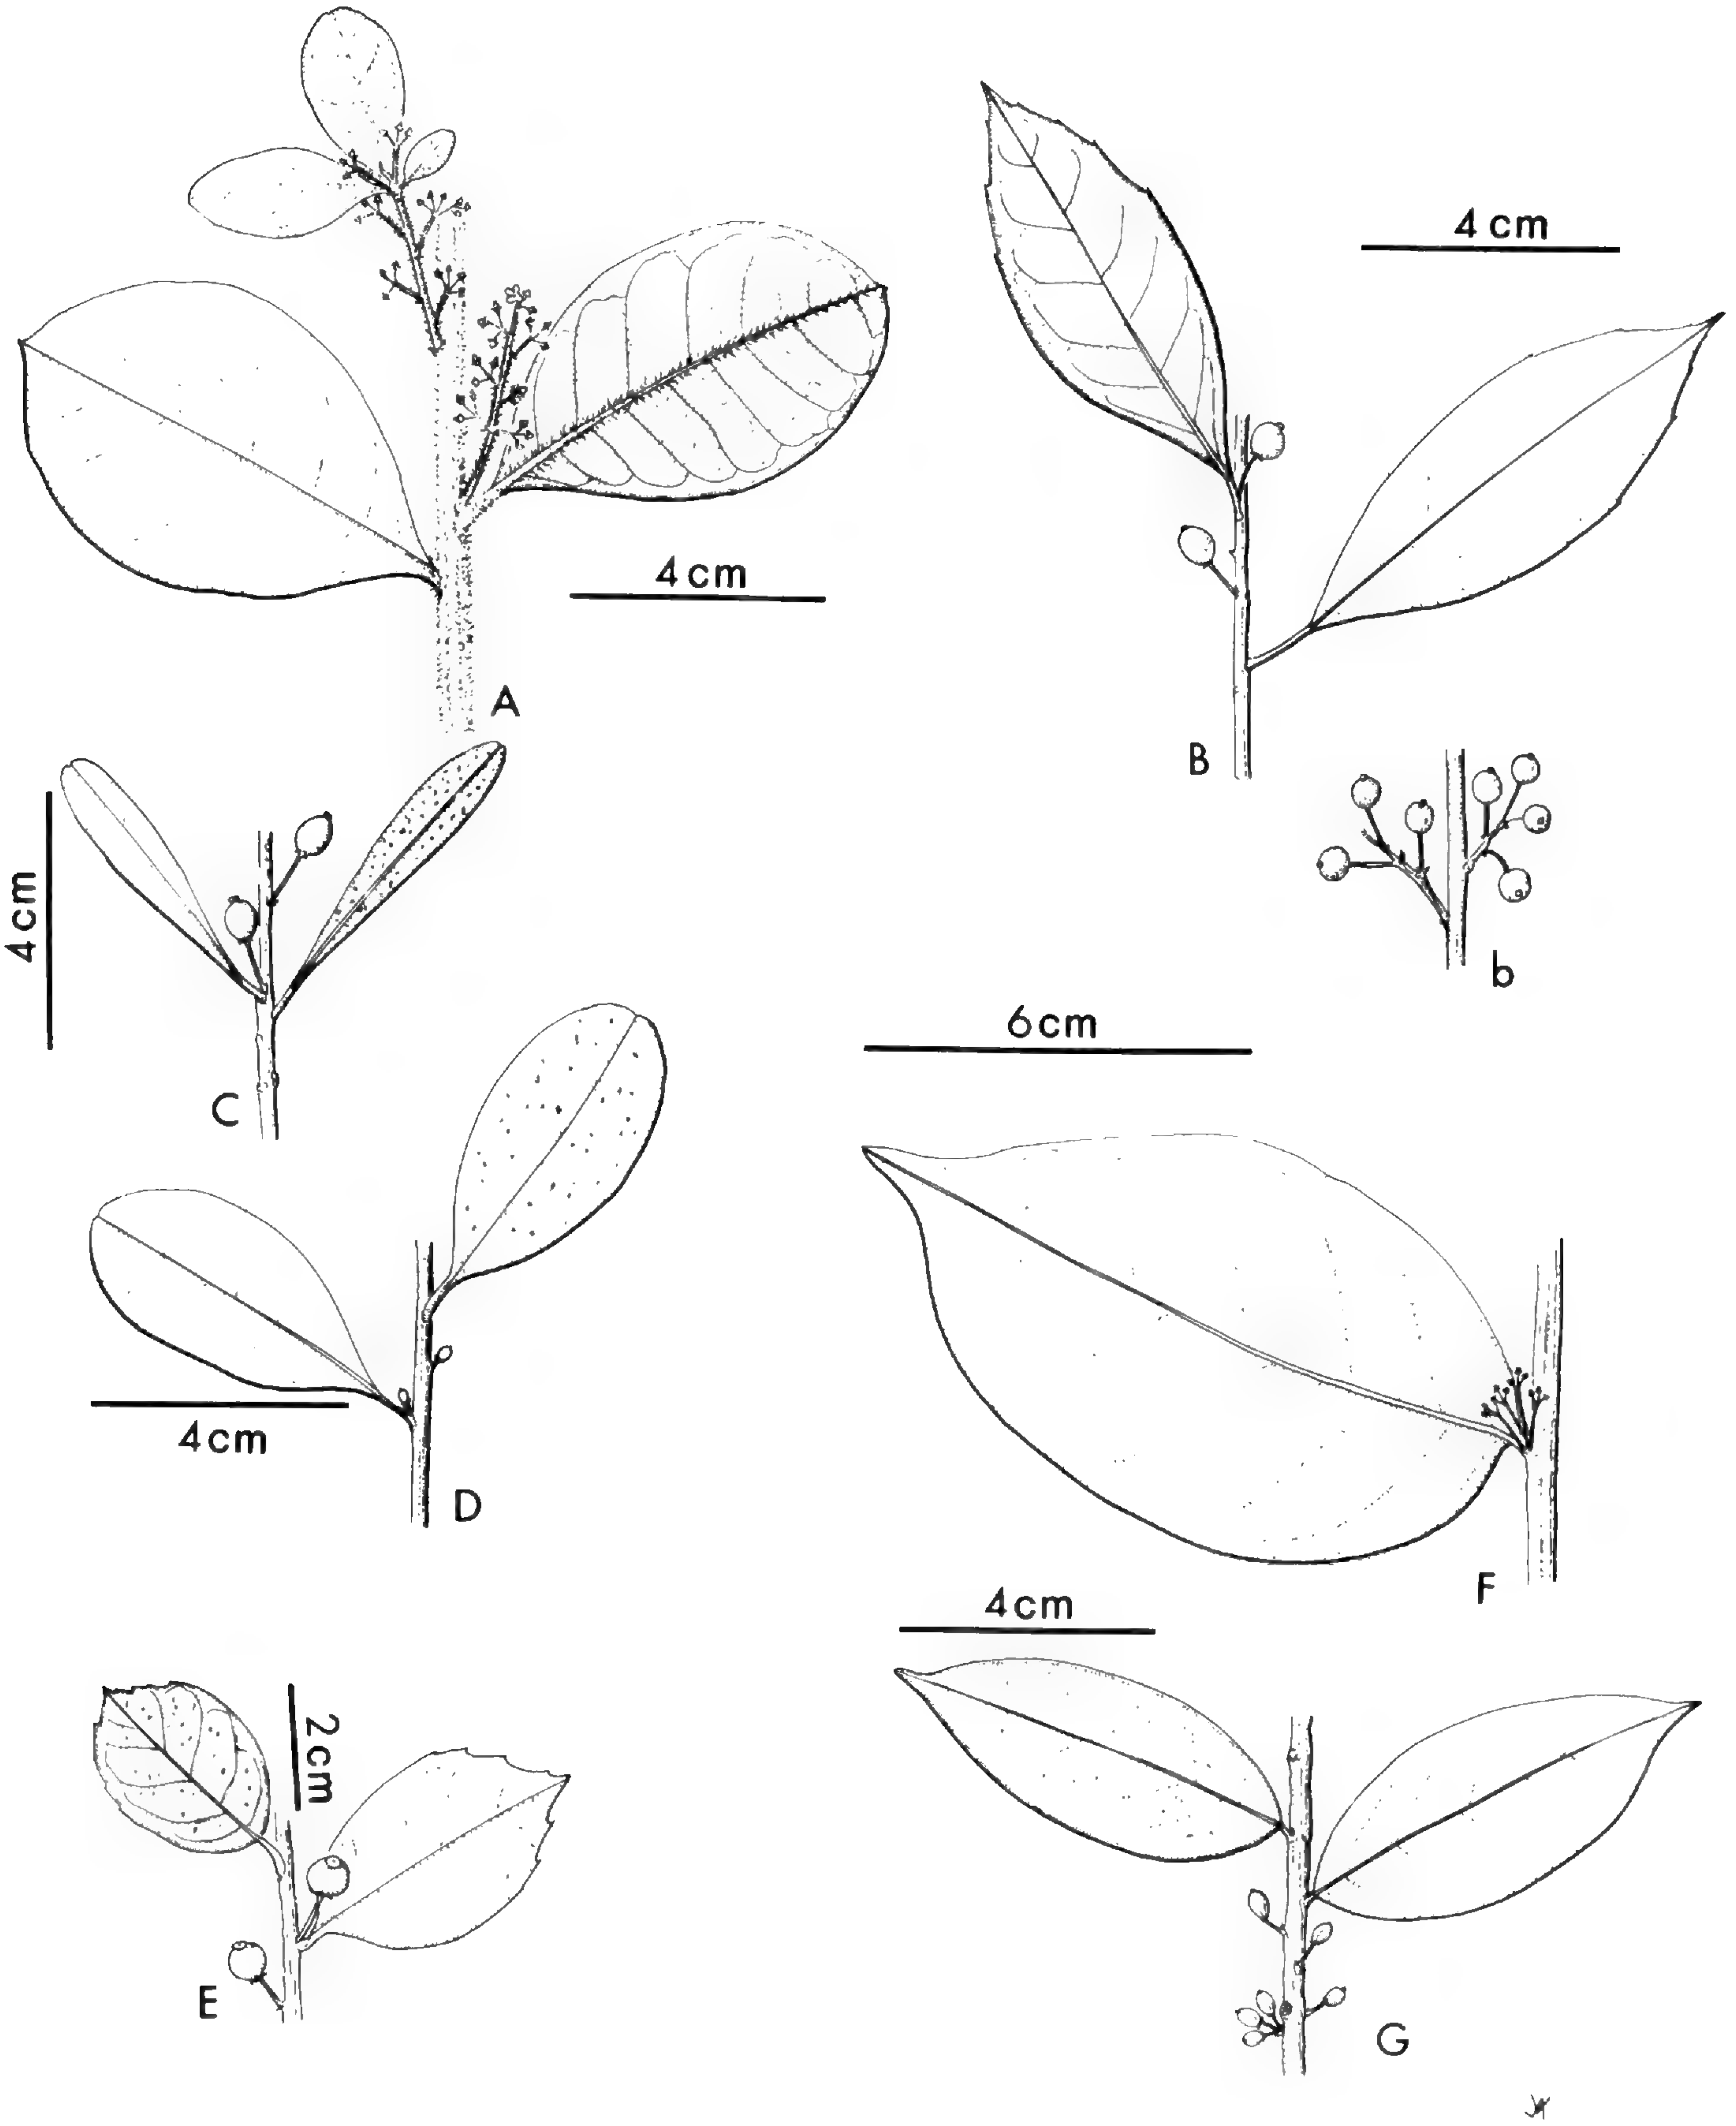

FIGURE 6.—*A.* Ilex longipilosa, *portion of flowering branch, staminate.*—*B.* Ilex acutidenticulata.—*b. Branched fruiting peduncles.*—*C.* Ilex spathulata.—*D.* Ilex brevipedicellata.—*E.* Ilex summa.—*F.* Ilex wurdackiana, *staminate branch.*—*G.* Ilex wurdackiana, *portion of fruiting branch.*

at base, 6.5–11 cm long, 2.5–4.5 cm wide, punctate, glabrous; lateral nerves 4–5 each side with less conspicuous intermediate nerves, subhorizontally spreading at 10–20°, impressed above, slightly elevated below; tertiary venation reticulate and rather conspicuously impressed above, subobsolete below. Petioles 6–8 mm long, glabrous. Infructescence solitary, axillary. Peduncle 5–6 mm long, 2–3-flowered, glabrous. Pedicels 3 mm long, glabrous. Flowers 4-merous. Calyx lobes shallowly suborbicular, rounded, 0.3 mm long, 1 mm wide, minutely erose, sparsely ciliolate. Calyx tube glabrous. Fruit globose, 5 mm diam. Pyrenes 4, trigonous, 5 mm long, 3 mm wide, dorsally smooth or essentially so.

This taxon is characterized by the elongated acumen of the obscurely crenulate-serrulate leaves, the solitary axillary inflorescence, the dorsally smooth pyrenes, and the epunctate leaves.

Ilex paruensis Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Dept. Atabapo, Serranía del Parú (Aroko), sector centro-sur, sabanas herbáceas en el borde sur de la tercera meseta central, 4°27′N, 65°32′W, 1,100 m, 7 Oct. 1979, *O. Huber 4437* (holotype, VEN).

Frutex 2-metralis, ramulis pubescentibus pilis arcte verticaliterque seriatis dispositis; foliorum laminis late obovatis apice rotundatis minute mucronulatis basi acutis 2.5–3.5 cm longis 1.5–2.3 cm latis subtus epunctatis supra arcte negro-punctatis scrobiculatisque, subtus costa media pubescenti pilis brevibus patentibus munita supra sulcata minute puberulenti; petiolis 2 mm longis crebiter minuteque puberulis; infructescentia foeminea solitaria fasciculata axillari lateralique; pedunculis 1–3-floris usque 3 mm longis dense puberulis, pedicellis 1–3 mm longis dense puberulis; calycis lobis fere obsoletis repando-rotundatis apice paullo apiculatis; stigmate depresso latiori quam longiori; fructu subgloboso 3 mm diam. (immaturo).

Shrub 2 m tall; stems minutely pubescent in vertical lines. Leaf blades coriaceous, broadly obovate, rounded at the minutely mucronulate apex, acute at the base, 2.5–3.5 cm long, 1.5–2.3 cm wide, epunctate below, scrobiculate and densely black-puncticulate above, the midrib puberulent below with spreading hairs, minutely puberulent in the sulcation above, elsewhere glabrous on both surfaces or sparsely puberulent near base of upper surface, revolute; lateral nerves 4–5 each side, inconspicuous both sides, faintly impressed below. Petioles 2 mm long, densely and minutely puberulent. Infructescence solitary or fasciculate, axillary and lateral. Peduncles 1–3-flowered, up to 3 mm long, densely puberulent. Pedicels 1–3 mm long, densely puberulent. Calyx lobes scarcely developed, broadly shallowly repand-rounded, slightly apiculate at the apex, glabrous. Stigma broadly flattened and depressed at the slightly umbonate summit. Immature fruit subglobose, 3 mm diam.

This species is related to *I. vacciniifolia* Klotzsch, from which it differs in the epunctate lower leaf surface, strongly black puncticulate upper surface, shorter fruiting peduncles and pedicels, mucronulate leaf apex, and glabrous, subobsolete calyx lobes.

Ilex paujiensis Steyermark, sp. nov. TYPE: Venezuela. Estado Bolívar: 3 km south of El Pauji, 4°30′N, 61°35′W, 900 m, 19 Oct. 1985, *Ronald Liesner & Bruce Holst 18796* (holotype, MO; isotype, VEN).

Arbor 4-metralis, ramulis glabris; foliis obovatis apice rotundatis interdum retusis basi cuneatis 6.5–11 cm longis 2.5–4.5 cm latis integerrimis glabris subtus valde negro punctatis; costa superne anguste sulcata; nervis lateralibus utroque latere 7–9; venulis tertiariis subtus tenuibus; petiolis 5–10 mm longis 1.5–2 mm diam. glabris; inflorescentia foeminea solitaria axillari lateralique; pedicellis fructiferis 2–3 mm longis minute puberulentibus; calyce minute puberulenti, lobis suborbicularibus rotundatis ciliolatis vel obsolete erosis 1 mm latis; petalis 3–3.5 mm longis 1.5 mm latis minute papillatis marginibus papillato-ciliolatis; bacca globoso 6 × 6 mm.

Tree 4 m tall with glabrous branchlets. Leaves coriaceous, obovate, rounded and sometimes retuse at apex, cuneately narrowed at base, mainly 6.5–11 cm long, 2.5–4.5 cm wide, 2–2½ times longer than broad, entire, glabrous, strongly black-punctate beneath, the upper midnerve narrowly sulcate; lateral nerves 7–9 each side, slightly elevated or impressed above, finely impressed below; tertiary venation faintly manifest beneath. Petioles 5–10 mm long, 1.5–2 mm wide, glabrous. Pistillate inflorescence solitary, axillary, lateral. Fruiting pedicels 2–3 mm long, minutely puberulent. Calyx tube minutely puberulent; calyx lobes suborbicular, rounded, some of them minutely ciliolate, others obsoletely erose, 1 mm wide. Petals 3–3.5 mm long, 1.5 mm wide, minutely papillate on the lower half of the upper surface, the margins papillate-ciliolate. Fruit globose, 6 × 6 mm.

Paratype. VENEZUELA. BOLÍVAR: region of ríos Icabarú and Hacha, 450–850 m, *Bernardi 2622* (VEN).

The elongate petioles and short fruiting pedicels ally this taxon to *Ilex gransabanensis* Steyerm., but *I. paujiensis* differs in having the punctations on the lower leaf surface larger and more conspicuous, less conspicuous lateral nerves, more cuneately acute leaf bases, and narrowly sulcate upper midnerves.

The collection of *Bernardi 2622* at VEN, presently treated as a paratype of *Ilex paujiensis*, was identified by Edwin as *I. andarensis* Loes. and forms the basis for his inclusion of that species in his treatment for the Venezuelan Guayana (1965). *Ilex andarensis*, originally described from Andara Mountain, Peru, was based on a *Spruce s.n.* collection and is completely different from the *Bernardi 2622* specimen, having, among other differences, ovate, oval-oblong, or elliptic leaf blades which are obtuse, rounded, or cuneately obtuse at the base and acute or obtusely acuminate at the apex with an acumen 7–12 mm long.

Ilex polita Steyermark, sp. nov. TYPE: Venezuela. Bolívar: Guayaraca, southern base, Auyán-tepui, between escarpment and Río Guayaraca, 5°44′N, 62°32′W, 950 m, 25–27 Nov. 1982, *G. Davidse & O. Huber 22679* (holotype, MO; isotype, VEN).

Frutex 2-metralis, ramulis glabris; foliis superne nitidis ovatis ovalibus oblongis vel elliptico-oblongis apice obtuse vel rotundatis basi obtusis vel rotundatis 4–7.5 cm longis 1.8–4.5 cm latis integerrimis glabris subtus epunctatis; costa supra anguste paullo sulcata; nervis lateralibus utroque latere 5–9; petiolis 4–10 mm longis glabris; inflorescentia foeminea solitaria axillari lateralique; pedunculo sub fructu 7–10 mm longo; pedicellis sub fructu 3–5 mm longis ubi solitariis 1–2 mm longis ubi inflorescentiis ramosis; floribus 4-meris; calycis tubo minute puberulo, lobis suborbicularibus apice rotundatis vel subacutis 1.2–1.5 mm latis marginibus ciliolatis.

Shrub 2 m tall with glabrous branchlets. Leaves coriaceous, shining and mainly enervate above, ovate, oval, oblong, or elliptic-oblong, obtuse or rounded at apex, obtuse or rounded at base, 4–7.5 cm long, 1.8–4.5 cm wide, entire, glabrous, epunctate below, 1.3–2.6 times longer than broad, revolute; midnerve narrowly and shallowly sulcate above, somewhat elevated below; lateral nerves 5–9 each side, ascending at an angle of 15–20°, obsolete above, faintly impressed or slightly elevated below; tertiary venation slightly manifest below. Petioles 4–10 mm long, glabrous. Pistillate inflorescence solitary, axillary, lateral. Peduncle 7–10 mm long in fruit. Pedicels, when solitary, 3–5 mm long in fruit, 1–2 mm long in fruit in cymose inflorescences, sparsely puberulent. Flowers 4-merous. Calyx tube sparsely and minutely puberulent, the lobes suborbicular, rounded or slightly subacute at apex, 0.5 mm long, 1.2–1.5 mm wide, ± densely ciliolate.

Paratypes. VENEZUELA. BOLÍVAR: Auyán-tepui, Guayaraca, 950 m, *Davidse & Huber 22733* (MO, VEN); Río Aparamán, affluent of Río Acanán near Yuray-merú rapids, 1.5 km S of SW corner of Amaruay-tepui, 5°54′N, 62°15′W, 500 m, *Liesner & Holst 20114* (MO, VEN).

This species is characterized by the combination of its densely ciliolate calyx lobes, shallowly sulcate upper midnerve, and oblong, elliptic-oblong, ovate, or oval leaf blades lustrous on the upper surface and obtuse or rounded at the apex.

Ilex spathulata Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Dept. Atabapo, Cerro Marahuaca, slopes upstream from Río Yameduaka, 3°38′N, 65°28′W, 1,225 m, 17–18 Feb. 1985, *Ronald Liesner 17599* (holotype, MO; isotype, VEN). Figure 6C.

Frutex 2-metralis; ramulis glabris; foliis anguste spathulatis apice rotundatis emarginatis basi conspicue angustatis 2.5–4.5 cm longis 0.5–1.2 cm latis integerrimis glabris subtus punctatis; costa superne sulcata; nervis lateralibus principalibus 5–6; venulis tertiariis obsoletis vel fere; petiolis 5–8 mm longis glabris; inflorescentia foeminea solitaria axillari, 1–2-flora; pedicellis sub anthesi 4–4.5 mm longis sub fructu 10–12 mm longis minute puberulentibus; calyce sub anthesi 0.7–1 mm longo 1.5 mm lato glabro, lobis suborbicularibus rotundatis; inflorescentia masculina fasciculata vel solitaria axillari lateralique cymosa 2–5-flora, pedunculo 1.5 mm longo puberulenti, pedicellis 2 mm longis; bacca (immatura) globosa 6 × 5.5 mm.

Shrub 2 m tall, the branchlets glabrous. Leaves subcoriaceous, narrowly spathulate, rounded and emarginate at apex with a thickened blunt tip in the sinus, conspicuously narrowed at the base and decurrent, 2.5–4.5 cm long, 0.5–1.2 cm wide, (2½–)4½–5 times longer than broad, entire, glabrous, punctate beneath, revolute; midnerve sulcate above; principal lateral nerves 5–6 each side, impressed above, slightly elevated below; tertiary venation obsolete or inconspicuous above, slightly more conspicuous below. Petioles 5–8 mm long, glabrous. Pistillate inflorescence solitary, axillary, lateral, 1–2-flowered. Pedicels in flower 4–4.5 mm long, in fruiting specimens 10–12 mm long, minutely puberulent. Calyx 0.7–1 mm long, 1.5 mm wide in anthesis, glabrous; lobes suborbicular, rounded, 0.5 mm long, 0.8 mm wide. Petals 2–2.5 mm long, 1 mm wide. Staminate inflorescence fasciculate or solitary, axillary and lateral, cymosely 2–5-flowered, pedunculate; peduncle 1.5 mm long, puberulent; pedicels 2 mm long. Immature fruit globose, 6 mm × 5.5 mm.

Paratype. VENEZUELA. TERRITORIO FEDERAL AMAZONAS: Cerro Marahuaca, same locality as type, 19 Feb. 1985, *Liesner 17688* (MO, VEN).

This taxon is characterized by the narrowly spathulate leaves, mainly 4½–5 times longer than broad and the completely glabrous calyx. From *Ilex huachamacariana* Edwin it may be distinguished by having shorter fruiting pedicels, more conspicuous lateral nerves, and more conspicuous tertiary venation on the lower leaf surface. From *I. gleasoniana* Steyerm. it differs in the much narrower and thinner leaf blades and in the glabrous calyx.

Ilex summa Steyermark, sp. nov. TYPE: Venezuela. Bolívar: Dist. Piar, Camarcaibarai-tepui, summit, 5°53′N, 61°59′W, 2,400 m, 26 Mar. 1987, *Bruce K. Holst 3617* (holotype, MO; isotype, VEN). Figure 6E.

Frutex 2-metralis, ramulis glabris; foliis ovatis apice apiculatis vel subacutis basi rotundatis vel late obtusis 2.5–4.3 cm longis 1.5–3 cm latis, marginibus superioribus tertiis dentibus 3–5 acutis vel setulosis praeditis glabris ubique punctatis valde revolutis; costa superne sulcata; nervis lateralibus utroque latere 4–5 supra manifeste sulcatis subtus elevatis divaricatis; venulis tertiariis supra obsoletis subtus grosse reticulatis; petiolis 3–6 mm longis glabris; inflorescentia foeminea solitaria axillari lateralique; pedunculis sub fructu 4–6 mm longis; pedicellis sub fructu 4–9 mm longis glabris; bacca globoso 6–7 mm diam.; pyrenis 4 trigonis 4–4.5 mm longis dorsaliter unisulcatis.

Shrub 2 m tall with glabrous branchlets. Leaves coriaceous, ovate, apiculate or subacute at apex, rounded or broadly obtuse at base, 2.5–4.3 cm long, 1.5–3 cm wide, 1.4–1.6 times longer than broad, the upper ⅓ of the margins with 3–5 acute to setulose teeth, glabrous, black-punctate on upper and lower surfaces, the margins strongly revolute; midnerve sulcate above with minute puberulence in sulcation, elevated below; lateral nerves 4–5 each side, prominently sulcate above, elevated below, spreading divaricately, dichotomously branched 2–4 mm from the margins; tertiary venation obsolete above, grossly reticulate below. Petioles 3–6 mm long, glabrous. Pistillate inflorescence solitary, axillary, lateral. Peduncles in fruit 4–6 mm long, glabrous. Pedicels in fruit 4–9 mm long, glabrous. Stigma depressed in fruit. Fruit globose, 6–7 mm diam. Pyrenes 4, trigonous, 4–4.5 mm long, dorsally unisulcate.

This species differs from *Ilex acutidenticulata* Steyerm. in having smaller, broadly ovate leaves rounded or broadly obtuse at base and shortly apiculate at the apex; more numerous marginal teeth; shorter, glabrous petioles; and more divaricately spreading lateral nerves prominently sulcate above and elevated below.

Ilex wurdackiana Steyermark, sp. nov. TYPE: Venezuela. Bolívar: Cerro Venamo, northwest slopes, SE of road camp km 125, to line of NE-facing, sandstone bluffs, 1,100–1,140 m, 21 Apr. 1960, *J. A. Steyermark & S. Nilsson 449* (holotype, VEN). Figure 6F, G.

Frutex epiphytica, ramulis superioribus puberulentibus; foliis rigidi-coriaceis subsessilibus late ovatis vel oblongo-lanceolatis apice acutis vel acuminatis basi late rotundatis vel subcordatis 4–10.5 cm longis 2–6 cm latis integerrimis glabris subtus valde punctatis; costa superne elevata nervis lateralibus utroque latere 4–6 supra subsulcatis vel valde sulcatis subtus elevatis; venulis tertiariis supra obsoletis subtus grosse reticulatis paullo elevatis; petiolis 1–3 mm longis glabris; inflorescentia masculina fasciculata axillari lateralique, pedunculis 7–8 filiformibus cymosis 4–6 mm longis glabris; pedicellis filiformibus 1–2 mm longis glabris; floribus 4-meris; calycis lobis suborbicularibus rotundatis 0.3–0.5 mm longis 0.7 mm latis glabris; inflorescentia foeminea solitaria axillari lateralique; pedicellis sub fructu 2.5–4 mm longis; bacca immatura ovoideo-subgloboso 2.5–3.5 mm longo 3 mm lato.

Woody epiphyte; upper portions of stems puberulent. Leaves stiff-coriaceous, subsessile, broadly ovate or oblong-lanceolate, acute to acuminate at apex, broadly rounded to subcordate at base, 4–10.5 cm long, 2–6 cm wide, entire, glabrous, strongly punctate beneath; upper midrib prominently elevated; lateral nerves 4–6 each side, subsulcate to prominently sulcate above, elevated below; tertiary venation obsolete above, grossly reticulate below. Petioles 1–3 mm long, glabrous. Staminate inflorescence fasciculate with 7–8 filiform, cymosely branched, glabrous peduncles 4–6 mm long; pedicels filiform, 1–2 mm long, glabrous. Flower 4-merous; calyx lobes suborbicular, rounded, 0.3–0.5 mm long, 0.7 mm wide, glabrous. Petals broadly oblong, rounded at apex, 0.7–1 mm long, 0.8 mm wide. Anthers suborbicular-oblong. Pistillate inflorescence solitary, axillary, lateral. Fruiting pedicels 2.5–4 mm long, glabrous. Stigma depressed-flattened. Immature fruit ovoid-subglobose, 2.5–3.5 mm long, 3 mm wide.

Paratype. VENEZUELA. BOLÍVAR: laderas del Cerro Uei, entre los brazos del Río Uei (afluente del Río Venamo y Cuyuni), selva nublada, 865–1,050 m, 27–28 Dec. 1970, *J. A. Steyermark, G. C. K. & E. Dunsterville 104565* (VEN).

This species is noteworthy in its epiphytic shrubby habit. Other distinguishing characters are the conspicuously elevated upper midrib, subsessile leaves, these entire or with a few minute excrescences, broadly rounded to subcordate at base, and the fasciculate staminate inflorescence with filiform peduncles and pedicels. The species is endemic to the region of the Cerro Venamo and tributaries of the Río Venamo and Río Cuyuni.

It is a great pleasure to dedicate this distinct species to Dr. John J. Wurdack, who has identified much material belonging to the genus *Ilex* and who has rendered invaluable help to the author on many occasions.

SAPINDACEAE

ALLOPHYLUS

Allophylus parimensis Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Sierra Parima, vecindades Simarawochi, Río Matacuni, 3°49′N, 64°36′W, 6–7 km west of the Brazil–Venezuela frontier, 795–830 m, 18 Apr.–23 May 1973, *Julian A. Steyermark 107033* (holotype, MO; isotype, VEN). Figure 7.

Arbor 10-metralis, ramulis novellis modice pubescentibus pilis subadpressis praeditis; foliis trifoliolatis petiolatis, laminis lanceolato-ellipticis apice acuminatis basi acutis, foliolis lateralibus sessilibus 4–5 cm longis 1–1.3 cm latis (immaturis), terminali (intermedia) 5.5–6 cm longis 1.5–1.8 cm latis subintegris vel marginibus superioribus denticulatis 1–5 dentibus tenuibus adpressis setulosis instructis, supra glabris subtus praesertim costa sparsim adpresso-pubescentibus; nervis lateralibus utroque latere tenuibus 8–9; petiolis (novellis) 1.5–2.5 cm longis dense adpresso-pubescentibus; thyrsis anguste racemiformibus 3.5–5 cm longis 6–8 mm latis densifloris multifloris; floribus solitariis vel plerumque in cincinnis 2–3-floris dispositis vel interdum axibus infimis elongatis racemiformibus 5–6-floris; pedunculo pedicellisque atque rhachidi adpresso-pubescentibus; sepalis valde ciliatis exterioribus ubique glabris interioribus extus minute pulverulentibus intus glabris; petalis intus dense villosulis; filamentis glabris; disco modice hispidulo.

Tree 10 m tall; young branchlets moderately subappressed pubescent. Leaves 3-foliolate; leaflets lance-elliptic (immature) acuminate at apex, acute at base, the lateral sessile 4–5 cm long, 1–1.3 cm wide; terminal (intermediate) leaf subsessile, 5.5–6 cm long 1.5–1.8 cm wide, entire or the upper margins with 1–5 appressed, slender, setulose teeth, glabrous above, sparsely appressed-pubescent below on surface, midnerve, and lateral nerves; lateral nerves slender, 8–9 on both sides. Young petioles 1.5–2.5 cm long, densely appressed-pubescent. Inflorescence a narrow racemiform thyrse, axillary in the upper leaf axils, with 20–30 short, lateral, sessile or pedunculate cincinni, the upper axes mainly 1-flowered, the others usually 2–3-flowered, sometimes the lowest racemiform, elongated, 5–6-flowered and up to 12 mm long; rachis of inflorescence densely subappressed-pubescent, the hairs antrorsely suberect-ascending; pedicels 1–2 mm long, sparsely puberulous; peduncle 1–2 cm long, densely appressed-pubescent. Outer sepals ovate-oblong, rounded, cucullate, 1.5 mm long, 1 mm wide, strongly ciliate, elsewhere glabrous both sides; inner sepals with incurved margins, suborbicular from a short claw, broader than long, 1.3 mm long, 1.6 mm wide, strongly ciliate, glabrous within, minutely puberulent without. Petals broadly obovate or suborbicular, obovate, rounded at summit, narrowed to the base, 1.1 mm long, 0.7 mm wide above the middle, glabrous without, densely ciliate, within densely barbate-villosulous on the 2-lobed scale and lamina. Disk fleshy, shallowly lobed, moderately hispidulous. Filaments glabrous, 0.8 mm long. Ovary bilobed, suborbicular, densely hispidulous.

This species is allied to *Allophylus strictus* Radlk. and *A. laevigatus* (Turcz.) Radlk., from both of which it differs in the hispidulous disk, glabrous filaments, and sparsely pubescent style. It further differs in the sparingly 1–5-denticulate upper leaf margins with slender appressed teeth, the sparsely puberulous pedicels, more densely pubescent interior of the petals, more densely and closely flowered inflorescence with a densely pubescent rachis, and the sometimes racemosely elongated lowest axes bearing up to 6 flowers.

RUBIACEAE

COUSSAREA

Coussarea evoluta Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Cerro de la Neblina, on hills 1.5 km south of Base Camp on Río Mawarinuma, 0°50′N, 66°10′W, 140–340 m, 4 Dec. 1984, *R. Liesner & D. Bell 17493* (holotype, MO; isotype, VEN). Figure 8.

Stipulae suborbiculares late rotundatae 2–5 mm longae; inflorescentia magna longipedunculata 15–17 cm longa 7–10 cm lata pedunculo incluso, axibus lateralibus elongatis infimis 2–3.5 cm longis; corollae lobis ad dimidium vel magis longitudinem tubi corollae attingentibus recurvatis 7–10 mm longis; floribus sessilibus dense fasciculatis.

Tree, 8 m tall, the stem glabrous; stipule suborbicular, shallow, broadly rounded, 2–5 mm long, 5–8 mm broad, glabrous. Petiole 1.5–2.3 cm long, 3 mm thick, glabrous. Leaf blades large, subcoriaceous, oblong-elliptic, abruptly obtusely acuminate at apex, acumen 1–2 cm long, acute at base, 18–29 cm long, 5.5–13 cm wide, glabrous both sides, domatia absent; midrib prominent and elevated below, impressed above; lateral nerves 10–12 each side of the midrib, ascending from a 25–35° angle; tertiary venation grossly reticulate beneath with large areoles, subelevated on lower surface. Inflorescence pedunculate, 15–17 cm long including the peduncle, 7–10 cm wide at the base, cymose-paniculate, the lateral axes subverticillate; peduncle 6–7.5 cm long, microscopically sparsely puberulent; lowest axes verticillate or subverticillate, usually 3–4, widely spreading, 2–3.5 cm long, the other axes shorter, the lowest tier separated by 4–5 cm from the middle tier, the middle tier separated by 2–3.5 cm from the upper tier; lateral axes usually branched at the apex into 2–3 short, mostly unequal axes 7–15 mm long or unbranched, or with short axes 1–2 mm long, each ending in sessile groups of 2–7 flowers. Flowers sessile; calyx and hypanthium 2.5–3.5 mm long, microscopically sparsely puberulent; hypanthium obconic-urceolate or oblong-obconic, 1.2 mm long, 1 mm wide, obtusely ribbed, minutely puberulent; calyx tube deeply campanulate-urceolate, 2 mm long, 1.5 mm wide, minutely sparsely puberulent; calyx teeth 5, linear or subsubulate, recurved, 0.5 mm long, minute-

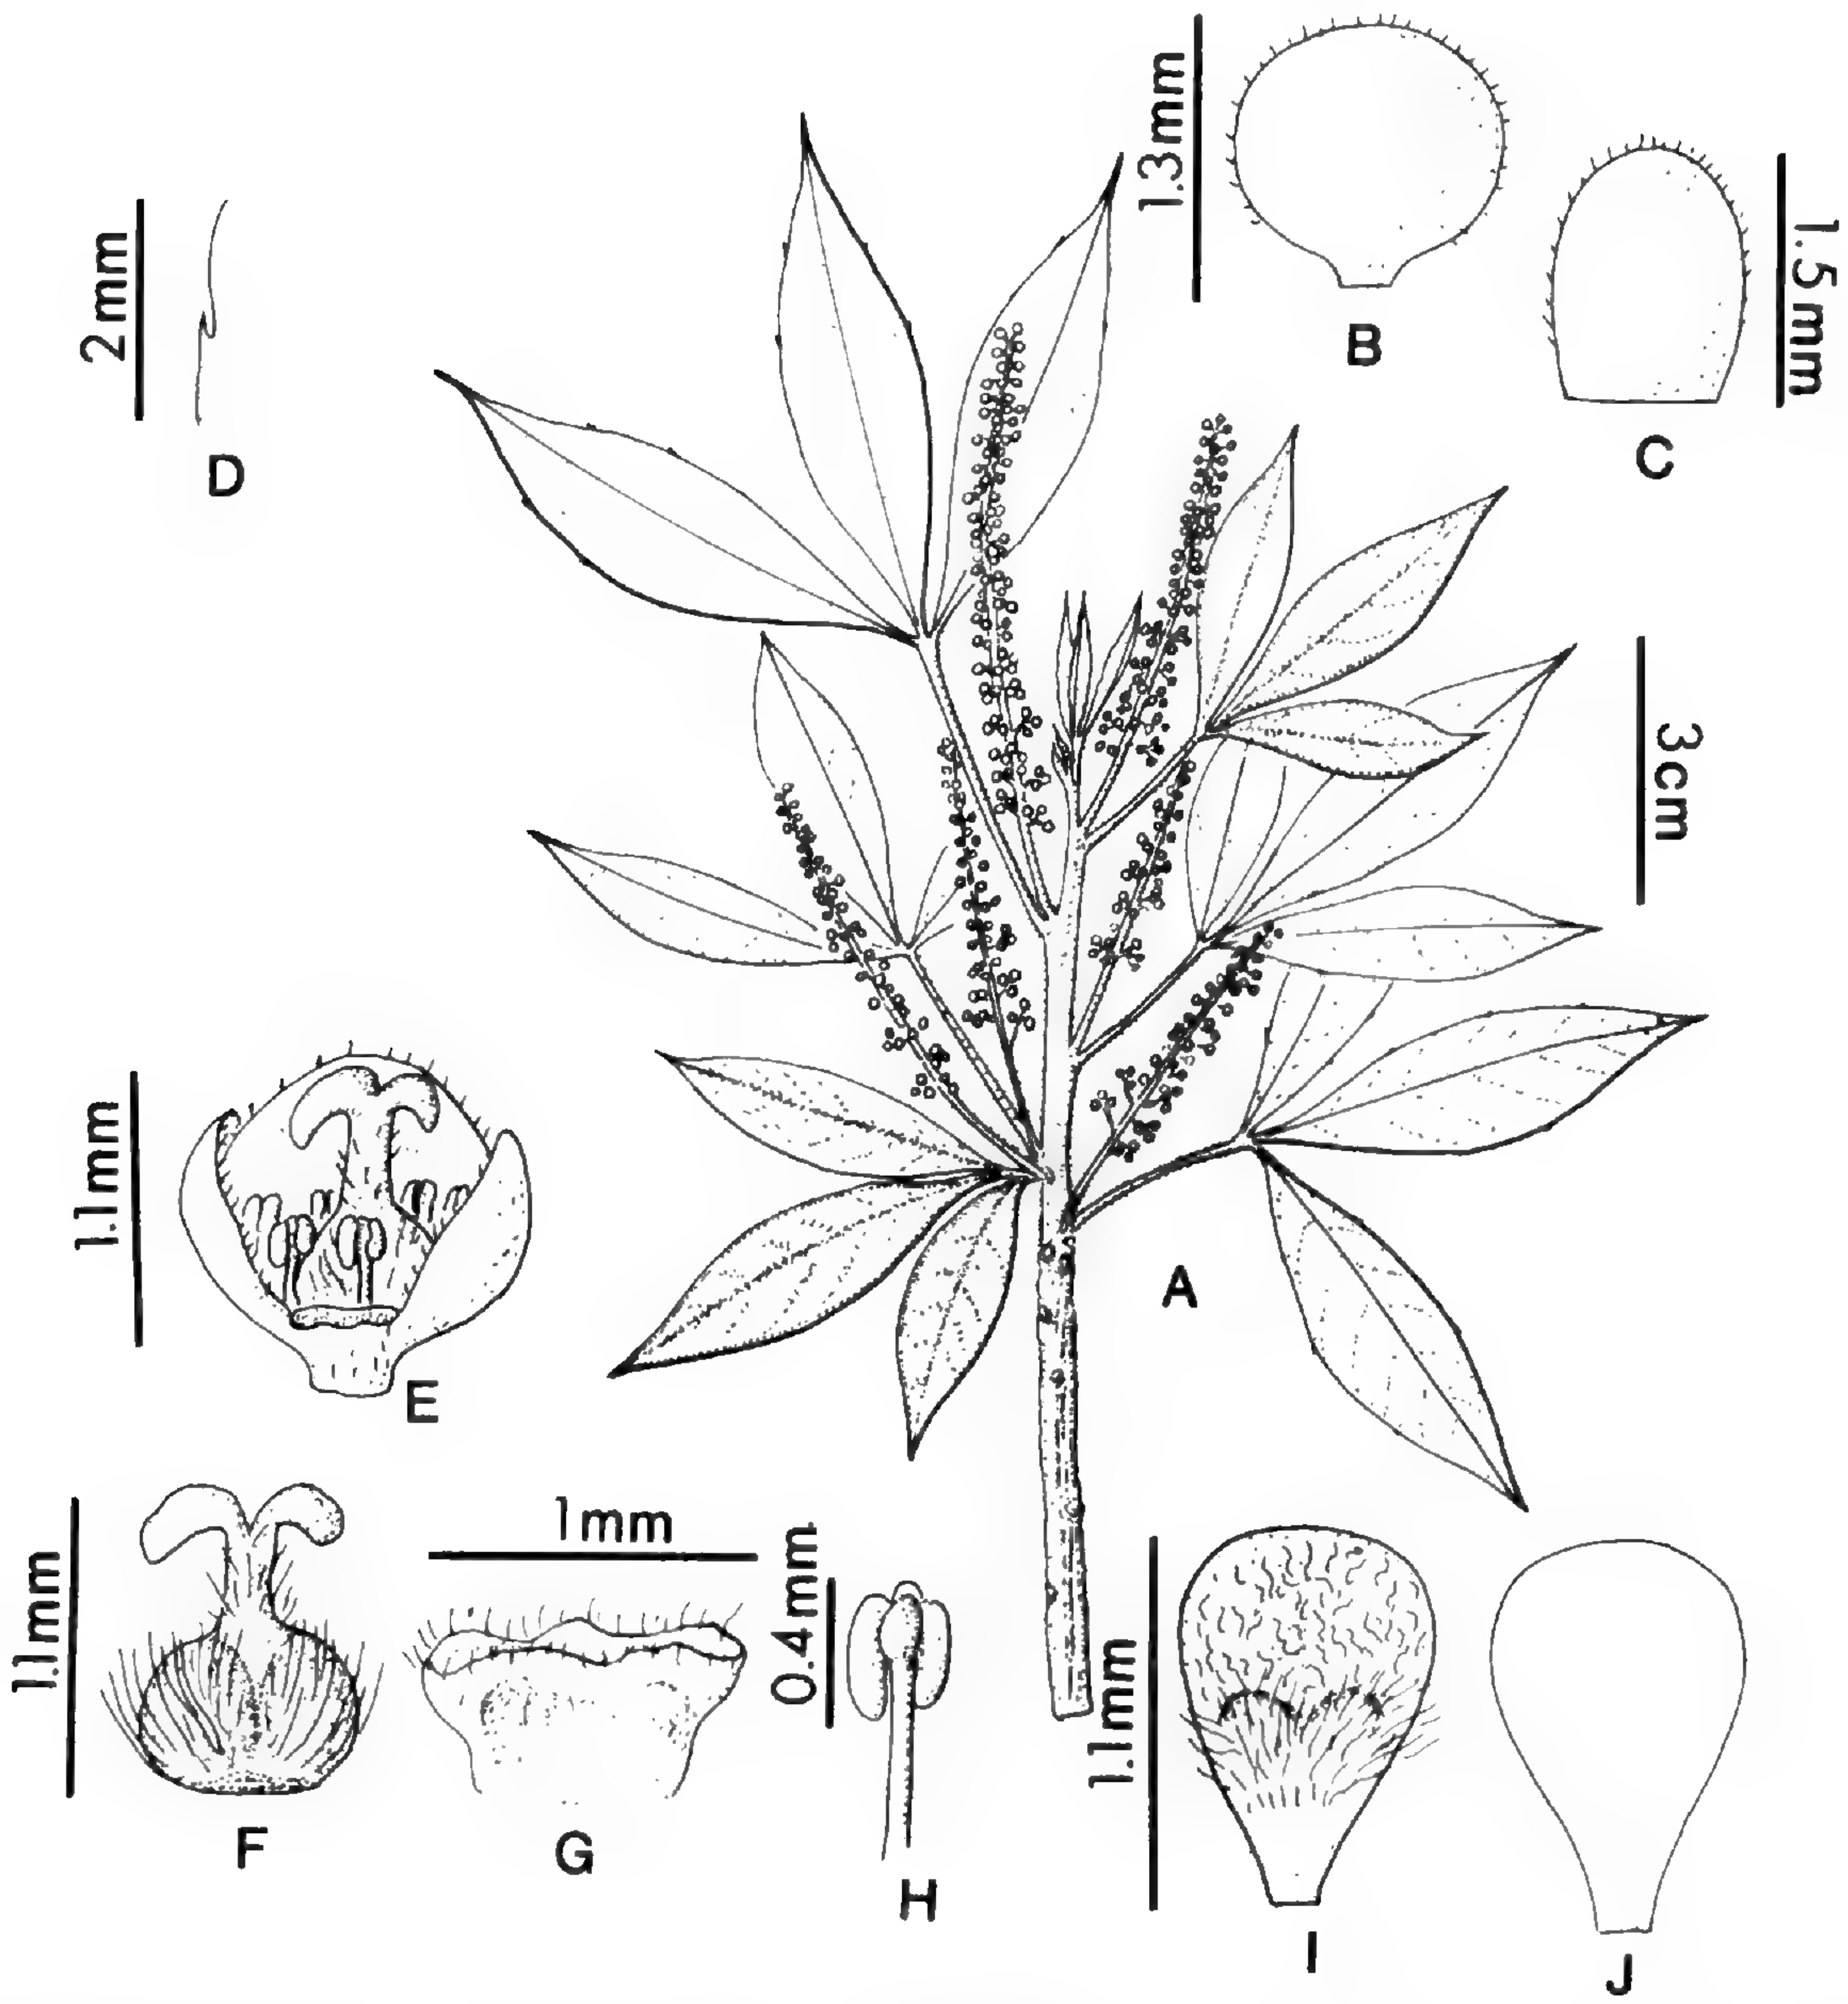

FIGURE 7. Allophylus parimensis.—*A. Habit of flowering branch.—B. Convex dorsal side, inner sepal.—C. Convex dorsal side, outer sepal.—D. Portion of upper margin of leaflet.—E. Flower with one of inner sepals removed.—F. Pistil.—G. Disk.—H. Stamen.—I. Petal, abaxial view.—J. Petal, adaxial view.*

ly hirtellous. Corolla salverform, tube 12.5–13 mm long, 1 mm wide; 4 corolla lobes linear, recurved, 7–10 mm long, 1 mm wide, glabrous within, microscopically puberulent without and at apex, the tube densely papillate-puberulent without. Stamens 4 in the upper 5 mm of corolla tube, included; anthers linear, 4.5 mm long, obtuse at apex with rounded connective, rounded at base. Disk short-columnar, truncate, 0.8 mm long.

This species is characterized by the large inflorescences with elongate lateral axes, compact clusters of sessile flowers, elongated peduncles, corolla lobes at least half the length of the corolla tube, and shallow, rounded stipules.

FARAMEA

Faramea boomii Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Cerro de la Neblina, Base Camp, Río Mawarinuma, terra firma forest, 0°50′N, 66°10′W, 4 Dec. 1984, 140 m, *B. Boom & A. Weitzman 5278* (holotype, MO; isotypes, NY, VEN, GH, PORT, K, BR, COL, U, INPA, P, MG, B, AAU, US).

Stipulae aristatae, aristis 2–3 mm longis; foliorum laminis elliptico-oblongis apice abrupte obtuseque caudatis 10–15.5 cm longis 3–6 cm latis, ad marginem valde incrassatis; inflorescentia latiore quam latiore, floribus breviter pedicellatis; pedicellis 1–1.5 mm longis glabris; bracteis nullis; corolla 25 mm longa, tubo 17 mm longo, lobis lineari-ligulatis 8–9 mm longis basi 1.5 mm latis; antheris 5 mm longis apice breviter cuspidatis.

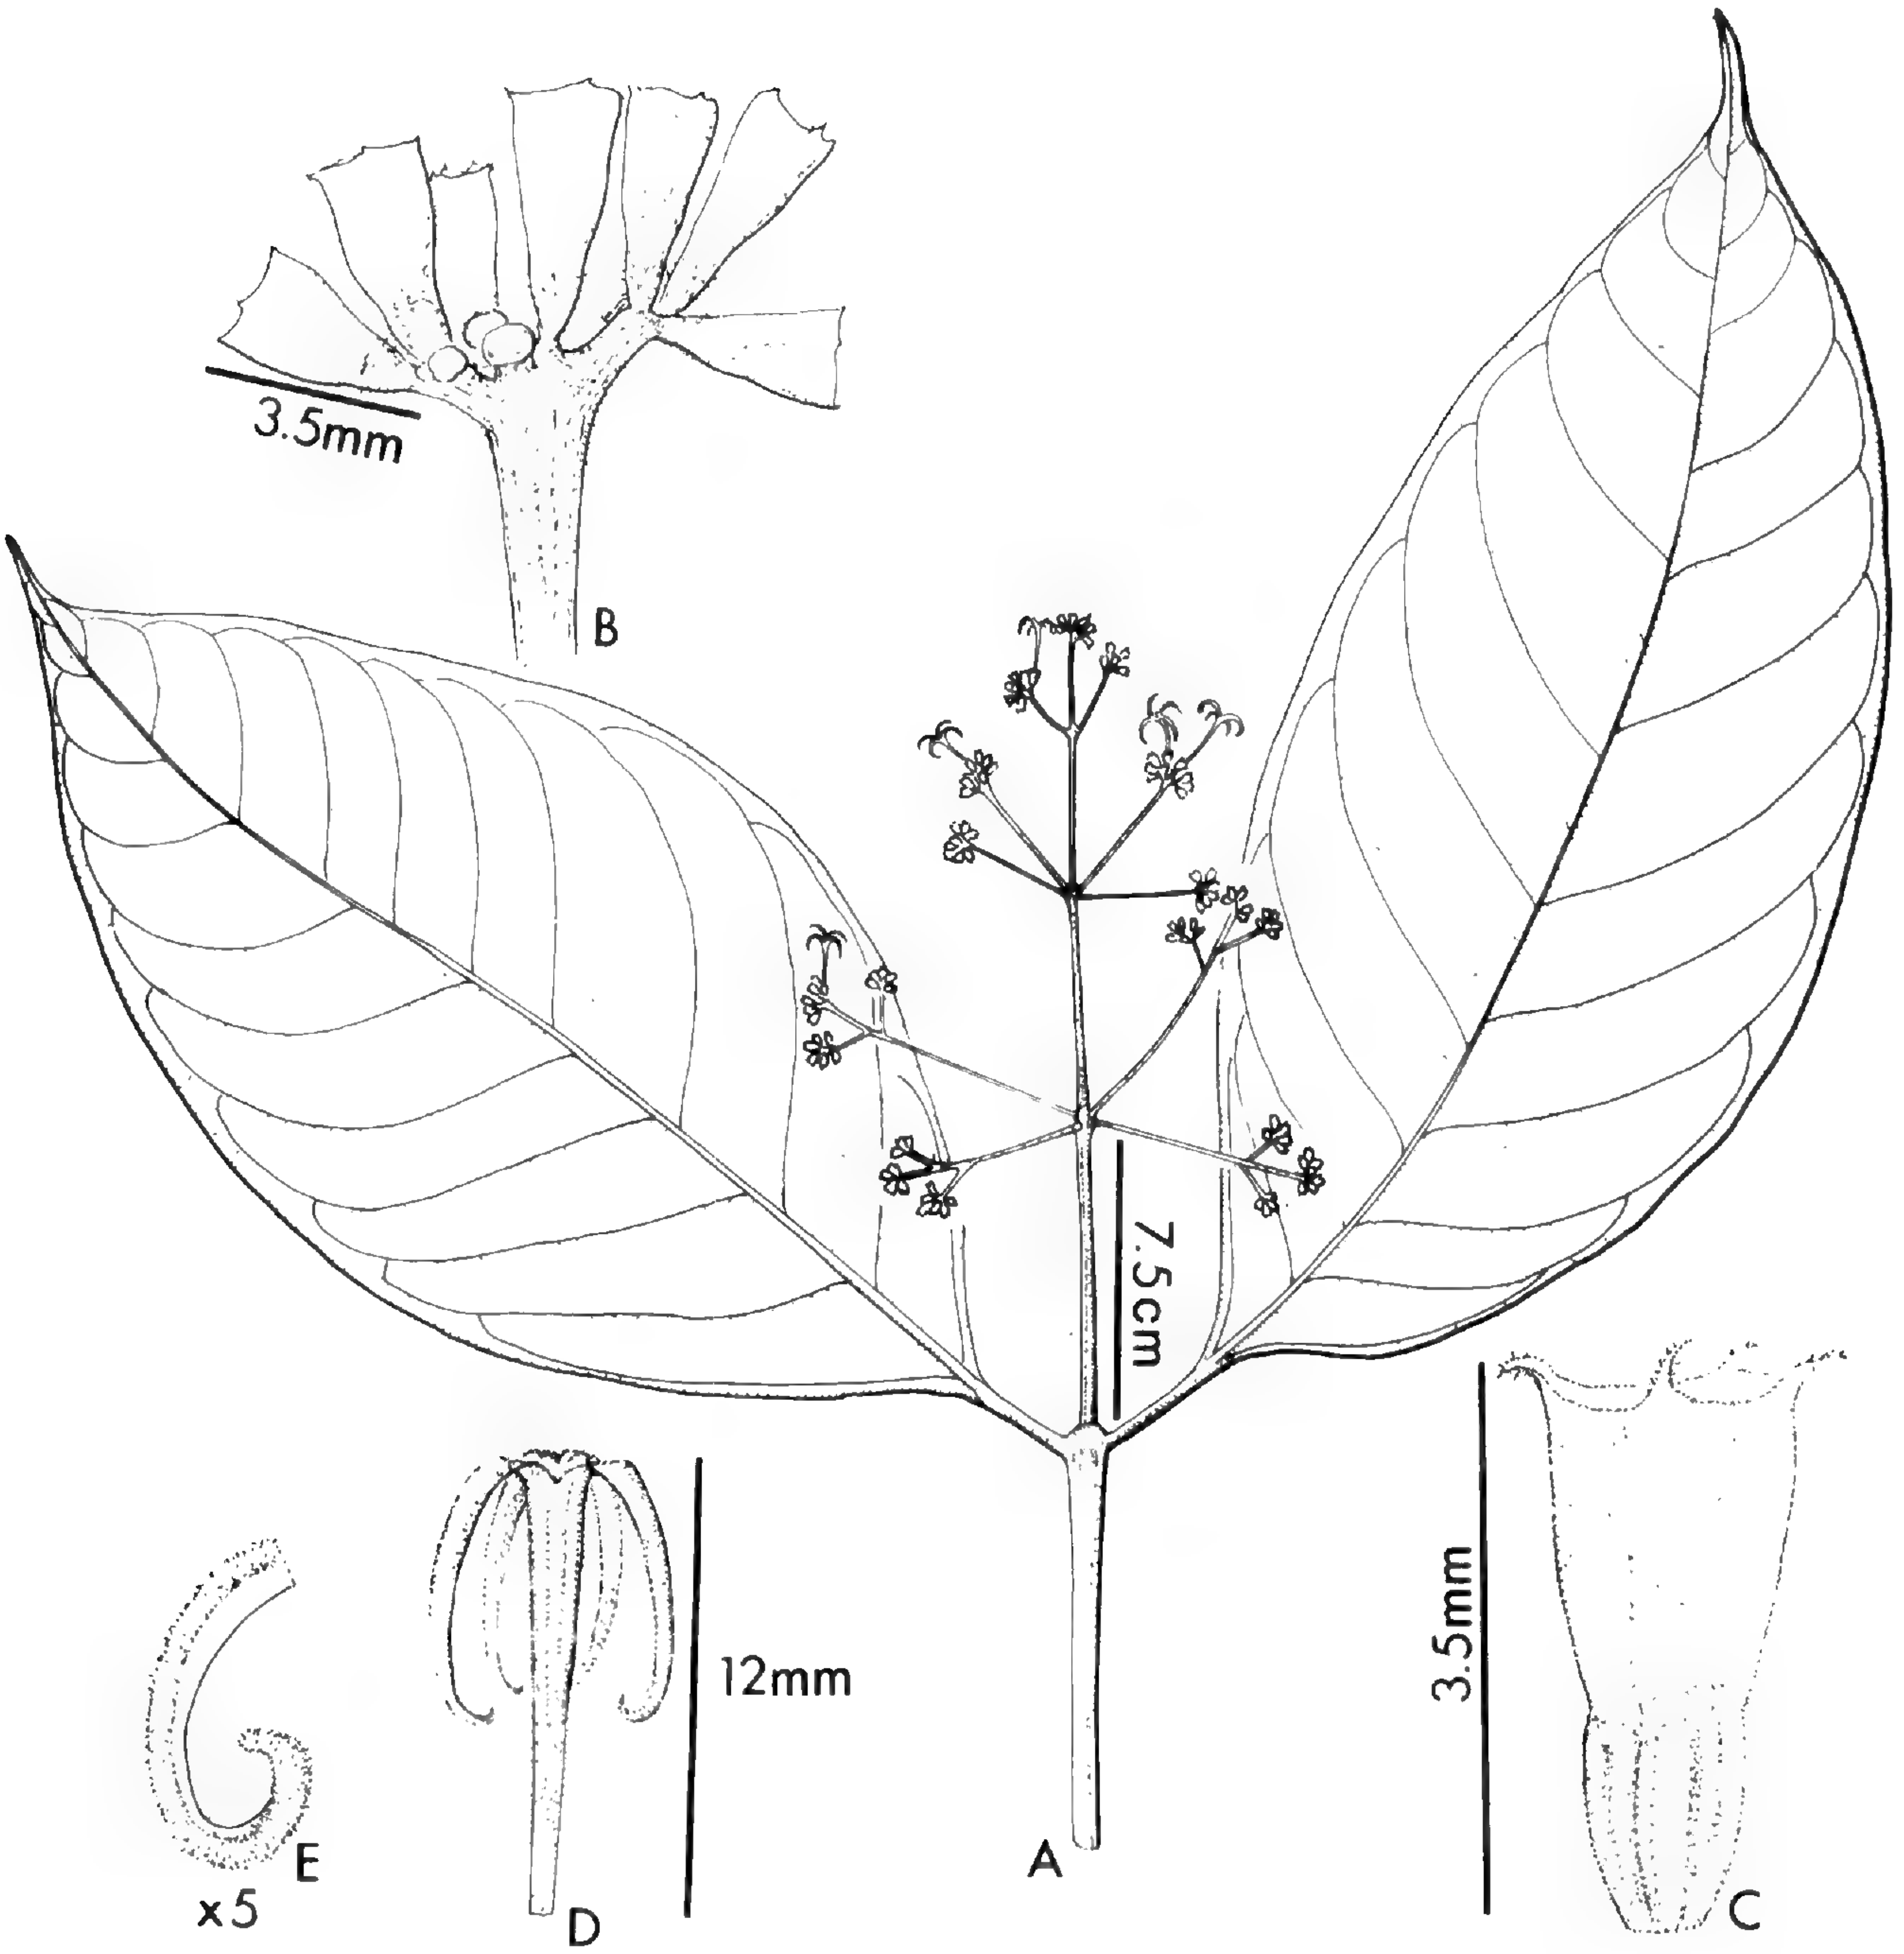

FIGURE 8. Coussarea evoluta.—*A. Habit of flowering branch.*—*B. Detail of portion of inflorescence, corollas absent.*—*C. Calyx and hypanthium.*—*D. Corolla.*—*E. Distal portion of corolla lobe.*

Tree 12 m tall, the young stems glabrous. Stipules persistent, laterally connate, the sheath 2–2.5 mm long, 3 mm wide, abruptly aristate, the arista indurated, 2–3 mm long, arising from just below the summit of the sheath, the part protruding above the summit 2 mm long. Leaf blades elliptic-oblong, abruptly obtusely caudate, acute at base, 10–15.5 cm long, 3–6 cm wide, the obtuse acumen 12–13 mm long, 1.5–2 mm wide, glabrous throughout, with a strong marginal nerve; principal lateral nerves widely spaced 8–13 mm distant, widely spreading-ascending at 10–25° angle, impressed above, slightly elevated below, the intermediate nerves finer and less conspicuous below; petiole 10–13 mm long, glabrous; tertiary venation scarcely evident above, grossly and irregularly reticulate below, slightly manifest. Inflorescence terminal, pedunculate, 3.5 cm long, 6 cm broad, cymosely branched in 3 main divaricately spreading, glabrous axes 10–13 mm long, 0.5 mm diam., each axis branched into 2 lateral axes 5 mm long, mainly 3-flowered with a central short axis bearing a solitary flower; central flower 1 mm long pedicellate, other flowers 1–1.5 mm long pedicellate; pedicels glabrous. Bracts obsolete, not manifest. Calyx and hypanthium 2.5 mm long, glabrous; hypanthium columnar-urceolate, 1.5

mm long, 1.2 mm wide; calyx broadly cupulate, truncate or essentially so at apex, 0.8–1 mm long, 1.2–1.3 mm wide, eglandular within. Disk shortly columnar, 0.8 mm long. Corolla white, salverform, 25 mm long, the tube 17 mm long, 2 mm wide above, narrowing to 0.8 mm wide at base; 4 lobes linear-ligulate, narrowed to a rounded apex, 8–9 mm long, 1.5 mm wide at base, 0.5 mm wide at apex. Stamens 4, included; anthers linear, in the upper third of the corolla tube, cuspidate at apex, 5 mm long, 0.5 mm wide, the cusp 0.3 mm long.

From *Faramea neblinae* Steyerm. this species differs in the aristate stipules, marginally thickened nerves of the leaves, shorter pedicels, and shorter calyx and hypanthium. From *F. crassifolia* Benth. it differs in the longer corolla and anthers, differently shaped leaves, more evident lateral and tertiary nerves on the lower leaf surface, and absence of inflorescence bracts. From *F. angustifolia* Benth. & Hook. it differs in the truncate calyx and longer corolla and anthers. It differs from *F. panurensis* Muell. Arg. by having apiculate anthers, shorter peduncles, thickened marginal nerves, longer anthers, and vaginate stipules.

Faramea morilloi Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Parcela Fénologica, 16 km de Cruce con la carretera a Puerto Ayacucho–Sanariapo, via a Gavilán, 100 m, 17 Nov. 1977, *G. Morillo 6716* (holotype, VEN).

Frutex 1.5–2-metralis glaber; stipulis aristatis, artistis 4–5 mm longis; foliis lanceolato-ellipticis apice acuminatis basi acutis 8–10.5 cm longis 1.5–3.5 cm latis; nervis lateralibus principalibus utroque latere 9–11; petiolis 2–3 mm longis; inflorescentia axillari solitaria; pedicellis sub anthesi 3–5 mm longis sub fructu 5–6 mm longis; bracteis duobus apice pedicelli insidentibus subulatis 10–12 mm longis; hypanthio calyceque 5 mm longis 1.1 mm latis, hypanthio 1 mm longo; calyce sub fructu deciduo; calycis tubo 2 mm longo lobis inaequalibus subulatis 1–2 mm longis; corolla hypocrateriformi, tubo 17 mm longo 1–1.2 mm lato, lobis quattuor angusto lanceolato-subulatis 7 mm longis 1–1.5 mm latis; staminibus quattuor inclusis, antheris linearibus 3 mm longis; stylo 15 mm longo; fructu subgloboso rugoso 9 mm longo 11 mm lato; seminibus orbicularibus 7 mm diam. dorsaliter 8-costatis.

Shrub 1.5–2 m tall, glabrous. Stipular sheath 2 × 2 mm, aristae acicular, 4–5 mm long. Leaves papyraceous, lance-elliptic, acuminate at apex, acute at base, 8–10.5 cm long, 1.5–3.5 cm wide; principal lateral nerves 9–11 each side, with fainter intermediate nerves, widely spreading, conspicuously elevated and anastomosing below, inconspicuously impressed above; tertiary venation faintly reticulate above. Petioles 2–3 mm long. Inflorescence solitary, axillary, shortly pedicellate. Pedicels in anthesis 3–5 mm long, in fruit 5–6 mm long. Two bracts at apex of pedicel subulate, 10–12 mm long. Calyx and hypanthium 5 mm long, 1–1.15 mm wide; hypanthium short-columnar, 1 mm long; calyx deciduous in fruit; calyx tube short-cylindric, 2 mm long, 1.5 mm wide, twice longer than the hypanthium, the lobes unequal, 2 elongated teeth with a lateral subulate appendage, one of the teeth with 2 shorter subulate projections 0.6 mm long on one side and another short subulate projection on the side of a longer tooth. Corolla hypocrateriform, the tube very slender, 17 mm long, 1–1.2 mm wide; 4 lobes narrowly lanceolate-subulate, recurved at tip, 7 mm long 1 mm wide above base, 1.5 mm wide at base. Stamens 4, included, inserted at the summit of the corolla tube. Anthers linear, 3 mm long; filaments 1 mm long, attached 4 mm below orifice of tube. Stigmas subulate, 3 mm long. Fruit depressed-globose, rugose, broader than high, 9 mm high, 11 mm broad. Seed 1, orbicular, 7 mm diam., with 8 longitudinal ridges radiating from dorsal side.

With its solitary axillary flowers, this taxon is related to *Faramea egregia* Sanders and *F. spathacea* Muell. Arg. ex Standley. From both of these it is distinguished by the smaller calyx and hypanthium, smaller corolla tube and lobes, and shorter petioles. The rugose fruits and ridged seeds are noteworthy. From *F. brevipes* Steyerm. it differs in the deciduous fruiting calyx, acutely acuminate leaves, and setaceous (vs. subfoliaceous) bracts subtending the calyx and hypanthium.

Faramea paludicola Steyermark & Boom, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Depto. Río Negro, upper Caño Baria, "swampy" area between Río Mawarinuma and headwaters of Río Baria, ca. 0°52′N, 66°15′W, 130 m, 26 Mar. 1984 (fl. buds), *R. Liesner 16960* (holotype, MO; isotypes, NY, VEN).

A *Faramea torquata* Muell. Arg. foliis nervis marginalibus valde prominentibus differt.

Shrub 2 m tall. Stipule with shallow coriaceous sheath broader than long, 7 mm wide, 4 mm high, glabrous, with a rigid awn 3 mm long arising from the center in a depression below the summit. Leaves coriaceous, elliptic-oblong, abruptly caudate at apex, acute at base, 23–30 cm long, 7–11 cm wide, conspicuously marginally nerved, glabrous on both sides, acumen obtuse, 13–18 mm long, 1.5–2 mm wide; lateral nerves strongly elevated below, impressed above, anastomosing 7–11 mm from margin, principal elevated nerves 15–18 each side; midrib stout, elevated above, impressed below; tertiary venation finely reticulate, subelevated both sides. Petiole glabrous, stout, vaginate in upper half, open adaxially, 15–17 mm long, 4 mm wide. Inflorescence slenderly pedunculate, terminal, 2–3 pedicels arising together, purple, 3–3.5 cm long, 1 mm wide, with 3–4 axes 8–12 mm long arising umbellately and divaricately, these separated 8–10 mm distance by a second higher tier of 3 axes 6–7 mm long, terminating in a final cluster of closely positioned several axes 2–3 mm long; axes of inflorescence purple, microscopically papillate but appearing glabrous; peduncle appearing glabrous, the base subtended by 2 bracteoles united by a suborbicular sheath 1 mm long terminating abruptly in a 2–2.5 mm glabrous awn. Flowers 3–5-umbellate at the ends of the lowest primary axes on pedicels 1–2 mm long. Flowers on purple pedicels, 2–3 mm long, 1 mm wide, ebracteolate. Calyx and hypanthium microscopically papillate-puberulent, 2–2.5 mm long; hypanthium obconic, 1.5–2 mm long, 2 mm wide at summit, gradually narrowed to a base 1 mm long; calyx 2–2.5 mm wide at summit, 0.8–1 mm high, subtruncate or slightly undulate; corolla green in bud, 4 mm long, 1 mm wide at base, 0.8 mm wide at the rounded tip, microscopically papillate-puberulent; corolla lobes in bud 2.5 mm long, ligulate, obtuse; anthers 1.5 mm long, filaments 1 mm long, attached at base of corolla; gynoecium immature. Fruit unknown.

Faramea yavitensis Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Yavita, 28 Jan. 1942, *Llewelyn Williams 14026* (holotype, VEN; isotype, F).

Frutex 2-metralis glaber; stipulis aristatis, aristis 4 mm longis; foliis elliptico-oblongis apice abrupte caudatis, acumine 7–12 mm longe, basi cuneatim acutis 12–16 cm longis 4–6.5 cm latis, nervis lateralibus utroque latere 7–10, venatio tertiaria inconspicua; petiolis 1.2–1.5 cm longis; infructescentia epedunculata, axibus secundariis tribus primariis umbellatis 2.7–3.2 cm longis; axibus secundariis tribus 8–10 mm longis apicem versus dilatatis ramosis, axibus sub fructu 4–5 mm longis; pedicellis sub fructu 4–5 mm longis; bracteis sub pedicellis subulatis persistentibus 2.5 mm longis; bracteis sub axibus primariis persistentibus subulatis 5.5 mm longis, sub axibus secundariis subulatis 3.5 mm longis; calycis tubo sub fructo persistenti 1–1.5 mm longo 1 mm lato, dentibus tribus vel quattuor, setaceis persistentibus sub fructu 2–3.5 mm longis; fructu subgloboso 4–5 mm longo 6–7 mm lato.

Glabrous shrub 2 m tall. Stipular teeth linear, 4 mm long, persistent on upper nodes, deciduous or not evident on lower nodes. Leaves elliptic-oblong, abruptly caudate at apex with acumen 7–12 mm long, cuneately acute at base, 12–16 cm long, 4–6.5 cm wide; lateral nerves 7–10 each side, divaricately spreading at an angle of 5–25°, elevated below, slightly elevated or impressed above; tertiary venation inconspicuous with large, areolate, impressed reticulation on both sides. Petioles 1.2–1.5 cm long. Infructescence epedunculate, the 3 primary rays umbellate, 2.7–3.2 cm long, 1.5 mm wide, each ray terminating in 3 secondary axes 8–10 mm long and dilated apically; secondary axes ending in branches with 2 lateral fruiting pedicels 4–5 mm long on either side of a central sessile fruit. Bracts at base of axes persistent, subulate, those subtending pedicels 2.5 mm long, those subtending secondary axes 3.5

mm long, those subtending primary axes 5.5 mm long. Calyx teeth persistent in fruit, setaceous, 2–3.5 mm long. Fruit depressed-globose, 4–5 mm high, 6–7 mm broad.

This taxon is related to *Faramea multiflora* A. Rich. and its varieties (for discussion of these, see Mem. New York Bot. Gard. 17: 390–395. 1967) but differs from it and related species in having the persistent fruiting calyx with elongated teeth.

Faramea yutajensis Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: below summit of east slope of unnamed peak, 8 km NW of Yutajé settlement, 4 km west of Río Coro Coro, west of Serranía de Yutajé, 5°41′N, 66°10′W, 1,500–1,760 m, 4 Mar. 1987, *R. Liesner & B. Holst 21640* (holotype, MO; isotype, VEN).

Frutex 2-metralis glaber; stipulis aristatis, aristis 2.2 mm longis; foliis oblanceolatis vel lanceolato-ellipticis apice abrupte obtuseque acuminatis basi acute attenuatis 8–14 cm longis 2–4.7 cm latis; acumen 5–12 mm longis, 3 mm latis, nervis lateralibus principalibus utroque latere 7–11 subhorizontaliter patentibus; venatio tertiaria subtus reticulata; petiolis 3–9 mm longis; inflorescentia terminali axillarique fere sessili vel pedunculata, pedunculo solitario 10–15 mm longo glabro infra apicem 2 mm lato basi 1.5 mm lato; bracteis duobus sub fructu ovatis acutis 13–23 mm longis 6–8 mm latis glabris; fructu globoso 9–10 mm longo 10–11 mm lato calyce persistente 2 mm longo 2.5 mm lato coronato.

Glabrous shrub, the stem 1-angled or ridged on each side. Stipular sheath triangular, carinate, 1 mm long, 1.2 mm wide at base, tapering into an acicular awn 2.2 mm long. Leaves oblanceolate or lance-elliptic, abruptly and obtusely acuminate at apex, the acumen 5–12 mm long, 3 mm wide, conspicuously acutely attenuate at base, 8–14 cm long, 2–4.7 cm wide, slightly decurrent on petiole; principal lateral nerves 7–11 each side, subhorizontally spreading, anastomosing near margin, slightly elevated below, slightly sulcate above, intermediate nerves shorter and less conspicuous; tertiary venation reticulate and slightly manifest below, faintly reticulate above. Petioles 3–9 mm long. Inflorescence terminal and axillary, nearly sessile or on a peduncle 10–15 mm long. Peduncles slightly dilated to 2 mm toward summit, 1.5 mm wide at base, solitary. Subtending two bracts at base of fruit ovate, acute, 13–23 mm long, 6–8 mm wide. Fruit globose, 9–10 mm high, 10–11 mm wide, crowned by the persistent calyx tube, this 2 mm long and 2.5 mm wide.

This species is distinguished by having solitary primary inflorescence axes with only one or few flowers which terminate the peduncle and by the subtending enlarged bracts. *Faramea yutajensis* differs from *Faramea anisocalyx* Poeppig & Endl. by having smaller green bracts and by having the solitary primary ray bearing one to few flowers. From *F. parvibractea* Steyerm. and *F. cardonae* Steyerm. it differs in the solitary peduncle with one to few flowers.

FERDINANDUSA

Ferdinandusa boomii Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Cerro de la Neblina, Base Camp, Río Mawarinuma, 0°50′N, 66°10′W, 8 Dec. 1984, 140 m, *B. Boom & A. Weitzman 5274* (holotype, MO; isotypes, NY, VEN, GH, INPA, PORT, U, COL, BR, K).

A *F. schultesii* Steyerm. corollis longioribus, pedicellis longioribus, foliis majoribus plerumque basi late rotundatis vel subcordatis recedit; corollis 40–41 mm longis, tubo 35 mm longo; pedicellis 2–4 mm longis; foliis 7.3–14 cm longis 5–9 cm latis basi rotundatis vel paullo subcordatis.

Tree 10 m tall; stems densely puberulent; petioles glabrous both sides, 8–15 mm long. Leaf blades coriaceous, ovate to oblong-ovate, abruptly shortly and obtusely acuminate at apex, rounded or slightly subcordate at the base, 7.3–14 cm long, 5–9 cm wide, the acumen 5–6 mm long, 2–3 mm wide, glabrous on both sides; lateral nerves 7–8 each side of midrib, arcuate-ascending to the margins; tertiary venation conspicuously reticulate above, the smaller areolae 2–3 mm diam. Inflorescence terminal with 3–5 pedunculate cymes, 4–4.5 cm long, 4–4.5 cm wide, each cyme 4–12-flowered; peduncle of each cyme 1–2 cm long, minutely puberulent-hirtellous with divaricate hairs; axes of cyme similarly pubescent. Calyx and hypanthium 2–2.5 mm long, the hypanthium columnar-obconic; calyx lobes 4, deltoid, obtusely acute, 0.2–0.5 mm long, 0.7 mm wide at base, sparsely short ciliolate on margins and in sinuses, apparently eglandular within. Disk shorter than to equaling calyx lobes. Corolla 40–41 mm long, glabrous without and within, the tube 35 mm long, 2.5 mm wide throughout except at orifice where 5 mm wide; 4 lobes 4 mm long, 4.5–5 mm wide, lobed above the middle, glabrous within and at sinuses; 4 stamens unequally inserted above style, in the upper ⅛ of the tube; anthers broadly oblong, 1.2 mm long, rounded at both ends; filaments 5 mm long. Style ending 7 mm below orifice of corolla.

From *Ferdinandusa schultesii* Steyerm. to which this species is related, it is separated by the longer corolla and corolla tube, longer pedicels, and larger leaves generally broadly rounded to subcordate at the base.

MORINDA

Morinda longipedunculata Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Dept. Río Negro, Cerro de la Neblina, Canyon Grande, along Río Mawarinuma between the mouth of the canyon and the first major fork of the river, 7 airline km ENE of Puerto Chimo, 0°50′N, 66°02′W, 350–400 m, 9–14 July 1984, *G. Davidse & J. S. Miller 27327* (holotype, MO; isotype, VEN). Figure 9.

Frutex 2-metralis; foliis late oblanceolatis apice abrupte caudatis basi cuneatis 17–30 cm longis 6–8 cm latis supra glabris subtus modice hirtellis pilis patentibus instructis; pedunculis axillaribus 20 cm longis breviter puberulis; floribus 4-meris; calyce cupuliformi-campanulato 1.5 × 1.5 mm subtruncato extus hispidulo; corolla cylindrica extremitatibus angustatis alabastro 8 mm longa extus hispidula.

Shrub 2 m tall; upper part of stems densely pubescent with short, appressed-ascending hairs. Stipule deeply bifid, short-pubescent without, the subulate teeth 2.5 mm long. Petioles 1.5–2 cm long, moderately hirtellous. Leaf blades membranous, broadly oblanceolate, abruptly caudate at apex, long tapering to a cuneate decurrent base, 17–30 cm long, 6–8 cm wide, upper surface with scattered, pale raphides, glabrous, the lower surface moderately hirtellous with spreading hairs; midrib and lateral nerves densely pubescent with spreading hairs 0.5–0.6 mm long; lateral nerves 9–10 each side; tertiary venation inconspicuous below, scarcely manifest above. Peduncles axillary, greatly elongated, equaling or slightly shorter than leaves, 20 cm long, 2 mm wide, moderately shortly puberulous, apically branched into 3–4 primary axes 9 mm long in anthesis, the primary axes again branched into 3–4 secondary axes 3–4 mm long (in anthesis), 10 mm long (in fruit). Bracts at base of secondary axes shallowly 3–4-lobed, 2 mm long (fruiting). Flowers 4-merous, at summit of secondary axes, congested, sessile, several. Calyx cupuliform-campanulate, 1.5 × 1.5 mm, subtruncate with shallowly raised border, hispidulous without. Corolla cylindric-tubular, 8 mm long (late bud), 1.5 mm wide at the middle, slightly narrower at apex and base, outer surface hispidulous except glabrous in basal 1.2 mm; tube glabrous within; lobes suborbicular, rounded, 0.5 × 0.5 mm. Stamens inserted in the lower third of the corolla; anthers linear-oblong, 2.2 mm long. Disk cupuliform, 0.5 mm high. Ovary 4-celled. Fruit dark red, globose, 7–8 mm long, 8–8.5 mm diam., umbonate, 4-seeded.

This taxon is noteworthy for the exceptionally elongated peduncle.

PSYCHOTRIA

Psychotria anartiothrix Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Dept. Río Negro, lower part of Río Baria, inundated forest along river, 1°10′N, 66°25′W, 22–23 July 1984, 80 m, *Gerrit Davidse 27651* (holotype, MO; isotype, VEN).

Frutex 2-metralis, stipularum aristis acicularibus 5–6 mm longis minute puberulentibus glabrescentibus; foliis elliptico-lanceolatis extremitatibus acutis 4–8.5 cm longis 1–2.5 cm latis; inflorescentia dense cymoso-corymbosa,

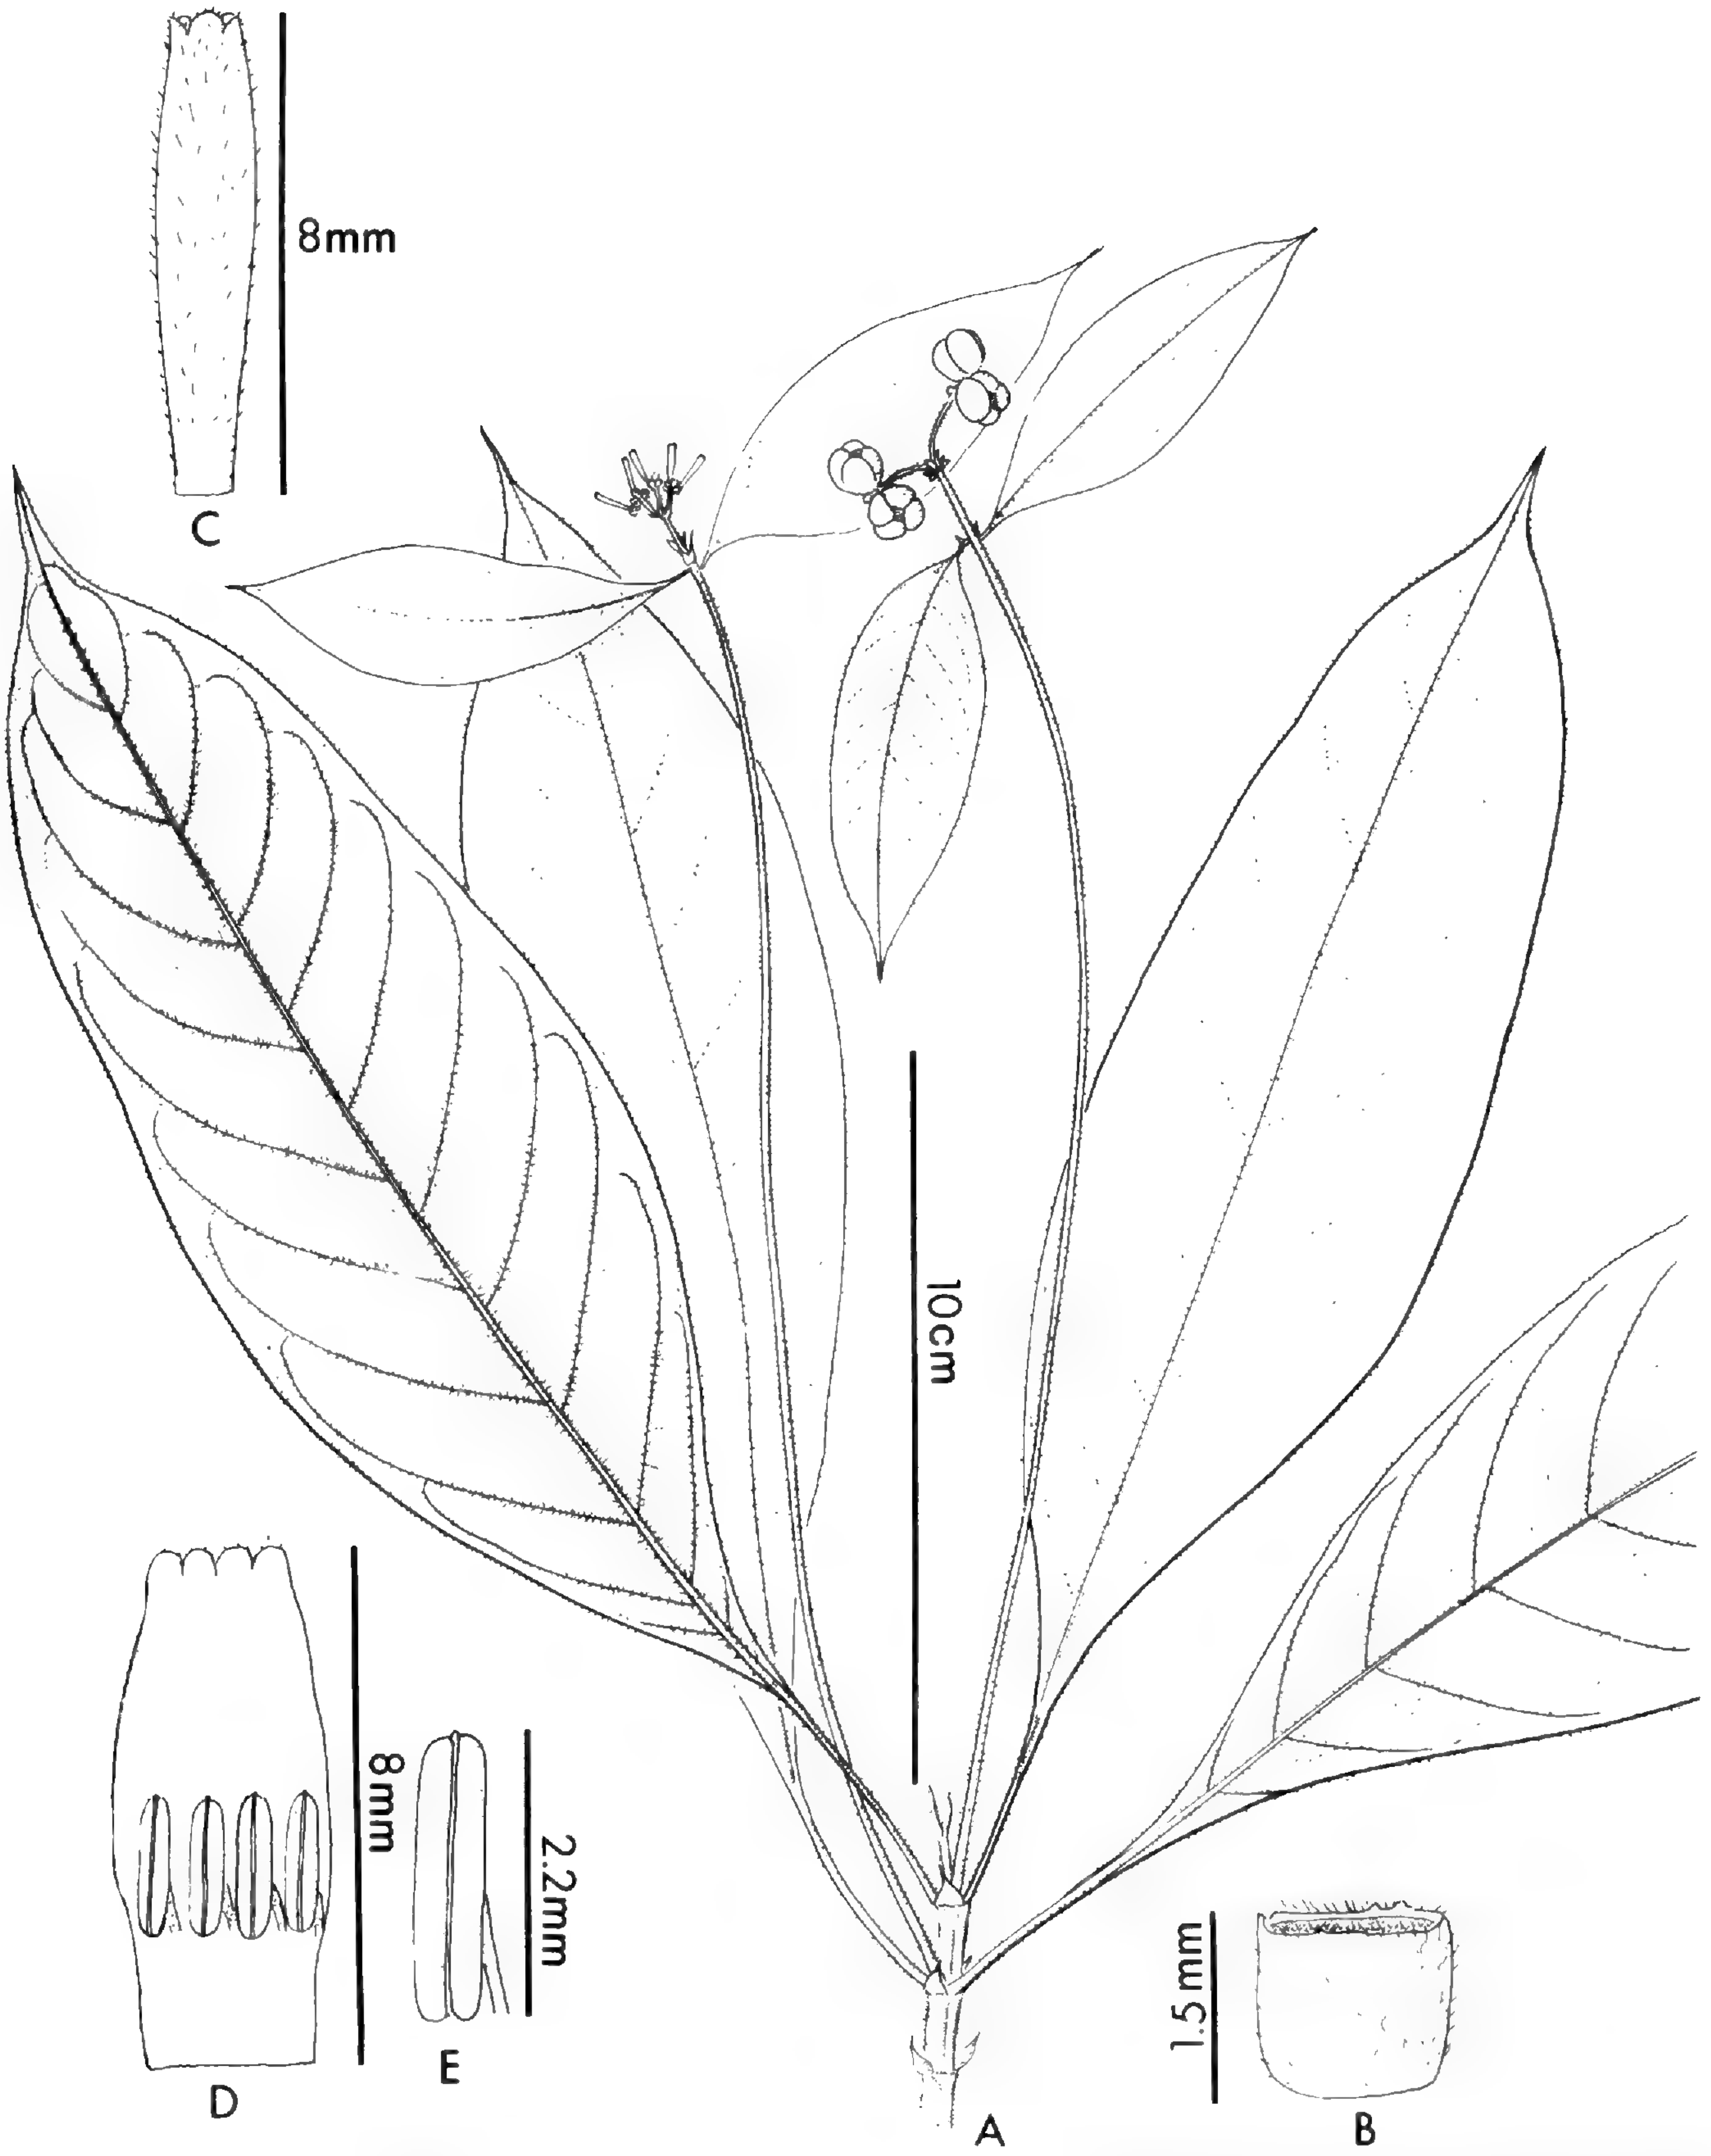

FIGURE 9. Morinda longipedunculata.—*A. Habit of flowering and fruiting branch.—B. Calyx and hypanthium.—C. Corolla, late bud stage.—D. Corolla, interior view.—E. Stamen, ventral view.*

axibus principalibus tribus angulis superioribus seriebus verticalibus pilis brevibus divaricatis rigidiusculis praeditis; corollae tubo hypanthioque similiter pubescentibus.

Shrub 2 m tall with glabrous stems. Stipular sheath 1 mm long, 2 mm wide, truncate, bearing on each side 2 acicular teeth 5–6 mm long arising 0.3 mm below summit of sheath, minutely puberulent becoming glabrous. Leaf blades subcoriaceous, elliptic-lanceolate, acute at base and apex, 4–8.5 cm long, 1–2.5 cm wide, glabrous throughout except for minutely hispidulous puberulous midrib on lower side, or completely glabrous; lateral nerves 8–9 on each side of midrib, arcuately ascending at 15–30°, subelevated below, slightly anastomosing near (1–2 mm) the margin, inconspicuous above; tertiary nerves slightly evident both sides. Inflorescence densely cymose-corymbose, 8 mm high, 1.6 cm broad, pedunculate; peduncle 1.4–1.8 cm long, 1 mm diam., microscopically puberulent on the angles with spreading hairs. Three main axes of inflorescence 2–3 mm long, 0.5–1 mm wide, densely flowered, shortly branched, microscopically puberulent with spreading, stiff, puberulent-hispidulous hairs in vertical lines on the angles. Flowers sessile; calyx and hypanthium 1.2 mm long in anthesis; hypanthium short-columnar, 0.5 mm long, 0.4 mm wide, minutely hispidulous on angles, glabrous elsewhere; calyx cupulate, 5-lobed, 0.7 mm long, 1.1 mm broad; teeth broadly shallowly triangular, subacute, 0.5 mm long, 0.8 mm wide, ciliolate on margins, dorsally puberulent, eglandular within. Corolla white, cylindric, broadened at orifice, 5 mm long; tube 3.5 mm long, 0.7 mm wide except 1 mm wide at orifice and 0.9 mm wide at base, sparsely puberulent-hispidulous in lines without, pilose in upper 1.5 mm within; 5 lobes fleshy and thickened with a corniculate apex 1.5 mm long, 0.6 mm wide, puberulent in lines. Stamens 5, included, attaining the orifice, the upper half of corolla; anthers linear, obtuse at apex, 0.8 mm long. Stigmas 2, rhomboid-ligulate, truncate at apex, papillate-puberulent, 0.3 mm long; style filiform, papillate, 3 mm long. Disk depressed cupulate, shorter than calyx lobes, 0.4 mm high. Fruit orange, globose, 5 × 5 mm; pyrene dorsally acutely 3-costate, ventrally flat with a narrow sulcate depression along the middle.

The minute puberulence of short, stiffish, divaricate hairs in more or less irregular vertical lines along the upper angles of the inflorescence axes, exterior of corolla tube, and the hypanthium is characteristic of this taxon.

Psychotria edaphothrix Steyermark, sp. nov. TYPE: Venezuela. Bolívar: 0–3 km west of El Polo (8.6 km west of El Pauji), 4°30′N, 61°40′W, 650–800 m, 5 Nov. 1985, *R. Liesner 19595* (holotype, MO; isotype, VEN). Figure 10.

Frutex 3-metralis; stipulae vagina 2 mm longa 5.5 mm lata glabra in dentes duos triangulari-lanceolatos longiattenuatos 4 mm longos 1.5 mm latos glabros desinenti; foliorum laminis oblongo-ellipticis vel late oblanceolatis apice acuminatis basi acutis utrinque glabris; nervis lateralibus principalibus utroque latere 17–21; venulis tertiariis cum nervis lateralibus conspicue transversim conjunctivis; inflorescentia capitulis subhemisphaericis tribus densifloris praedita, pedunculo 1.2–6 cm longo dense tomentoso pilis brunneis divaricatis munito; hypanthio dense tomentoso-hirsutulo; calycis lobis 0.8 mm longis ciliatis; corolla alba, sub anthesi 14 mm longa basi 2 mm lata omnino symmetrica, tubo intus basi pilis brevibus vestito.

Shrub 3 m tall, the stem glabrous. Stipule sheath 2 mm high, 5.5 mm wide, glabrous with 2 triangular-lanceolate, long-attenuate teeth on each side, 4 mm long, 1.5 mm wide at base, interior of sheath with numerous aculeiform processes. Leaves oblong-elliptic to broadly oblanceolate, acuminate at apex, acute at base, (9.5–)17–25 cm long, (3–)6–8.5 cm wide, glabrous both sides; lateral nerves 17–21 each side, ascending at an angle of 25–35°, elevated below, impressed above; tertiary veinlets conspicuously transversely connecting the secondary nerves, conspicuously elevated below with reticulate pattern. Inflorescence 2.5–4 cm high, 2.5–6 cm wide, divided into 3 densely-flowered, subhemispherical heads, these 1.7–2.5 cm high, 1–3 cm broad; peduncle 1.2–6 cm long, 1.5–2.5 mm wide, densely brown tomentose with spreading hairs. Main axes of inflorescence 0.8–2 cm long, ascending to divaricate, densely brown tomentose. Bracts of inflorescence lanceolate, caudate-acuminate, arising at the sides and apices of the axes, but not at their bases. Flowers 15–21 in one branched axis, 42–63 in one inflorescence, sessile, each flower subtended laterally by 2 lanceolate, caudate bracts 6 mm long, 1 mm wide, puberulous on both sides, the 2 bracts subtended by a larger middle bract 9 mm long, 2.5 mm wide, oblanceolate, acuminate-caudate, puberulous on both sides, with a larger outer bract, this lanceolate, caudate-acuminate, 13 mm long, 3 mm wide, puberulous on both sides. Calyx and hypanthium 2 mm long, the hypanthium 0.5 mm high, 1.5 mm wide,

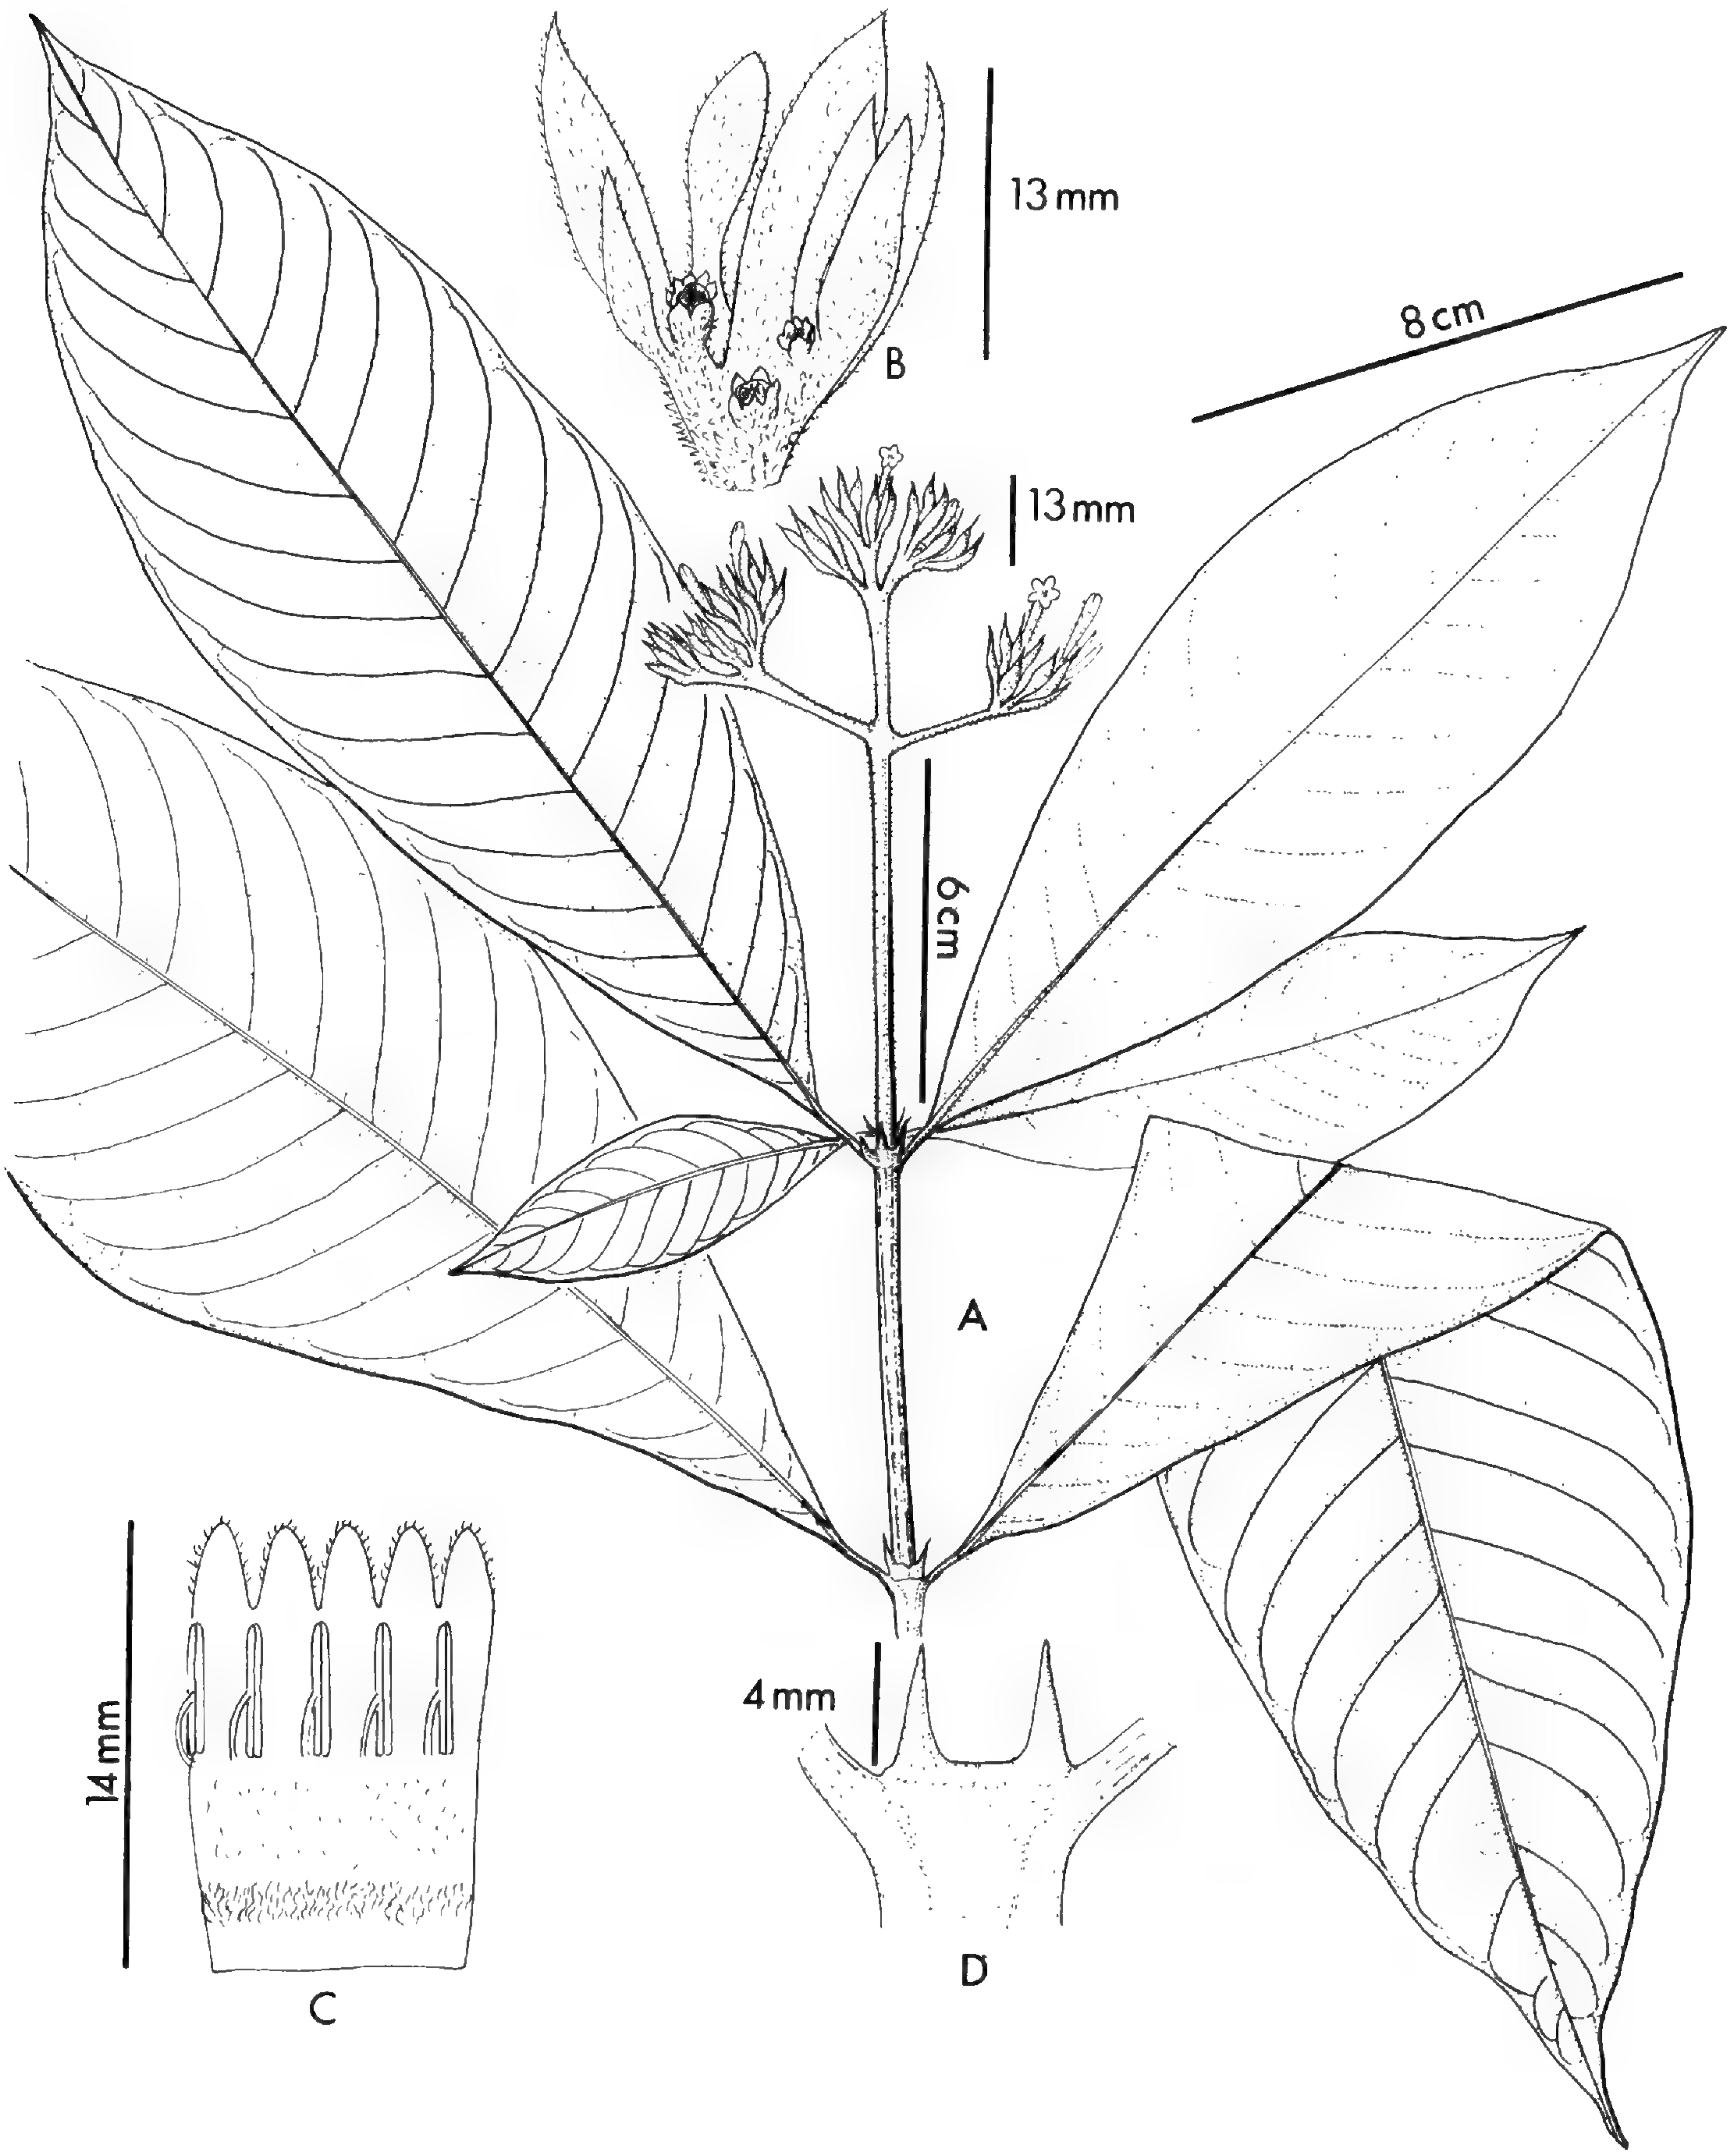

FIGURE 10. Psychotria edaphothrix.—*A. Habit of flowering branch.—B. Portion of inflorescence, corollas absent.—C. Corolla, interior view.—D. Stipule with bases of petioles.*

densely brown tomentose-hirsutulous; calyx lobes 5, deltoid, obtusely acute, 0.8 mm long, 1 mm wide at base, ciliate, glandular within in sinuses. Corolla white, cylindric, symmetric, 14 mm long, 3.5 mm wide below orifice, 2 mm wide at base, densely pilosulous without with spreading hairs, glabrous without at the very base, within shortly pubescent at base with a zone of hairs 1 mm above base; corolla lobes oblong-ovate, 2 mm long, 1.2–1.5 mm wide. Stamens 5, included in the upper half; anthers linear, obtuse at apex, 3 mm long, the filaments inserted half way up corolla tube. Disk subcupulate, about the height of the calyx tube.

Psychotria edaphothrix is somewhat intermediate between *Palicourea* and *Psychotria*, in some respects resembling *Palicourea longistipulata* (Muell. Arg.) Standley in the densely pubescent zone confined to the interior base of the corolla tube, aculeiform structures within the stipular sheath, pubescent exterior of the corolla, and large leaves with numerous lateral nerves. It differs, however, in the large subtending bracts of the compact inflorescence, densely tomentose calyx, glabrous stem and leaves, and white, symmetrical corolla and white bracts. In other respects the new taxon resembles *Psychotria maturacensis* Steyerm. of the Neblina area, but the stipular sheath is conspicuously bidentate on each side, the hypanthium is densely tomentose, the calyx lobes are conspicuous and densely ciliate, and the leaves have more lateral nerves on each side. Since the corolla is symmetrical and shows no gibbosity at base, I am including it in *Psychotria* as a borderline species.

Psychotria pectinata Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Cerro de la Neblina, white water tributary of Río Mawarinuma, ca. 3 km upstream (SE) of Base Camp, 0°49'N, 66°08'W, 150 m, 17 July 1984, *Ronald Liesner 15955* (holotype, MO; isotype, VEN). Figure 11.

Frutex 0.75–2 metralis, caulibus glabris; stipulae dentibus setaceis 4–5 mm longis 0.2–0.3 mm latis dense pectinato-ciliatis pilis brunneo-hirtellis vestitis; foliorum laminis anguste oblanceolatis vel lanceolato-ellipticis apice acutis vel acuminatis basi cuneatim acutis utrinque glabris 10–15 cm longis 1.5–2.5 cm latis; inflorescentia monocephala vel in capitula tria vel quattuor ramosa 5–6 mm longo 10–11 mm lato densiflora; pedunculo 3–13 mm longo 1 mm lato glabro; bracteis sub inflorescentia duas, anguste lanceolatis 4 mm longis; floribus parvis, corollae tubo 2 mm longo, lobis 1.8 mm longis valde corniculatis; fructu elliptico-oblongo 9 mm longo 5 mm lato obtuse 10-costato.

Shrub 0.75–2 m tall, the stems glabrous. Stipular sheath 2.5–3 mm long, 4 mm wide with 2 elongated, setaceous or lance-linear teeth 4–5 mm long, 0.2–0.3 mm wide, densely pectinate-ciliate with brown, hirtellous hairs. Petiole 5–15 mm long, glabrous. Leaves lanceolate-elliptic or narrowly oblanceolate, acute to acuminate at apex, cuneately acute at base, partly decurrent on the petiole, 10–15 cm long 1.5–2.5 cm wide, glabrous on both sides; lateral nerves 8–10 each side of the midrib, 1.5–3 mm distant, slightly impressed on both sides, the midrib slightly raised above. Inflorescence capitate, 5–6 mm high, 10–11 mm broad, monocephalous or branched into 3–4 heads, 15–40-flowered, axillary or terminal, with 2 spreading bracts at the base at the summit of the peduncle. Peduncle erect, 3–13 mm long, 1 mm wide, glabrous. Each axis of the inflorescence bearing ca. 5 closely crowded, pedicellate flowers and subtended by 3–4 lanceolate, acute, brown-ciliate bracts 1.5 mm long. Pedicels 0.5–1 mm long, glabrous. Calyx tube and hypanthium 1.5–2 mm long, glabrous; hypanthium obconic, 1 mm long, 1–1.5 mm above; calyx lobes 5, conspicuous, spreading and slightly squarrose, lanceolate, acute, 0.8–1.5 mm long, 0.5–0.6 mm wide, ciliolate. Disk higher than calyx tube in anthesis, fleshy, oblong-ovoid. Corolla white, small, the tube broadly cylindric, 2 mm long, 1.5 mm wide at summit, 1.3 mm wide at base, glabrous without; lobes 5, recurved, 1.8 mm long, 0.8 mm wide, conspicuously corniculate, the tube densely pubescent within at orifice. Stamens at orifice, slightly protruding above the tube; anthers 0.5 mm long; filaments 0.4 mm long. Style filiform, glabrous, 2 mm long, exserted. Fruit elliptic-oblong, 9 mm long, 5 mm wide, glabrous, obtusely 10-costate, crowned by the persistent calyx.

Paratypes. VENEZUELA. TERRITORIO FEDERAL AMAZONAS: Cerro de la Neblina, Río Mawarinuma, upstream from Base Camp, 0°50'N, 66°10'W, 140 m, 2 May 1984, *Stein, Gentry & Thomas 1715* (MO, VEN); Cerro de la Neblina, Caño Blanco, white water tributary of Río Mawarinuma, ca. 3 km upstream (SE) of Base Camp, 0°49'N, 66°8'W, 150 m, *Miller 1766* (MO, VEN); same locality, *Boom et al. 5714* (MO, GH, INPA, PORT, U, NY, VEN); same locality, *Croat 59612* (MO, VEN).

This species is readily distinguished by the densely hirtellous, pectinate-ciliate stipular

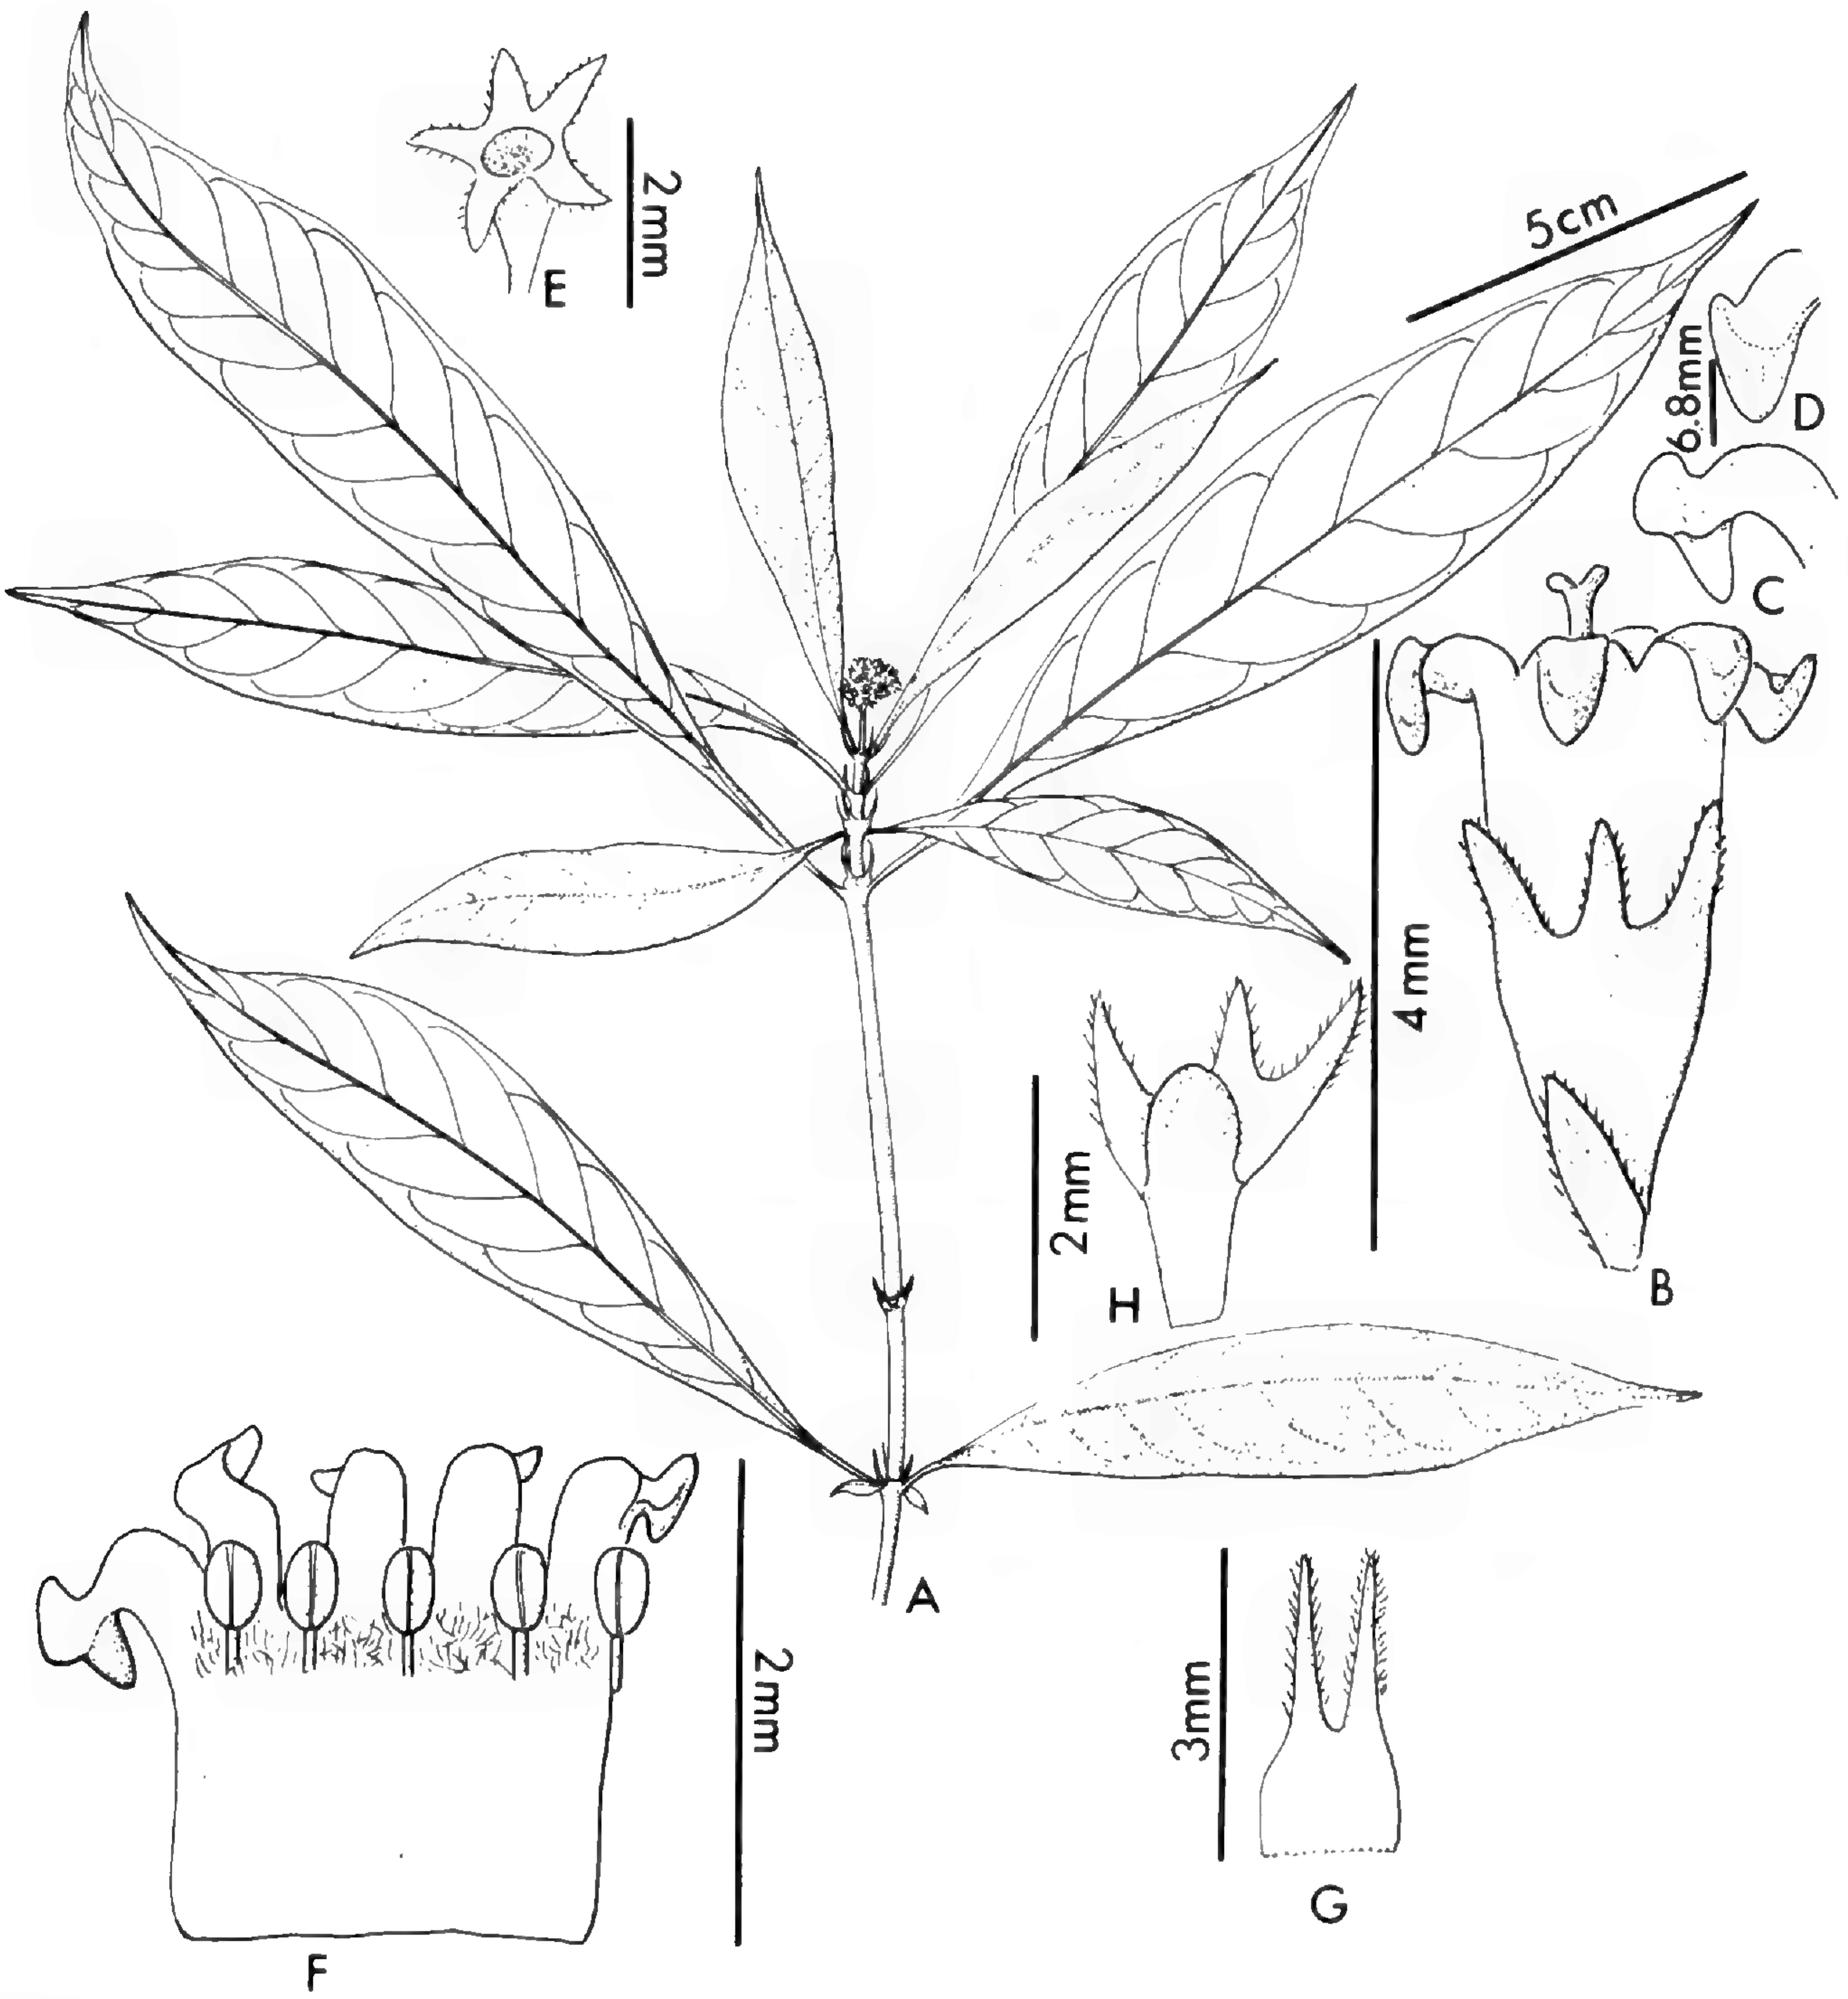

FIGURE 11. Psychotria pectinata.—*A. Habit of flowering branch.—B. Flower from outer portion of inflorescence with a subtending bract.—C, D. Showing corniculate corolla lobe.—E. Calyx and hypanthium.—F. Corolla, interior view.—G. Stipule.—H. Disk and portion of calyx and hypanthium.*

teeth, densely flowered heads of small flowers, brown-ciliate, elongate calyx lobes, and strongly corniculate corolla lobes. It was noted that within a densely flowered head of an inflorescence only one or a few flowers produce seed, and the majority do not possess a fertile ovary. There may be a tendency here for monoecism.

Psychotria steinii Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Cerro de la Neblina, summit, Camp 2, 2–8 km NE of Pico Phelps, 0°49′40″N, 65°59′W, 15 Apr. 1984, 2,100 m, *B. A. Stein & A. Gentry 1553* (holotype, MO; isotype, VEN). Figure 12.

Suffrutex vel subherbacea 0.35–1-metralis, caulibus plerumque glabris; foliorum laminis ovatis apice acuminatis basi acutis vel obtusis 2.5–4.5 cm longis 0.9–1.5 cm latis utrinque glabris marginibus valde ciliatis; petiolis 2–3 mm longis; inflorescentia terminali plerumque tribus simul, omnibus conspicue bracteatis, bracteis foliaceis 4–7 ovatis acutis vel acuminatis 8–13 mm longis 3–5 mm latis glabris vel basim versus sparsim hirtellis, marginibus ciliatis; pedunculo pubescenti; inflorescentiae axibus pubescentibus; corolla 11–11.5 mm longa, tubo intus minute papillato sed admodum glabro extus glabro.

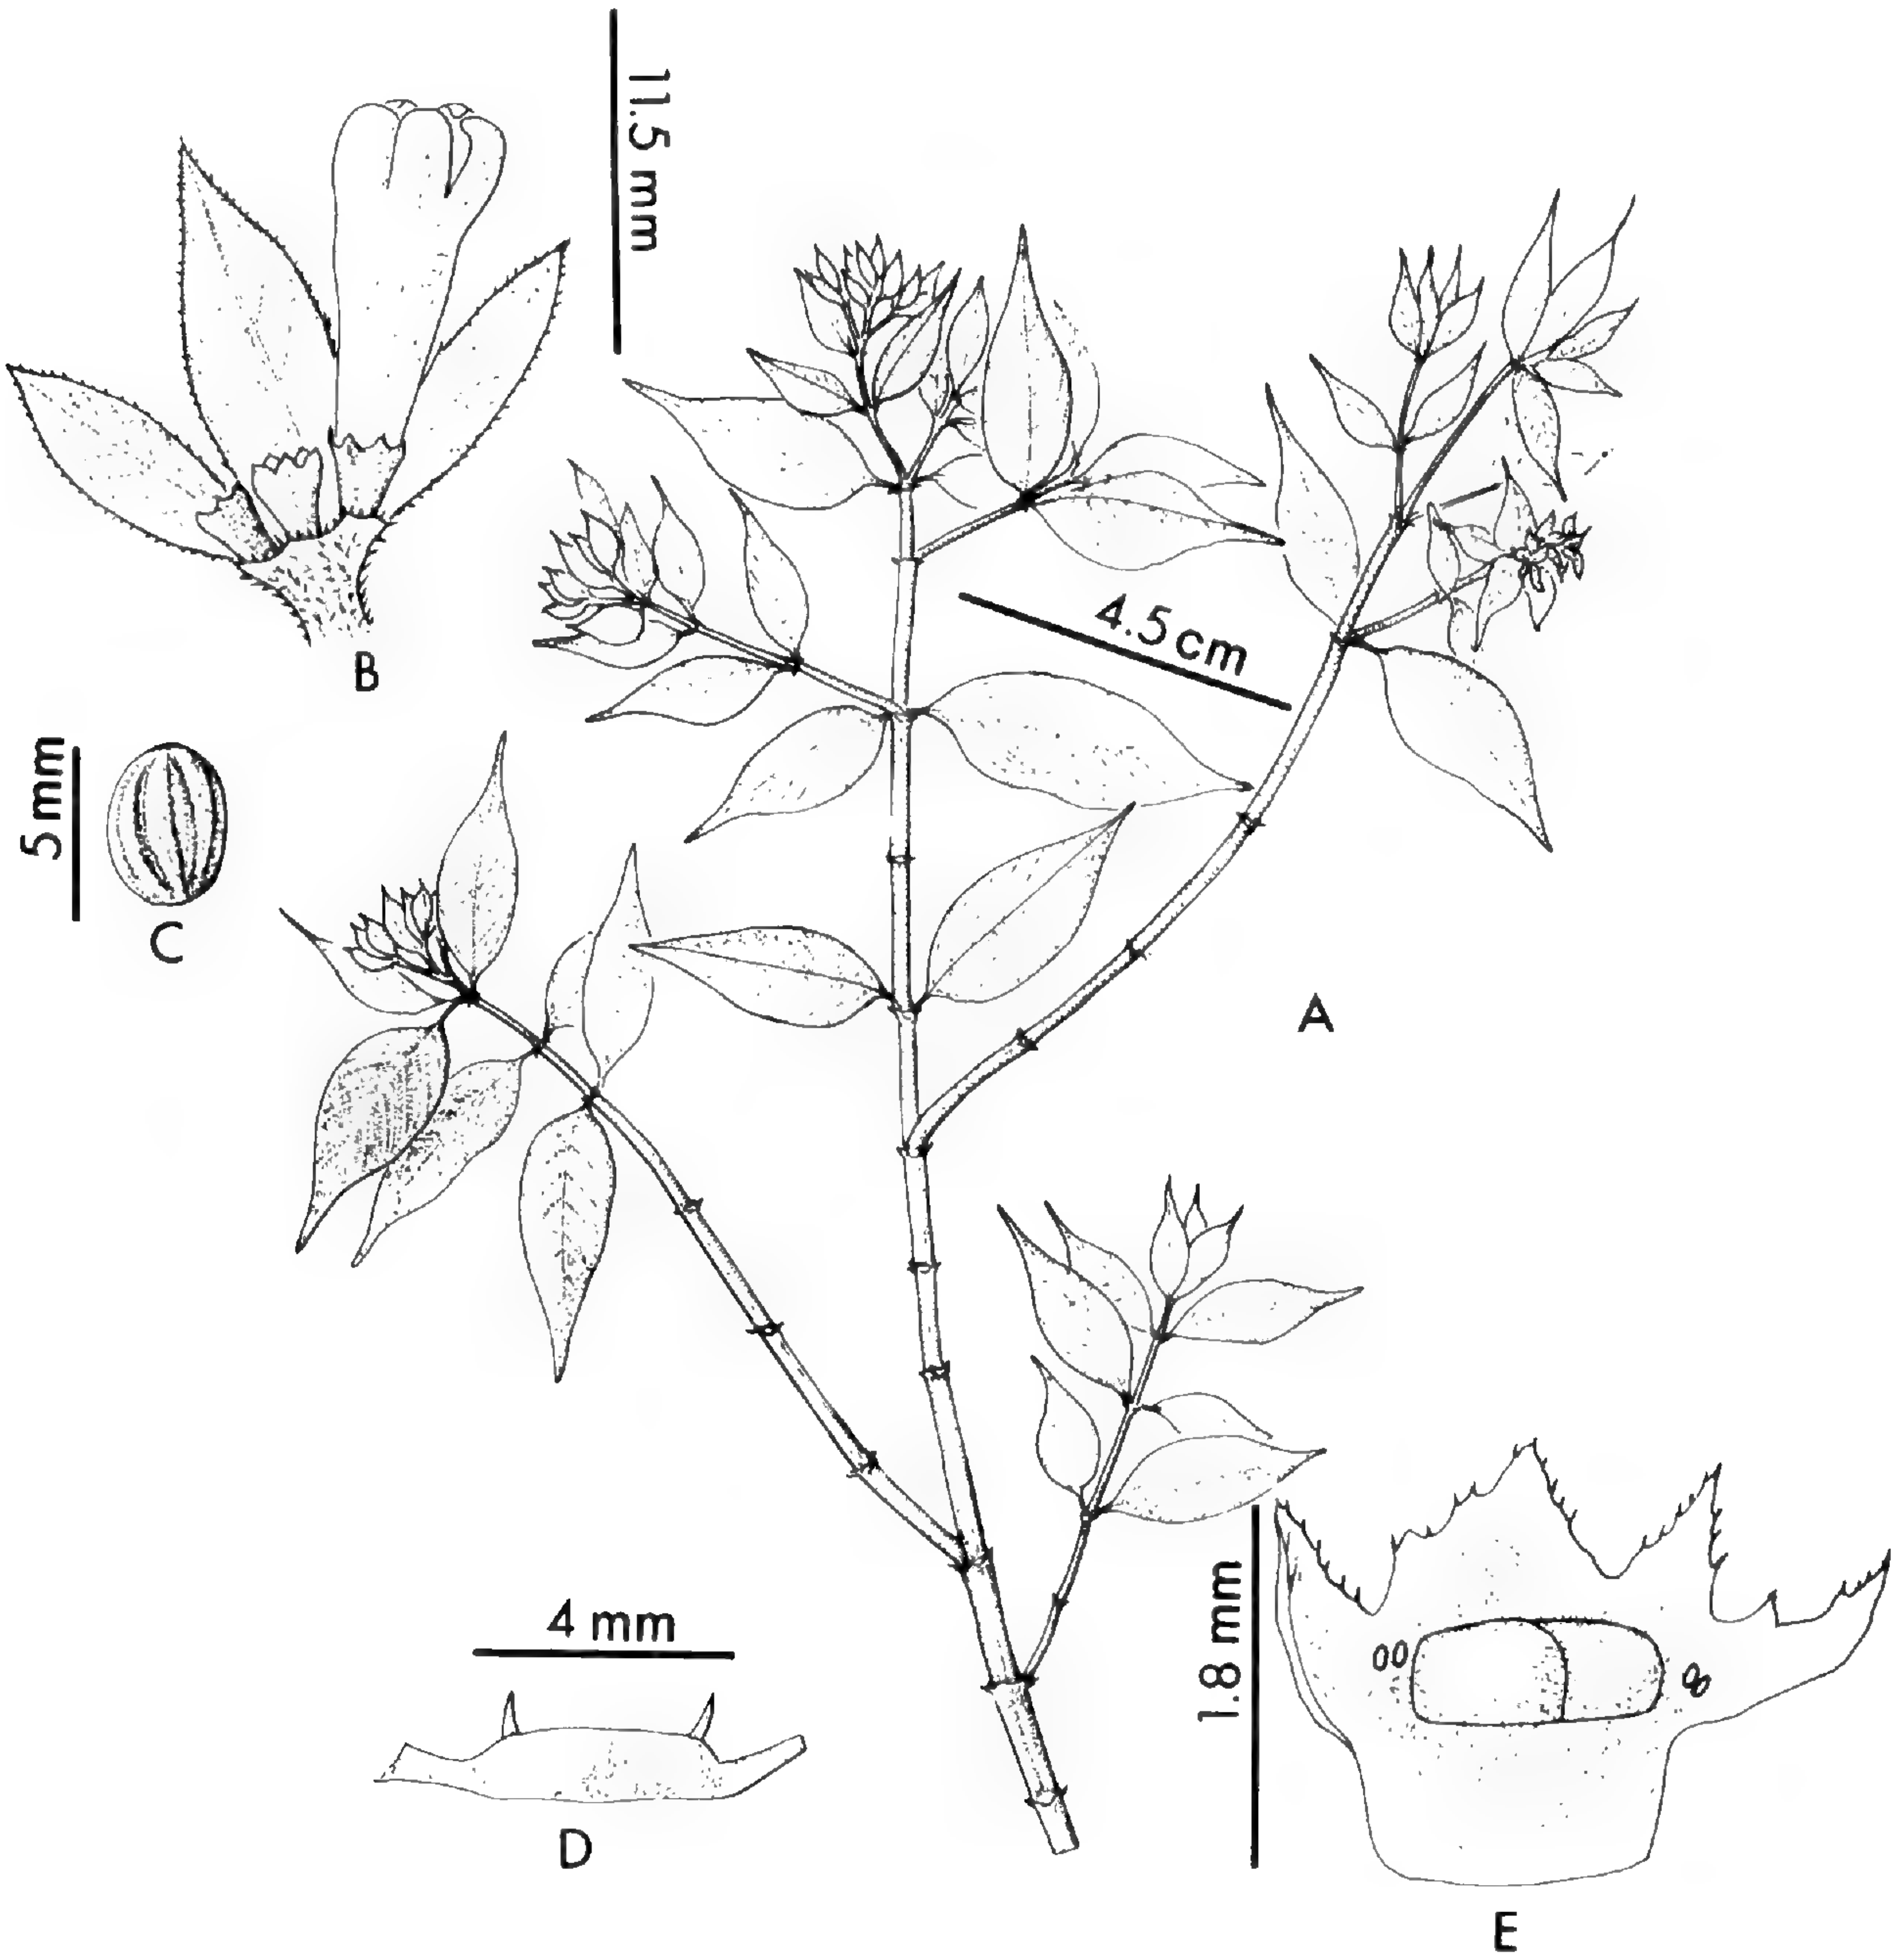

FIGURE 12. Psychotria steinii.—*A. Habit of flowering branch.—B. Portion of inflorescence.—C. Pyrene.—D. Stipule with bases of petioles.—E. Calyx, showing portion of interior with calycine glands and disk.*

Subherbaceous or suffruticose plant 0.35–1 m tall, the stems glabrous except at upper youngest nodes where hirtellous with spreading hairs. Stipule with a shallow sheath 0.2–0.5 mm high, 1–4 mm wide, glabrous, indurated with 2 teeth on each side, linear-lanceolate, acute, 0.5–0.8 mm long. Leaves shortly petiolate, leaf blades subcoriaceous, ovate, acuminate at apex, acute to obtuse at base, 2.5–4.5 cm long, 0.9–1.5 cm wide, glabrous on both surfaces, the margins strongly ciliate, the lower side with conspicuous cystoliths; midrib below glabrous to hirsutulous-ciliolate along margins; lateral nerves 6–8 on each side of the midrib, sulcate above, slightly elevated below, ascending at a 45° angle, ending near or at margins without anastomosing; tertiary venation inconspicuous; petioles 2–3 mm long. Inflorescence terminal, usually 3 together; each inflorescence with 4–7 conspicuous, foliaceous bracts arising at the summit of 2 short lateral axes 1–2 mm long and 1 central subsessile axis scarcely 1 mm long; bracts green, similar to leaves in shape but smaller, ovate to elliptic-oblanceolate, acute to acuminate, 8–13 mm long, 3–5 mm wide, glabrous or sparsely hirtellous toward base, the margins ciliolate, the narrower lateral bracts narrowed to a subpetiolate base, the broader bract subtending the inflorescence at a slightly lower level and not narrowed at base. Peduncle 3–10 mm long, 0.6–0.8 mm wide, densely hirtellous with spreading hairs 0.1 mm long. Flowers sessile, 2, or 2 on each axis. Calyx and hypanthium 1.5–1.8 mm long; hypanthium short columnar, 1 mm long, 1 mm wide at summit, glabrous; calyx 0.8–1 mm long, unequally 5-lobed, the tube 0.5–0.6 mm long, 1.5 mm wide, glabrous without; lobes broadly triangular, narrowed to a subacute apex, 0.5–0.7 mm long, ciliolate on margins, glabrous elsewhere, irregularly erose, glandular within at base of each of the 5 sinuses. Corolla white, tubular-infundibuliform, 11–11.5 mm long, the tube gradually enlarged upward, 7–8 mm long, 2 mm wide at base, 4 mm wide at orifice, glabrous without, within microscopically papillate but essentially glabrous; lobes 5, 4–4.5 mm long, 2 mm wide, ligulate-oblong, obtuse, glabrous without, microscopically papillate within but essentially glabrous. Stamens protruding slightly above orifice; anthers linear, 2.5 mm long, 0.4 mm wide at the orifice; filaments attached in upper half of tube, 2 mm long; disk shorter than calyx tube. Fruit blue, fleshy, subglobose, 11 mm long, 12 mm wide, 2-seeded; pyrenes broadly ovoid, dorsally 3-costate with 1 additional costa on each side, the inner face subconcave, 5 mm long, 3.5 mm wide.

Paratypes. VENEZUELA. TERRITORIO FEDERAL AMAZONAS: Cerro de la Neblina, Camp 12, Venezuelan-Brazilian frontier, 1,950 m, 26–27 Feb. 1985, *Boom et al. 5982* (MO, VEN, GH, INPA, NY).

This taxon is related to *Psychotria duidana* Standley of Cerro Duida and *P. oblata* of Mount Roraima. It is characterized by the essentially glabrous, although minutely papillate, interior of the corolla tube, much smaller, ciliolate leaves, densely pubescent peduncle, smaller corolla, and pubescent axes of the inflorescence above the peduncle.

Psychotria thesceloantha Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: upper Caño Baria, swampy area between Río Mawarinuma and headwaters of Río Baria, 0°52′N, 66°15′W, 130 m, 4 Dec. 1984, *R. Liesner 16963* (holotype, MO; isotype, VEN). Figure 13.

Suffrutex 1-metralis, caulibus glabris; stipulae vagina truncata 5 mm longa 9 mm lata glabra; foliorum laminis elliptico-ovatis apice acutis vel obtuse subacuminatis basi cuneatim acutis 21–24 cm longis 10–11 cm latis; inflorescentia axillari ut videtur monocephala 2 cm longa 4 cm lata brevipedunculata, petiolo 0.4 mm longo glabro; bracteis extimis quattuor capitulum cingentibus basi liberis, elliptico-ovatis, apice abrupte acuminatis basi rotundatis 2 cm longis 1.3–1.5 cm latis extus puberulentibus intus glabris; floribus omnibus a bracteolis duabus circumcinctis bracteolis lanceolato-linearibus acuminatis 13 mm longis 1.5 mm latis setuloso-serrulatis; calycis lobis aristatis 2.5–4 mm longis ciliato-plumosis.

Suffruticose plant 1 m tall, the stem glabrous, 4–5 mm diam. except 8–10 mm diam. at nodes. Leaves large, submembranous, leaf blades elliptic-ovate, the apex acute to obtusely subacuminate, the base cuneately acute, 21–24 cm long, 10–11 cm wide, glabrous below except minutely sparsely puberulent on midrib and nerves; lateral nerves 10–11 each side; tertiary venation not evident; petiole 4.5–5 cm long, glabrous to sparsely puberulent. Inflorescence axillary, subhemispheric, 2 cm long, 4 cm wide, appearing monocephalous on a short glabrous peduncle 0.4 mm long, not enveloped by the stipular sheath, consisting of 3–4 separate monocephalous heads in a compact mass appearing as monocephalous, each portion of the head hemispheric, 1.8–2 cm long, 2–2.8 cm wide, the complete head surrounded by 4 main outermost bracts separate to the base, elliptic-ovate, abruptly acuminate, rounded at base, carinate, 2 cm long, 1.3–1.5 cm wide, puberulent without, glabrous within; large bracts within the outermost bract broadly ovate, acute, ecarinate, 1.5 cm long, 1 cm wide, puberulent without, glabrous within; each of the 3–4 smaller heads consisting of multibracteate flowers, each surrounded by an obovate, abruptly acuminate bractlet 1.5 cm long, 0.5 cm wide, puberulent on both sides; each bractlet subtending 2 oblanceolate bracteoles rounded at apex, 1.2–1.3 cm long, 0.4 cm wide, puberulent without, sparsely puberulent within and subtending a group of 3 flowers; each pair of bracteoles subtending an ultimate pair of floral bracteoles, these lanceolate-linear, acumin-

FIGURE 13. Psychotria thesceloantha.—*A. Habit of flowering branch.—B. Individual flower without corolla, subtended by two bracteoles and a bract.—C. Inflorescence with bracts.—D. One of the inner bracts of the inflorescence.*

ate, 1.3 cm long, 1.5 mm wide, setulose-serrulate in the upper half of the margins. Hypanthium obconic-columnar, 2 mm long, 1 mm wide, glabrous; calyx lobes 5, setaceous, unequal, plumose-ciliate.

This unusual species has large, axillary, compound inflorescences that appear to be monocephalous but are composed of 3–4 condensed heads having the outermost and major bracts separate to the base. The ultimate three flowers are surrounded by narrowly oblanceolate, serrulate-ciliolate bractlets, with the large inner bracts acuminate and puberulent on both sides, while the calyx lobes are elongate, awnlike, and plumose-ciliate. In the present taxon the inflorescence is not enveloped by the stipular sheath as in *Psychotria celiae* Steyerm. of Cerro de la Neblina.

Psychotria yutajensis Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: Dept. Atures, summit of east slope of unnamed peak, 8 km NW of Yutajé settlement, 4 km west of Río Coro Coro, west of Serranía Yutajé, 5°41′N, 66°10′W, 1,500–1,760 m, 4 Mar. 1987, *R. Liesner & B. Holst 21649* (holotype, MO; isotype, VEN).

Frutex 1.5-metralis glaber; stipulis leviter dentatis, vagina 1.5 mm alta 4–6 mm lata, utroque latere bidentatis, dentibus late ovato-lanceolatis acutis 1–2 mm longis intus sericeis; petiolis 9–20 mm longis; inflorescentia terminali multiflora subcorymboso-cymoso vel cymoso-subhemisphaerica pedunculo excluso sub anthesi 2–2.5 cm longa 3–4 cm lata, axibus 5–8 cum rhachidi minute puberulentibus sub anthesi 3–15 mm longis sub fructu 10–23 mm longo, supremis brevissimis; pedunculo 10–12 mm longo 2 mm lato glabro; bracteis sub axibus lanceolato-triangularibus apice attenuatis; floribus 5-meris pedicellatis, pedicellis articulatis 0.5–1.5 mm longis 0.5–0.8 mm latis; calyce hypanthioque 2.3 mm longo, hypanthio doliiformi vel breviter cylindrico 1.2 × 1.2 mm minute puberulenti; calyce 1.2 mm longo 1.5 mm lato minute puberulenti, tubo 1 mm longo intus ad medium infra sinus 1-glandulifero, calycis dentibus triangulari-lanceolatis acutis 0.2–0.3 mm longis; corolla doliiformi 3 mm longa ad medium 1.6 mm lata, tubo 2.5 mm longo extus dense papillato-puberulenti, lobis lineari-oblongis obtusis 0.7 mm longis 0.4 mm latis dorso conspicue corniculatis, corniculis incrassatis; staminibus prope basim corollae insertis; bacca subbilobata 4–5 mm longa 6 mm lata calyce persistenti coronata; pyrenis subglobosis 3.5 × 3.5 mm dorso convexis ventraliter concavis.

Glabrous shrub 1.5 m tall. Stipular sheath shallow, 1.5 mm high, 4–6 mm wide, laterally 2-toothed on each side with the teeth broadly ovate-lanceolate, acute, 1–2 mm long, sericeous within. Leaves chartaceous, lanceolate-elliptic, broadest at the middle, acute at base and apex, 8–13 cm long, 2.5–5 cm wide. Petioles 9–20 mm long. Inflorescence terminal, many-flowered, 2–2.5 cm high excluding the peduncle, 3–4 cm wide in anthesis, 2.5–3.5 cm high, 4–7 cm wide in fruit, the 5–8 axes irregularly and ± trichotomously branched at the apices, in anthesis 3–15 mm long, in fruit 10–23 mm long, 1–1.5 mm wide, the upper ones the shortest. Peduncle green, becoming purple, 10–12 mm long, 2 mm wide, glabrous. Bracts at the base of the axes lance-triangular with subulate tips, 0.6–1 mm long, glabrous. Flowers numerous, 5-merous, pedicellate, pedicels green becoming gray-purple, 0.5–1.5 mm long, articulate. Calyx and hypanthium 2.3 mm long, the hypanthium barrel-shaped or shortly cylindric, 1.2 × 1.2 mm, minutely puberulent; calyx 1.2 mm high, 1.5 mm wide, minutely puberulent, the tube longer than the teeth, these triangular-lanceolate, acute, 0.2–0.3 mm long; interior of tube bearing 1 gland at the middle beneath each sinus and alternating with each calyx tooth. Corolla white, barrel-shaped, 3 mm long, 1 mm wide at base, 1.6 mm wide at the middle, 1.2 mm wide at the summit, tube 2.5 mm long, densely papillate-puberulent without, glabrous within; 5 lobes linear-oblong, obtuse, 0.7 mm long, 0.4 mm wide, conspicuously dorsally corniculate with a thickened appendage. Stamens 5, inserted at the base of the corolla; anthers 2 mm long, 0.3 mm wide. Style 0.8–1 mm long; stigmas linear-lanceolate, acute. Disk cupular, 0.3 mm high. Fruit green to purplish black, ± bilobed, 4–5 mm high, 6 mm broad, shallowly crowned by the persistent calyx. Pyrenes 2, subglobose, 3.5 × 3.5 mm, convex dorsally, concave ventrally.

This species is related to *Psychotria ceratantha* Standley & Steyerm. of the Venezuelan Guayana, from which it differs in the smaller corollas with internally glabrous tubes with the stamens attached at the base.

RUDGEA

Rudgea corocoroensis Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: 5–8 km NW of Yutajé settlement, 3 km west of Río Coro Coro, along stream on south slope below plateau, E side of unnamed peak, W of Serranía Yutajé, 5°40′N, 66°9′W, 700–1,000 m, 10 Mar. 1987, *R. Liesner & B. Holst 21827* (holotype, MO; isotype, VEN).

Arbor 4-metralis; stipularum vaginis 2–3 mm longis glabris apice vel infra apicem aculeis 5–7 rigidis 2–4 mm longis munitis; foliis anguste oblongo-lanceolatis apice acutis vel subobtusis basi obtusis vel subobtusis glabris; nervis lateralibus utroque latere 10–11 valde adscendentibus; venatio tertiaria obsoleta vel inconspicua; petiolis 3–7 mm longis glabris. Inflorescentia terminali thyrsoideo-paniculata pedunculo excluso 2–3 cm longa 1.5–2 cm lata, seriebus verticalibus tribus principalibus ordinatis, axibus infimis 4–5-verticillatis 4–8 mm longis dense pilosulis, aliis brevioribus; pedunculo 2–2.5 cm longo pilosulo; bracteis quattuor sub verticillo infimo suborbicularibus 3 × 3 mm marginibus ciliolatis; quoque axe in flores 6–7 aggregatos sessiles desinenti; bractea involucrali ciliolata patenti sub basi florium; pedunculo 2–2.5 cm longo pilosulo; hypanthio brevicampanulato 1 mm longo 1.5 mm lato; calycis tubo 2 mm longo 1 mm lato glabro, lobis 4–5 inaequalibus lanceolatis subacutis vel obtusis majoribus 1.2–1.8 mm longis 0.7 mm latis, brevioribus 1 mm longis dense ciliolatis; corolla infundibuliformi, tubo 2 mm longo orificio deorsumque 1 mm dense pilosulo extus glabro; lobis quinque lanceolatis-oblongis acutis 4 mm longis 1.2 mm latis extus glabris intus dense minuteque papillatis; staminibus paullo exsertis, antheris 1.2 mm longis.

Tree 4 m tall. Branchlets glabrous. Stipular sheath 2–3 mm long, glabrous, with 5–7 rigid aculeae arising at or just below the sheath summit. Leaf blade subcoriaceous, narrowly oblong-lanceolate, acute or obtuse at apex, obtuse to subobtuse at base, 7–10 cm long, 2–4 cm wide, glabrous on both sides, slightly revolute; lateral nerves 10–11 on each side, strongly ascending, scarcely anastomosing; tertiary venation obsolete or inconpsicuous. Petiole 3–7 mm long, glabrous. Inflorescence terminal, pedunculate, thyrsoid-paniculate, 2–3 cm long excluding the peduncle, 1.5–2 cm wide, in 3 main verticillate tiers, the lowest tier 12–17 mm distant below the middle tier; lowest axes 4–5-verticillate, 4–8 mm long, densely pilosulous, the other verticels with shorter axes; each axis subtended by spreading, glabrous, ciliolate involucral bract, terminating in a congested group of 6–7 sessile flowers. Peduncle 2–2.5 cm long, pilosulous, 4 suborbicular bracts 3 × 3 mm subtending base of main lowest verticels. Hypanthium short-campanulate, 1 mm long, 1.5 mm wide, glabrous. Calyx tube 2 mm long, 1 mm wide, glabrous. Calyx lobes 4–5, unequal, lanceolate, subacute to obtuse, the longer lobes 1.2–1.8 mm long, 0.7 mm wide, the shorter 1 mm long, densely ciliolate. Corolla white, subinfundibuliform, the tube 2 mm long, 1.5 mm wide at base, 2 mm wide above, densely pilose at orifice and 1 mm downward; lobes 5, lanceolate-oblong, acute with involute tip, 4 mm long, 1.2 mm wide, glabrous without, densely minutely gray papillate within. Stamens 5, slightly exserted, anthers 1.2 mm long; filaments 0.8 mm long, glabrous. Style 8 mm long, scabridulous-papillate, stigmas 2, 0.8 mm long.

This taxon is related to *Rudgea morichensis* Steyerm. from which it differs in the glabrous hypanthium, conspicuously lobed calyx, much shorter corolla tube, and shorter anthers. From *R. bolivarensis* Steyerm. it is distinguished by the lanceolate, longer calyx lobes and by the narrower, oblong-lanceolate leaf blades with shorter petioles.

SABICEA

Sabicea bariensis Steyermark, sp. nov. TYPE: Venezuela. Territorio Federal Amazonas: upper Río Baria, mostly non-inundated area along riverside, 0°55′N, 66°16′W, 140 m, 9 May 1984, *A. Gentry & B. Stein 47314* (holotype, MO; isotype, VEN).

Planta scandens, caulibus strigosis; foliorum laminis elliptico-ovatis apice subacuminatis basi acutis majoribus 11–13 cm longis 5.5–7 cm latis supra sparsim puberulis, costa media nervisque strigosis, subtus praeter costam mediam nervisque strigosis plerumque glabris; inflorescentia pedunculata 20–30-flora trichotome ramosa 2.3 cm longa 3.5 cm lata; floribus pedicellatis, pedicellis 3–5 mm longis; calycis lobis inaequalibus, majoribus ovatis acuminatis 3–4.5 mm longis 1.5–2.5 mm latis extus adpresso-pubescentibus intus glabris infra sinum squamellis duabus munitis.

Vine with strigose pubescent stems. Leaves firmly membranous, elliptic-ovate, subacuminate at apex, acute at base, the larger leaf blades 11–13 cm long, 5.5–7 cm wide, sparsely puberulous above, the midrib and lateral nerves strigose, the lower surface mainly glabrous except for strigillose midrib, the margins appressed-ciliolate; lateral nerves 10 each side, arcuate-ascending at 50–60° angle, impressed above, subelevated below; tertiary venation slightly evident, transversely connecting the secondary nerves; petioles 2–3.5 cm long, strigillose. Stipule reflexed, ovate, acute to acuminate, 10–12 mm long, 6–6.5 mm wide, strigose without, glabrous within. Inflorescence pedunculate, bracteate, 20–30-flowered, cymosely trichotomously branched, 2.3 cm long, 3.5 cm wide. Peduncle 4–5 mm long, densely antrorsely strigose. Lower axes of inflorescence 1.7 cm long with the flowers ca. 10-flowered. Lowest bracts subtending lowest axes of inflorescence 7–9 mm long, 3 mm wide, connate at their bases, divaricate, sparsely appressed-pubescent without, glabrous within; bracts subtending other axes paired, 7 mm long, 2 mm wide, appressed-pubescent without. Flowers on pedicels 3–5 mm long, these densely appressed pubescent. Calyx and hypanthium 5–7(–9.5) mm long, appressed-pubescent; hypanthium longer than the calyx lobes, 3.5–5.5 mm long, glabrous within; calyx lobes unequal, 4 larger and 1 smaller, the large ones erect-spreading, ovate, acuminate, 3–4.5 mm long, 1.5–2.5 mm toward the base, appressed-pubescent without, glabrous within, the smallest one 1.5 mm long, 1 mm wide, 2 unequal, elongate, dark squamellae situated below sinus of calyx lobes. Corolla narrowly cylindric, salverform, 14.5 mm long, the tube 10.5 mm long, 1.8 mm wide, densely antrorsely appressed pubescent without, glabrous within; 5 lobes lanceolate-ligulate, acute, 4 mm long, 1 mm wide at base, densely sericeous without, glabrous within. Anthers 2.8 mm long.

Paratypes. VENEZUELA. TERRITORIO FEDERAL AMAZONAS: 3–4 km upstream from Neblina Base Camp, gravel banks of main channel of Río Mawarinuma, 0°50′N, 66°10′W, 180 m, 4 Dec. 1984, *Kral 71981* (MO, VDB, VEN); upper Caño Baria, swampy area between Río Mawarinuma and headwaters of Río Baria, 0°52′N, 66°15′W, 130 m, 26 Mar. 1984, *Liesner 16967* (MO, VEN).

From other pedunculate species this differs from *Sabicea grandiflora* Steyerm. in the larger calyx lobes, nonarachnoid pubescence of the leaves, and divaricately spreading calyx lobes. From *S. morillorum* Steyerm. it is mainly distinguished by its nonarachnoid pubescence.

TEN NOVELTIES IN *XYRIS* (XYRIDACEAE) FROM THE PLANALTO OF BRAZIL

R. Kral[1] *and*
Maria das Graças de Lapa Wanderley[2]

ABSTRACT

Ten taxa of Xyris *(nine species and one variety), sent to the senior author for definitive treatment during the early 1980s, are herein described, figured, and proposed for addition to the flora of Brazil. All are from the Brazilian Planalto: five (*X. diaphanobracteata, X. jataiana, X. lutescens, X. pranceana, X. sceptrifera*) are from Goiás, four (*X. seubertii *var.* espinhacae, X. itambensis, X. obcordata, *and* X. villosicarinata*) are from Minas Gerais, and one (*X. dissitifolia*) is from Paraná. These new* Xyris *are presented alphabetically and each is contrasted with related species.*

Among the undetermined Xyridaceae from Brazil sent to the senior author for definitive treatment during the years 1980, 1981, and 1982 are ten that have long awaited publication as new taxa. They are arranged alphabetically.

1. **Xyris diaphanobracteata** Kral & Wanderley, sp. nov. TYPE: Brazil. Goiás: Rod. GO-12; km 5–10 ao sul de Alto Paraiso, campo arenoso, flor amarela, 24 May 1975, *G. Hatschbach 36815* (holotype, MBM; isotypes, US, VDB). Figure 1.

Planta perennis, caules breves, radices graciles. Folia ensiformi-linearia, 15–20 cm longa, disticha, flabellate expansa, solum basalia, vaginis scaporum longiora; laminae planae vel leviter tortae, 3–5 mm latae, compressae, flavovirentes, inconspicue multinervosae, papillosae, marginem versus crassinervae, ferrugineae; apices abrupte contracti, incurvato-acuti, incrassati; margines aciebus pallide villoso-ciliatis; vaginae carinatae, carinibus ciliatis, lateribus valde multicostatis, glabris, flavofuscatis, basin versus castaneis, rugulosis, marginibus in laminas gradatim convergentibus, infimis gradatim expansis, tum abrupte ad basim dilatatis, aciebus ad basim anguste scariosis, antrorse longiciliatis, pilis albidis. Vaginae scaporum basim versus ancipitae, pilosociliatae, glabrae, multicostatae, ferrugineae, nitidae, a medio ad apicem acute carinatae, carinibus rufis, ciliatis, laminis brevibus, obtusis. Scapi graciles, recti, 4.5–6 dm alti, leviter torti, anguste 2–3-costati, in sectione transversali elliptici, apicem versus ancipitii, costis longiciliatis, pilis albidis. Spicae late ovoideae, 1–1.5 cm longae, obtusae, multibracteatae, bracteis laxis, fere uniformis, spiraliter imbricatis, subscariosis, convexis, ecarinatis, late ovatis, 5–7 mm longis, rotundatis, testaceis, margine squarrosis, laceratis; area dorsalis indistincta; bracteae steriles plures. Sepala lateralia libera, valde curvata, leviter exserta, valde inaequilatera, oblanceolata, tenuia, 6–7 mm longa; ala carinalis lata, ciliato-fimbriolata. Laminae petalorum suborbiculatae vel reniformes, 7–8 mm longae, grosse erosae, flavidulae. Staminodia bibrachiata, brachiis complanatis, longipenicillatis. Antherae lanceolato-oblongae, sagittatae, ca. 2 mm longae. Capsula turgide obovoidea, ca. 3 mm longa, placenta basalis; semina numerosa, ellipsoidea, 0.5 mm longa, pallide vel profunde lampro-brunnea, prominente longitudine 12–14-costata.

Plants short-stemmed perennials with fine roots. Leaves ensiform-linear, 15–20 cm long, distichous, flabellately spreading, strictly basal, longer than the scape sheaths; blades flat to slightly twisted, 3–5 mm wide, flattened,

ANN. MISSOURI BOT. GARD. 75: 352–372. 1988.

yellow-green, inconspicuously multinerved, papillose, thick-nerved toward margin, reddish brown; apices abruptly narrowed, incurved-acute, thickened; margins with edges pale villous-ciliate; sheaths ciliate-carinate, the sides strongly multicostate, smooth, yellowish-fuscous, castaneous toward the base, rugulose, with margins gradually narrowing into the blades, gradually expanding below, abruptly dilated at base, there the edges narrowly scarious, antrorsely long-ciliate with white hairs. Scape sheaths ancipital toward base, pilose-ciliate, smooth, multicostate, reddish brown, shining, acutely carinate from middle to apex, the carinae reddish, ciliate, the blades short, obtuse. Scapes slender, straight, 4.5–6 dm high, slightly twisted, narrowly 2–3-costate, elliptic in cross section, ancipital toward the apex, the costae long-ciliate with white hairs. Spikes broadly ovoid, 1–1.5 cm long, obtuse, the bracts numerous, loose, nearly uniform, spirally imbricate, subscarious, convex, ecarinate, broadly ovate, 5–7 mm long, rounded, brownish yellow, marginally squarrose, lacerate; dorsal area indistinct; sterile bracts many. Lateral sepals free, strongly curvate, slightly exserted, strongly inequilateral, broadly oblanceolate, thin, 6–7 mm long; keel wide, ciliate-fimbriolate. Petal blades suborbicular to reniform, 7–8 mm long, strongly erose, yellow. Staminodia bibrachiate, the branches flattened, long-penicillate. Anthers lanceolate-oblong, sagittate, ca. 2 mm long. Capsule turgidly obovoid, ca. 3 mm long, the placentation basal; seeds numerous, ellipsoid, 0.5 mm long, palely or deeply lustrous brown, prominently longitudinally 12–14-costate.

This novelty most resembles *X. pterygoblephara* Steudel, particularly by having long, pale ciliation on scape and leaf edges; distichous, flabellately spreading, flattened leaves; and concolorous bracts. *Xyris diaphanobracteata* differs conspicuously in its broader spikes and uniform bracts (sterile ones more numerous) with thin, translucent texture and squarrose edges. The lateral sepals are broader, more strongly curvate, blunter, exserted, very inequilateral (rather than equilateral), and more prominently ciliate.

2. **Xyris dissitifolia** Kral & Wanderley, sp. nov. TYPE: Brazil. Paraná: Mun. Campiná Gde. do Sul, campo umido encosta de morro, flor amarella, alt. 1,500–1,700 m s/mar, 15 Jan. 1969, *Hatschbach & Ckoczicki 20752* (holotype, MBM; isotypes, US, VDB). Figure 2.

Planta perennis, caespitosa, radicibus gracilibus. Caules breves vel elongati, per bases laxas foliorum obtecti. Folia laxa, anguste linearia, 2–5 dm longa, disticha, erecta vel leviter flabellate expansa, vaginis scaporum longiora; laminae vaginis 2–5-plo longiores, subteretes vel angulosae aut leviter compressae, tortae, valde mediane sulcatae et paucicostatae, olivaceae, a medio ad apicem glabrae, basin versus ruguloso-papillosae, subteretes; apices gradatim contracti, ad apicem anguste obtusi, erecti, persaepe incrassati et triangulati; vaginae laxae, latae, ecarinatae vel carinatae, pallide lamprobrunneolae, a basi ad apicem gradatim contractae, apicem versus ligulam oblongam obtusam scariosam 3–4 mm longam fascientes, marginibus latis integris nitidis, dorsis rotundato-plicatis, valde unicostatis, praeter basin papillosis aut rugulosis. Vaginae scaporum laxae, basin versus conduplicatae tubulosae multicostae, nitidae, tortae, apicem versus apertae, laminis similibus laminis foliorum sed brevioribus. Scapi graciles, 3–6 dm alti, subteretes aut (in sectione transversali) elliptici, ca. 1 mm crassi, olivacei, apicem versus 1–2-costati et subtiliter striatae, costis glabris, basin versus persaepe obtuse triangulati aut sulcati. Spicae cylindro-oblongae vel late ellipsoideae aut obovoideae, pauciflorae, ca. 1 cm longae; bracteae laxe spiraliter imbricatae, convexae, pallide ferrugineae, papillosae, rotundatae, marbinibus integris, tum erosis, ad apicem persaepe villoso-ciliatis, trichomatibus sordidis; bracteae steriles 4–6, obovatae, ca. 4–7 mm longae, inferiores breviores, prominente unicostatae; bracteae fertiles paucae, oblongae vel obovatae, usque ad 9 mm longae, carinatae, eis intimis navicularibus; area dorsalis inconspicua, brevis, anguste elliptica, pallide brunneola. Laminae petalorum late ovatae, ca. 1 cm longae, subacutae, leviter erosae, luteolae. Staminodia bibrachiata, brachiis oblongis complanatis, ad apicem longipenicillatis. Antherae late lanceolatae, ca. 2 mm longae, sagittatae; filamenta plana, ca. 3 mm longa. Capsula oblonga vel obovoidea, ca. 5 mm longa, apiculata, placenta basali. Semina matura non visa sed immatura lineari-fusiformia, 1.5 mm longa, bicaudata, brunneola, longitudine minute striata.

Plants perennial, cespitose, slender-rooted. Stems short or elongated, covered by the lax bases of leaves. Leaves loose, narrowly linear, 2–5 dm long, distichous, erect or slightly flabellately spreading, longer than the scape sheaths; blades 2–5 times longer than the sheaths, subterete to angulate or slightly com-

pressed, twisted, medially strongly sulcate and few-ribbed, olivaceous, smooth from middle to apex, rugulose-papillose and subterete toward base; apices gradually contracted, narrowly obtuse at tip, erect, usually thickened and triangulate; sheaths lax, wide, ecarinate or carinate, pale lustrous brown, gradually narrowing from base to tip, producing near the apex a scarious, oblong, obtuse ligule 3–4 mm long, the margins broad, entire, shining, the backs rounded-plicate, strongly unicostate, papillose or rugulose except for the base. Scape sheaths lax, conduplicate toward base, tubular, multicostate, shining, twisted, open toward apex, with blades similar to leaf blades but shorter. Scapes slender, 3–6 dm high, subterete, or elliptic in cross section, ca. 1 mm thick, olivaceous, toward apex 1–2-costate and finely striate, the costae smooth, toward base often obtusely triangulate or sulcate. Spikes oblong-cylindric or broadly ellipsoid to obovoid, few-flowered, ca. 1 cm long; bracts loosely spirally imbricate, convex, pale reddish brown, papillose, rounded, with margins entire, then erose, at apexes often villous-ciliate with sordid trichomes; sterile bracts 4–6, obovate, ca. 4–7 mm long, the lowest shortest, prominently unicostate; fertile bracts few, oblong to obovate, up to 9 mm long, the inner ones navicular, carinate; dorsal area inconspicuous, short, narrowly elliptic, pale brown. Petal blades broadly ovate, ca. 1 cm long, subacute, slightly erose, yellow. Staminodes bibrachiate, the branches oblong, flat, long-penicillate at apex. Anthers broadly lanceolate, ca. 2 mm long, sagittate; filaments flat, ca. 3 mm long. Capsule oblong to obovoid, ca. 5 mm long, apiculate, the placenta basal. Immature seeds linear-fusiform, 1.5 mm long, brownish, minutely longitudinally striate. Mature seeds not seen.

Additional specimens examined. BRAZIL. PARANÁ: Serra Ibitiraquire, Abrigo 1 (Mun. Campiná Gde. do Sul), campo umido encosta de morro, alt. 1,700 m, 23 Jan. 1970, *Hatschbach 23404* (MBM, US, VDB); Serra Capivari Grande (mun. Campiná Gde. do Sul), encostas graminosas umidas de morro, alt. 1,500 m, 8 Feb. 1971, *Hatschbach 26322* (MBM, US, VDB).

This species, with its slender, long leaf blades, loose and distichous leaf sheaths along definite stems, papillose-backed bracts with small, pale brown dorsal areas, and villous sepal tips, shows some characters of *Xyris filifolia* Nilsson but has more stem, hairier sepal keels, and less evident dorsal areas. On the other hand, the vestite sepals liken it to *X. rigida* Kunth, or *X. regnellii* Nilsson, but leaf characters do not agree, nor do characters of fertile bract or scape.

3. **Xyris itambensis** Kral & Wanderley, sp. nov.

TYPE: Brazil. Minas Gerais: Serra do Ispinhaco, sandy soil, eastern slopes of Pico do Itambe; elev. ca. 1,550 m; sandstone outcrops with shrubby vegetation, adjacent grassy slopes, and valley of small stream; mostly sandy soil but with overlying black humus in many places, 12 Feb. 1972, *W. R. Anderson, M. Stieber, J. H. Kirkbride, Jr. 35879* (holotype, UB; isotypes, NY, US). Figure 4.

Planta perennis, densicaespitosa, glabra; caules breves; radices graciles. Folia erecta vel leviter expansa, 1.5–3 dm longa, solum basalia, vaginis scaporum longiora, torta et flexuosa, lucida; laminae vaginis 3–6-plo longiores, teretes vel subteretes, filiformes, 0.5–0.6 mm crassae, virides, longitudine subtiliter striatae, basin versus minute rugulosae; apices gradatim contracti, anguste conici; vaginae ecarinatae, ad basim abrupte dilatatae, lamproferrugineae, fimbriociliatae, prominente longitudine costatae, superne gradatim contractae, lamprospadiceae, marginibus latis, tenuibus sed firmis, integris vel parce villoso-fimbriatis, in medio longitudine multicostatae, ad apicem ligulam erectam oblongam acutam 4–6 mm longam fascientes. Vaginae scaporum ad basim teretes, laxe conduplicatae, multicostatae, tortae et leviter flexuosae, purpureae vel pallide ferrugineae, apicem versus apertae, marginibus latis integris purpureis et ad apicem cuspidatis. Scapi gracillimi, 3.5–5.5 dm alti, torti et flexuosi, olivacei, subteretes, laeves, ecostati vel unicostati, costibus glabris. Spicae late ellipsoideae vel anguste obovoideae, 6–8 mm longae, 4–5 mm crassae, pauciflorae, pluribracteatae,

bracteis sterilibus pluribus, convexis, inferioribus suborbicularibus vel late ovatis, 2–3.5 mm longis, superioribus navicularibus usque ad 5 mm longis; bracteae fertiles late oblongae vel obovatae, ad 5–6 mm longae, marginibus tenuibus, laceratis, ad apicem parce rufovillosulis, intimis valde plicatis; area dorsalis elliptica, ca. 2 mm longa. Sepala lateralia libera, curvata, oblonga, ca. 5–6 mm longa, acuta, leviter inaequilatera, ala carinali angusta, a medio ad apicem rufofimbriolata. Laminae petalorum oblongae, 6–6.5 mm longae, late acutae, sed integrae, luteolae. Antherae lanceolato-oblongae, 1.5 mm longae, emarginatae et sagittatae, filamentis longiores. Staminodia bibrachiata, brachiis subteretibus, longipenicillatis. Placenta centralis. Semina matura non visa sed immatura cylindrico-fusiformia, 1.2 mm longa.

Plants perennial, densely cespitose, smooth; stems short; roots slender. Leaves erect to slightly spreading 1.5–3 dm long, strictly basal, longer than the scape sheaths, twisted and flexuous, lustrous; blades 3–6 times longer than sheaths, terete or subterete, filiform, 0.5–0.6 mm thick, green, longitudinally finely striate, minutely rugulose toward base; tips gradually narrowing, narrowly conic; sheaths ecarinate, abruptly dilated at base, shining red-brown, fimbrio-ciliate, prominently longitudinally costate, gradually narrowing above, lustrous brown, with margins broad, thin but firm, entire to sparsely villous-fimbriate, at middle longitudinally multicostate, at apex producing an erect, oblong, acute ligule 4–6 mm long. Scape sheaths terete at base, laxly conduplicate, multicostate, twisted and somewhat flexuous, purplish or pale red-brown, open toward apex, with margins broad, entire, purplish, and at apex cuspidate. Scapes very slender, 3.5–5.5 dm high, twisted and flexuous, olivaceous, subterete, smooth, ecostate to unicostate, with costae smooth. Spikes broadly ellipsoid to narrowly obovoid, 6–8 mm long, 4–5 mm thick, few-flowered, several-bracted, the sterile bracts several, convex, the lower ones suborbicular to broadly ovate, 2–3.5 mm long, the upper sterile bracts navicular, up to 5 mm long; fertile bracts broadly oblong to obovate, to 5–6 mm long, with thin, lacerate margins, sparsely red-villosulous at apex, the inner ones strongly plicate; dorsal area elliptic, ca. 2 mm long. Lateral sepals free, curvate, oblong, ca. 5–6 mm long, acute, slightly inequilateral, the keel narrow, red-fimbriolate from middle to tip. Petal blades oblong, 6–6.5 mm long, broadly acute, entire, yellow. Anthers lanceolate-oblong, 1.5 mm long, emarginate and sagittate, longer than the filaments. Staminodia bibrachiate, the branches subterete, long-penicillate. Placenta central. Immature seeds cylindric-fusiform, 1.2 mm long. Mature seeds not seen.

In habit the new species resembles *X. filifolia* Nilsson, a slender species which also has small but prominent dorsal areas and strongly ligulate leaves with very slender and terete blades. The scapes, unlike those of *X. filifolia*, are terete, the tips of the fertile bracts are villosulous with red hairs, and the lateral sepal keels are densely villosulous above the middle. *Xyris itambensis* relates also to the complex involving *X. rigida* Kunth, but is more slender, has fewer flowers, and has subequilateral (rather than strongly inequilateral) sepals.

4. **Xyris jataiana** Kral & Wanderley, sp. nov. TYPE: Brazil. Goiás: Mun. Jatai Rod. Jatai–Caiapenia, km 50 (mun. Jatai), Goiás; flor amarela, do brejo, 24 July 1977, *G. Hatschbach 40060* (holotype, MBM; isotypes, US, VDB). Figure 5.

Planta perennis, glabra, densicaespitosa; radices graciles, fibrosae; rhizomata ascendentia, per bases persistentes veternas foliorum obtecta. Caules elongati vel breves. Folia rhizomatum et caulium subdisticha, rigida, torta et flexuosa, 2–4 dm longa, vaginis scaporum longiora; laminae vaginis 5–8-plo longiores, tortae, anguste lineares, 0.8–1.5 mm latae, compressae, flavovirentes, longitudine 4–5-nervosae, inferne sulcatae; apices leviter contracti, asymmetrice anguste rotundati callosi; margines filo metalico similes, luteoli vel brunneoli, persaepe nitidi, quam in centro laminae crassiores; vaginae ecarinatae, anguste plicatae, atrocastaneae, nitidae, marginibus tenuibus, integris, gradatim convergentibus, ad apicem ligulam erectam acutam plene 10 mm longam fascientes, et hic quam laminis distincte latiores, infime gradatim dilatatae. Vaginae scaporum laxae, plerumque apertae, tortae, basin

versus paucicostatae, castaneae, apicem versus carinatae, laminis brevibus erectis compressis vel triangulatis, obtusis. Scapi erecti, leviter torti, teretes, 5–6 dm alti, inferne fusci, compressi, apicem versus teretes, ecostati, luteovirides. Spicae multiflorae, multibracteatae, anguste obovoideae, 1–1.5 cm longae, attenuatae; bracteis convexis, ecarinatis, ferrugineofuscis, spiraliter imbricatis, rotundatis, integris vel minute erosis; bracteae steriles plures, anguste obovatae, 2–4 mm longae, fertilibus breviores et in eas gradatim transientes; bracteae fertiles late obovatae, ca. 4.5–5 mm longae, apice rotundatae; area dorsalis distincta, ovata vel elliptica, ca. 1.5–2 mm longa, olivacea vel atroferruginea. Sepala lateralia libera, leviter inaequilatera, anguste oblanceolata, ca. 5 mm longa, acuta; ala carinalis ciliata, basin versus angusta, apicem versus lata, firma. Laminae petalorum late ellipticae, 5–5.5 mm longae, luteolae, apice anguste rotundatae, erosae. Staminodia bibrachiata, brachiis longipenicillatis. Antherae oblongae, ca. 2 mm longae. Capsula matura non visa.

Plants perennial, glabrous, densely cespitose from slender roots. Rhizomes ascending, their bases covered by persistent old leaves. Stems short or elongated. Leaves of rhizomes and stems subdistichous, rigid, twisted and flexuous, 2–4 dm long, longer than the sheaths of the scapes; blades 5–8 times longer than sheaths, twisted, narrowly linear, 0.8–1.5 mm wide, flattened, yellowish green, longitudinally 4–5-nerved, sulcate below; apices somewhat contracted, asymmetrically narrowly rounded, callused; margins wirelike, yellowish to brown, often shining, thicker than the central part of the blade; sheaths ecarinate, narrowly folded, deeply castaneous, lustrous, with thin, entire margins, these gradually converging, at the apex forming an erect, acute ligule 10 mm long, this distinctly wider than the blade, gradually dilating below. Sheaths of scapes lax, largely open, twisted, few-ribbed toward the base, castaneous, carinate toward the apex, with blades short, erect, compressed or triangulate, obtuse. Scapes erect, slightly twisted, 5–6 dm long, brown below, compressed, terete toward the apex, ecostate, yellow-green. Spikes many-flowered, many-bracteate, narrowly obovoid, 1–1.5 cm long, attenuate; bracts convex, ecarinate, reddish brown, spirally imbricate, rounded, entire to minutely erose; sterile bracts several, narrowly obovate, 2–4 mm long, shorter than the fertile bracts and grading into them; fertile bracts broadly obovate, ca. 4.5–5 mm long, apically rounded; dorsal area distinct, ovate to elliptic, ca. 1.5–2 mm long, olivaceous to dark reddish brown. Lateral sepals free, slightly inequilateral, narrowly oblanceolate, ca. 5 mm long, acute; carinal keel ciliate, toward the base narrow, toward the apex wide, firm. Petal blades broadly elliptic, 5–5.5 mm long, yellow, narrowly rounded, erose. Staminodia bibrachiate, the branches long-hairy. Anthers oblong, ca. 2 mm long. Mature capsule not seen; placentation basal. Seeds not seen.

This species, with its distinct, elongate ligule broader than the leaf blade base, multiflowered spikes with (often) reddish brown dorsal areas, and free lateral sepals with ciliate keels, shows affinities to the rare *X. downsiana* Smith, a species thus far known only from Pará. However, *X. jataiana* has a longer ligule; its leaf blade margins are more broadly incrassate; the leaf apecies are bluntly callus tipped; the flowers are larger; and the lateral sepals are more nearly equal. Mature fruit and seeds of either of these species are unavailable.

5. **Xyris lutescens** Kral & Wanderley, sp. nov. TYPE: Brazil. Goiás: Mun. Posse, Nova Vista, brejo da borda de chapada, 8 Oct. 1976, *G. Hatschbach 39021* (holotype, MBM; isotypes, US, VDB). Figure 6.

Planta perennis, solitaria vel cespitosa, basibus bulbosis, atrocastaneis. Radices graciles. Caules breves. Folia ensiformi-linearia, 10–20 cm longa, torta, erecta vel leviter expansa, vaginis scaporum longiora; laminae planae vel leviter tortae, 3–4-plo vaginis longiores, 1.2–2.2 mm latae, valde compressae, flavovirentes, punctatae, inconspicue longitudine multinervosae; apices abrupte contracti, incurvato-acuti, incrassati; margines angusti, leviter incrassati, nitidi, luteoli; vaginae ecarinatae vel asymmetrice carinatae, multicostatae, lateribus stramineis, transversim rugulosis, marginibus pallide longiciliatis, in laminas gradatim convergentibus, infime gradatim expansae tum abrupte ad basim dilatatae, acies scariosae. Vaginae scaporum laxae, luteo-carinatae, tortae, acute 2–multi-costatae, laminis laminis foliorum similibus sed brevibus. Scapi graciles, flexuosi, torti, subteretes, glandacei, 4–6 dm alti, valde 2–pluricostati et angulosi, apicem versus ca. 1 mm crassi, costis papillosis vel tuberculatis aut glabris, intervala punctata. Spica multiflora, cylindro-ovoidea vel anguste ellipsoidea, 1–2 cm longa, 5–8 mm crassa, attenuata, bracteis spiraliter imbricatis, tenuibus, pallide luteobrunneolis, ecarinatis, marginibus tenuissimis

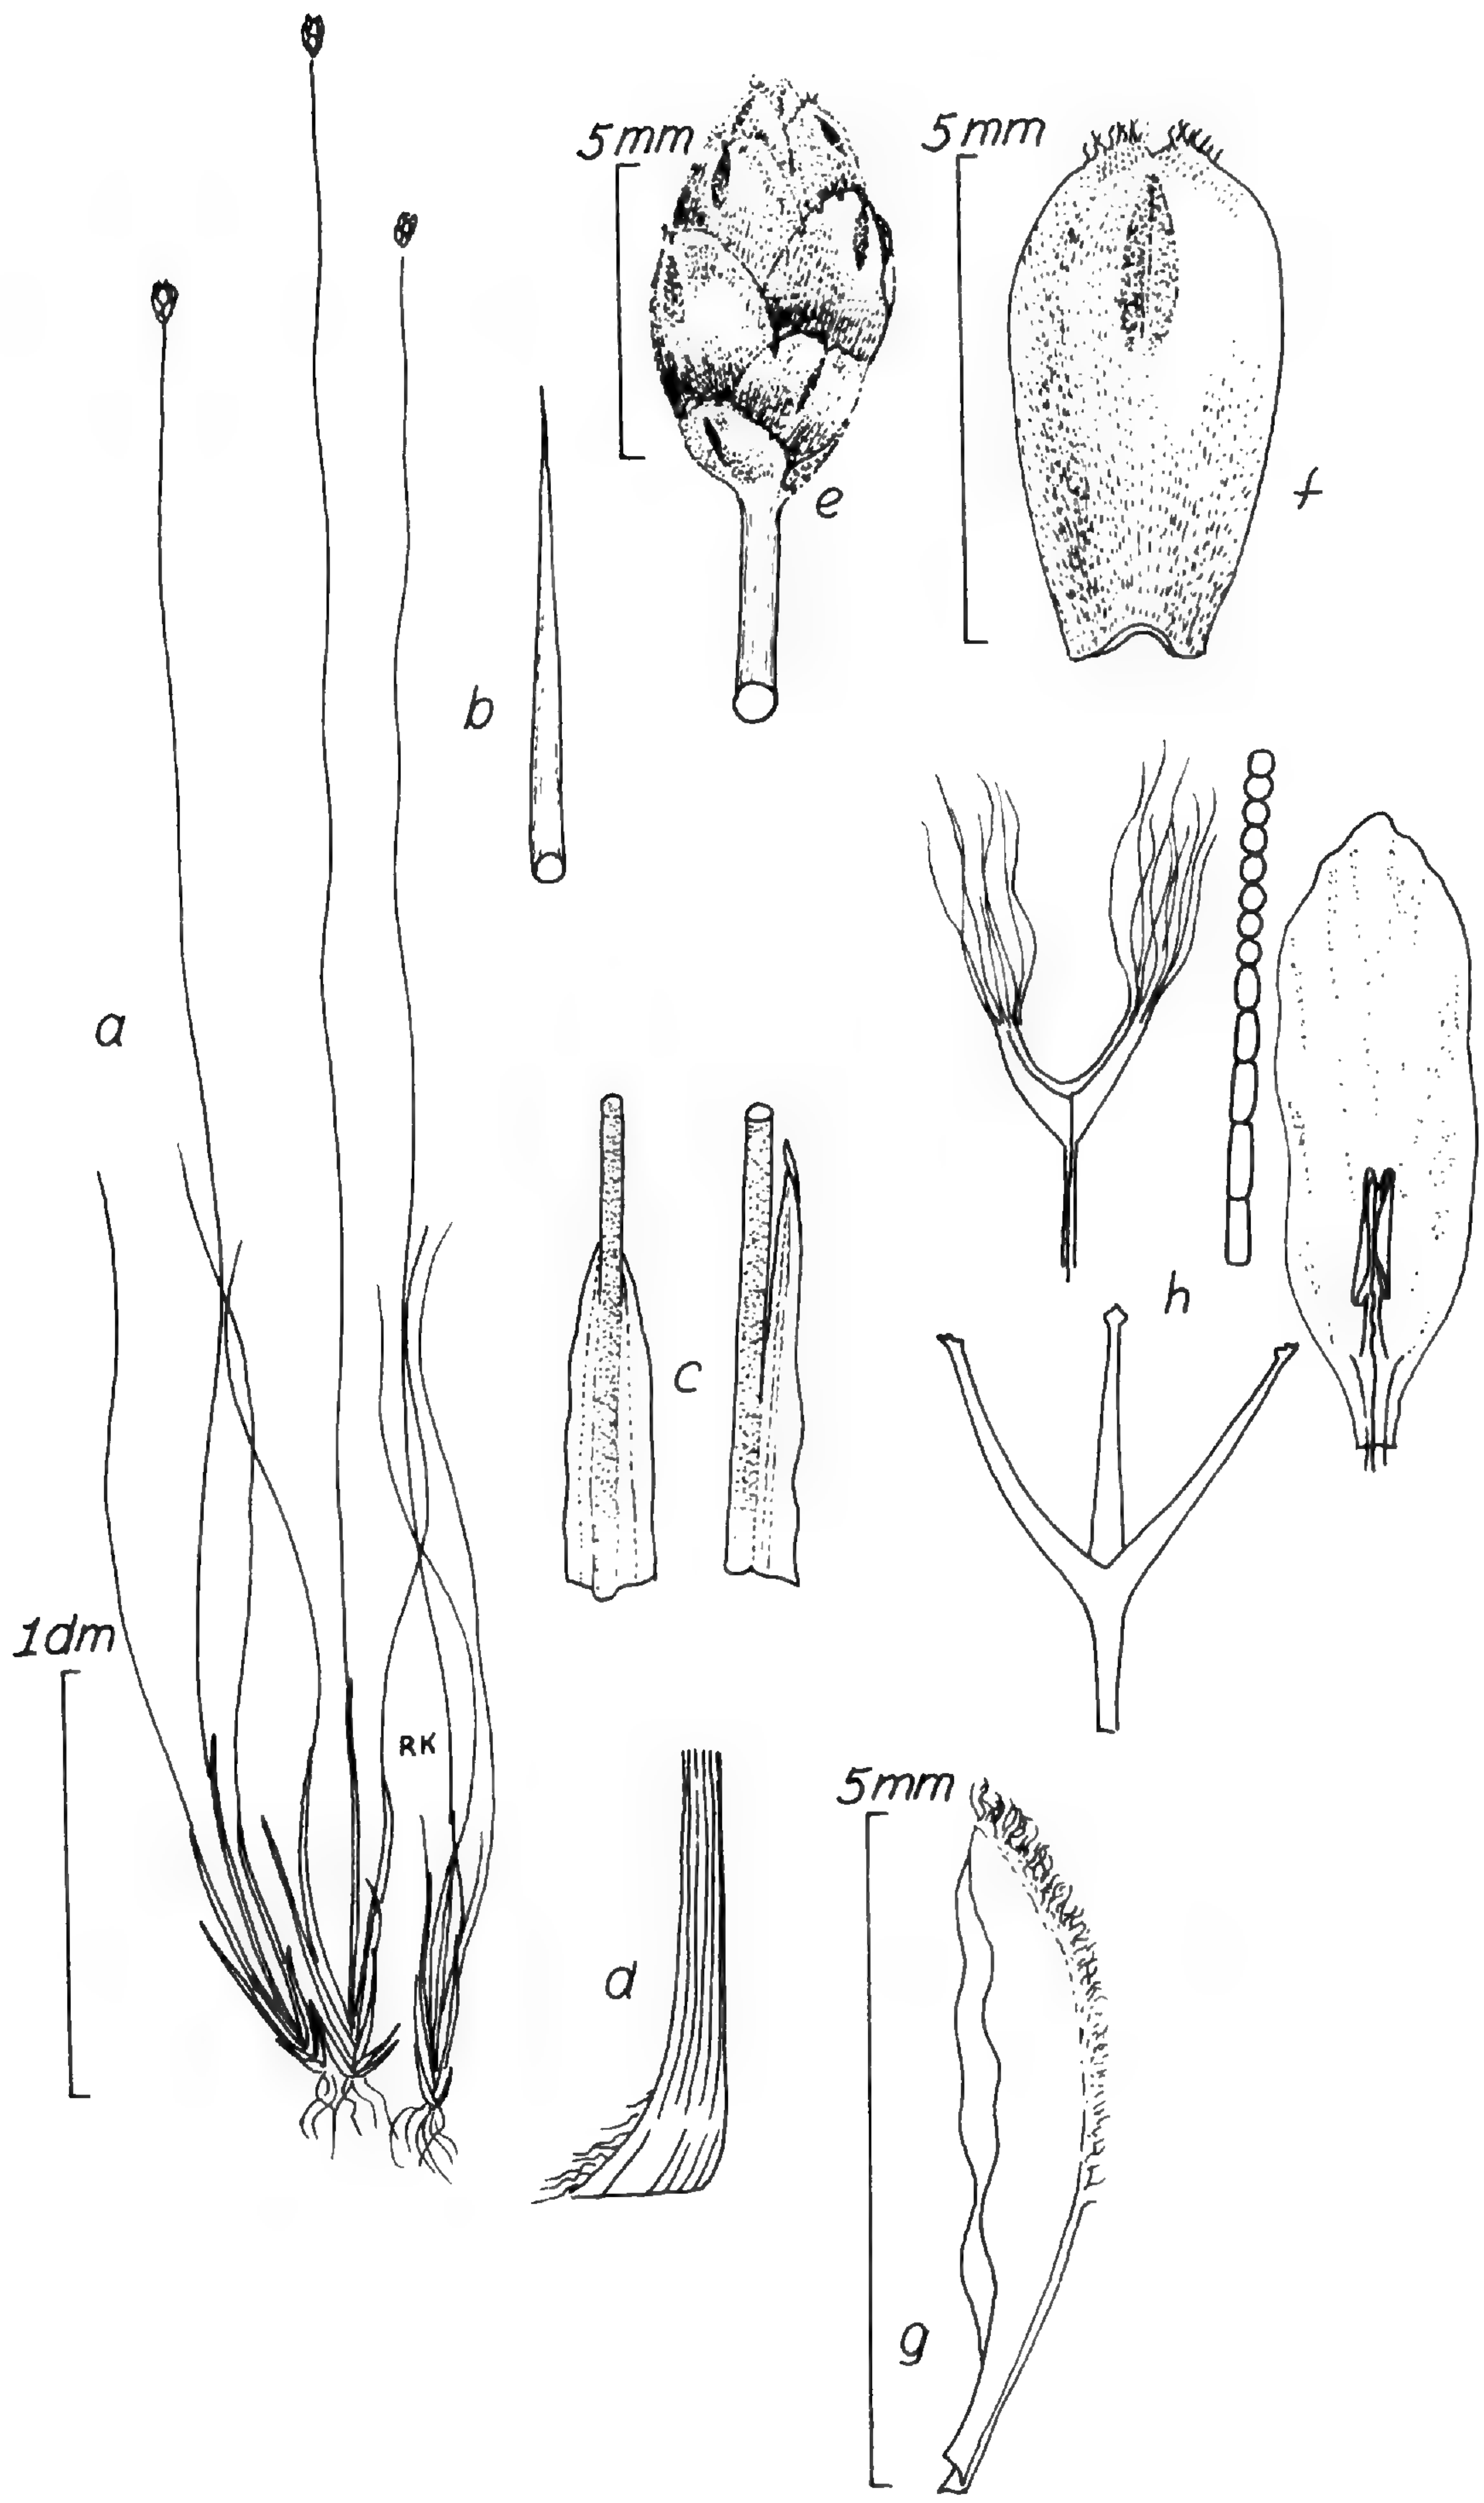

FIGURE 4. Xyris itambensis (Anderson et al. 35879).—*a. Habit sketch.*—*b. Leaf apex.*—*c. Dorsal (left) and side (right) views of leaf-sheath junction.*—*d. Leaf base.*—*e. Spike.*—*f. Fertile bract.*—*g. Lateral sepal.*—*h. Petal blade and stamen, staminode, enlarged version of beard hair, stylar apex.*

et profunde laceratis; bracteae steriles ovatae vel suborbiculatae, 2.5–3.5 mm longae, fertilibus breviores et in eas gradatim transientes; bracteae fertiles late obovatae vel suborbiculatae, usque 5 mm longae; area dorsalis indistincta. Sepala lateralia libera, valde inaequilatera, oblanceolata, ca. 5 mm longa, acuta, tenuissima; ala carinalis lata, supra medium irregulariter ciliatolacerata. Laminae petalorum late obovatae, ca. 5 mm longae, late rotundatae, leviter erosae, luteolae. Staminodia bibrachiatis, brachiis longipenicillatis, erectis, pilis clavatis. Antherae late oblongae, ca. 1 mm longae, retusae et sagittatae, filamentis ca. 2-plo breviores. Capsula ellipsoidea, leviter compressa, ca. 2.5 mm longa, acuta; placenta basalis. Semina cylindrico-ellipsoidea, 0.8–0.9 mm longa, translucida, pallide ferruginea, longitudinaliter et prominente 16–18-costata.

Plants perennial, solitary, with bulbous, deep chestnut bases. Roots slender. Stems contracted. Leaves ensiform-linear, 10–20 cm long, twisted, erect to slightly spreading, longer than the scape sheaths; blades flat or slightly twisted, 3–4 times longer than the sheaths, 1.2–2.2 mm wide, strongly flattened, yellow-green, punctate, inconspicuously longitudinally multinerved; apices rather abruptly contracted, incurved-acute, thickened; margins narrow, slightly incrassate, shining, yellowish; sheaths ecarinate or asymmetrically carinate, multicostate, with sides stramineous, transversely rugulose, the margins long-ciliate with pale hairs, narrowing gradually into the blades, gradually spreading below, then abruptly dilating at the base, the edges scarious. Sheaths of scapes loose, yellowish-carinate, twisted, sharply 2–many-ribbed; blades similar to blades of leaves but short. Scapes slender, flexuous, twisted, subterete, yellow with tints of brown, 4–6 dm high, strongly 2–many-costate and angulate, ca. 1 mm thick toward the apex, the costae papillose to tuberculate or glabrous, the intervals punctate. Spikes many-flowered, cylindro-ovoid to narrowly ellipsoid, 1–2 cm long, 5–8 mm thick, attenuate, the bracts spirally imbricate, thin, pale yellow-brown, ecarinate, the margins very thin and deeply lacerate; sterile bracts ovate to suborbicular, 2.5–3.5 mm long, shorter than the fertile bracts and grading into them; fertile bracts broadly obovate to suborbicular, to 5 mm long; dorsal areas indistinct. Lateral sepals free, strongly inequilateral, oblanceolate, ca. 5 mm long, acute, very thin; keel wide, irregularly ciliate-lacerate from the middle to the apex. Blades of petals broadly obovate, ca. 5 mm long, broadly rounded, slightly erose, yellowish. Staminodia bibrachiate, the branches pubescent with long, clavate trichomes. Anthers broadly oblong, ca. 1 mm long, emarginate or sagittate, half as long as the filaments. Capsule ellipsoid, slightly compressed, ca. 2.5 mm long, acute; placentation basal. Seeds cylindro-ellipsoid, 0.8–0.9 mm long, translucent, pale red-brown, longitudinally and strongly 16–18-ribbed.

This species, with sheath edges gradually converging to blade bases, and lacking dorsal areas on its thin, pale-margined, broad, ragged bracts, appears to blend characteristics of the species complex around *X. ciliata* Thunb. The yellow tints of both spike and complanate foliage are distinctive, together with the strongly and sharply multicostate scape. In most xyrids the anthers are longer than the free portions of the filaments, or at least these are equal; in *X. lutescens* the anthers are considerably shorter than the filaments.

6. **Xyris obcordata** Kral & Wanderley, sp. nov. TYPE: Brazil. Minas Gerais: Serra do Espinhaço, wet sand among outcrops, cut-over gallery forest and adjacent outcrops, Rio Jequití, ca. 25 km E of Diamantina, elev. 790 m, 17 Mar. 1970, *H. S. Irwin, S. F. da Fonseca, R. Souza, R. Reis dos Santos & J. Ramos 27763* (holotype, UB; isotypes, NY, US). Figure 7.

Planta perennis, densicaespitosa, basibus infirmis. Caules breves. Radices graciles. Folia laxa, 1–2 dm longa, indistincte disticha, glabra, vaginis scaporum longiora; laminae planae, valde compressae, vaginis 1–2-plo longiores, 2–3.5 mm latae, longitudine indistincte multinervosae, virides; apices abrupte contracti, anguste acuti, leviter incrassati, incurvati; margines tenues, uniforme subtiliter albociliati; vaginae carinatae (carinibus integris), stramineae, marginibus scariosis, integris, in laminas gradatim convergentibus, basin versus gradatim dilatatae. Vaginae scaporum laxae, tortae, humile costatae, ad folia in coloribus, laminis apiceque similes. Scapi graciles, 2.5–4 dm alti, ca. 1 mm lati, virides, in sectio transversali elliptici vel anguste elliptici, longitudine subtiliter acute striatonervosae, a medio ad apicem valde bicostati et vulgo ancipiti, costis compressis, latis, subtiliter antrorse albo-

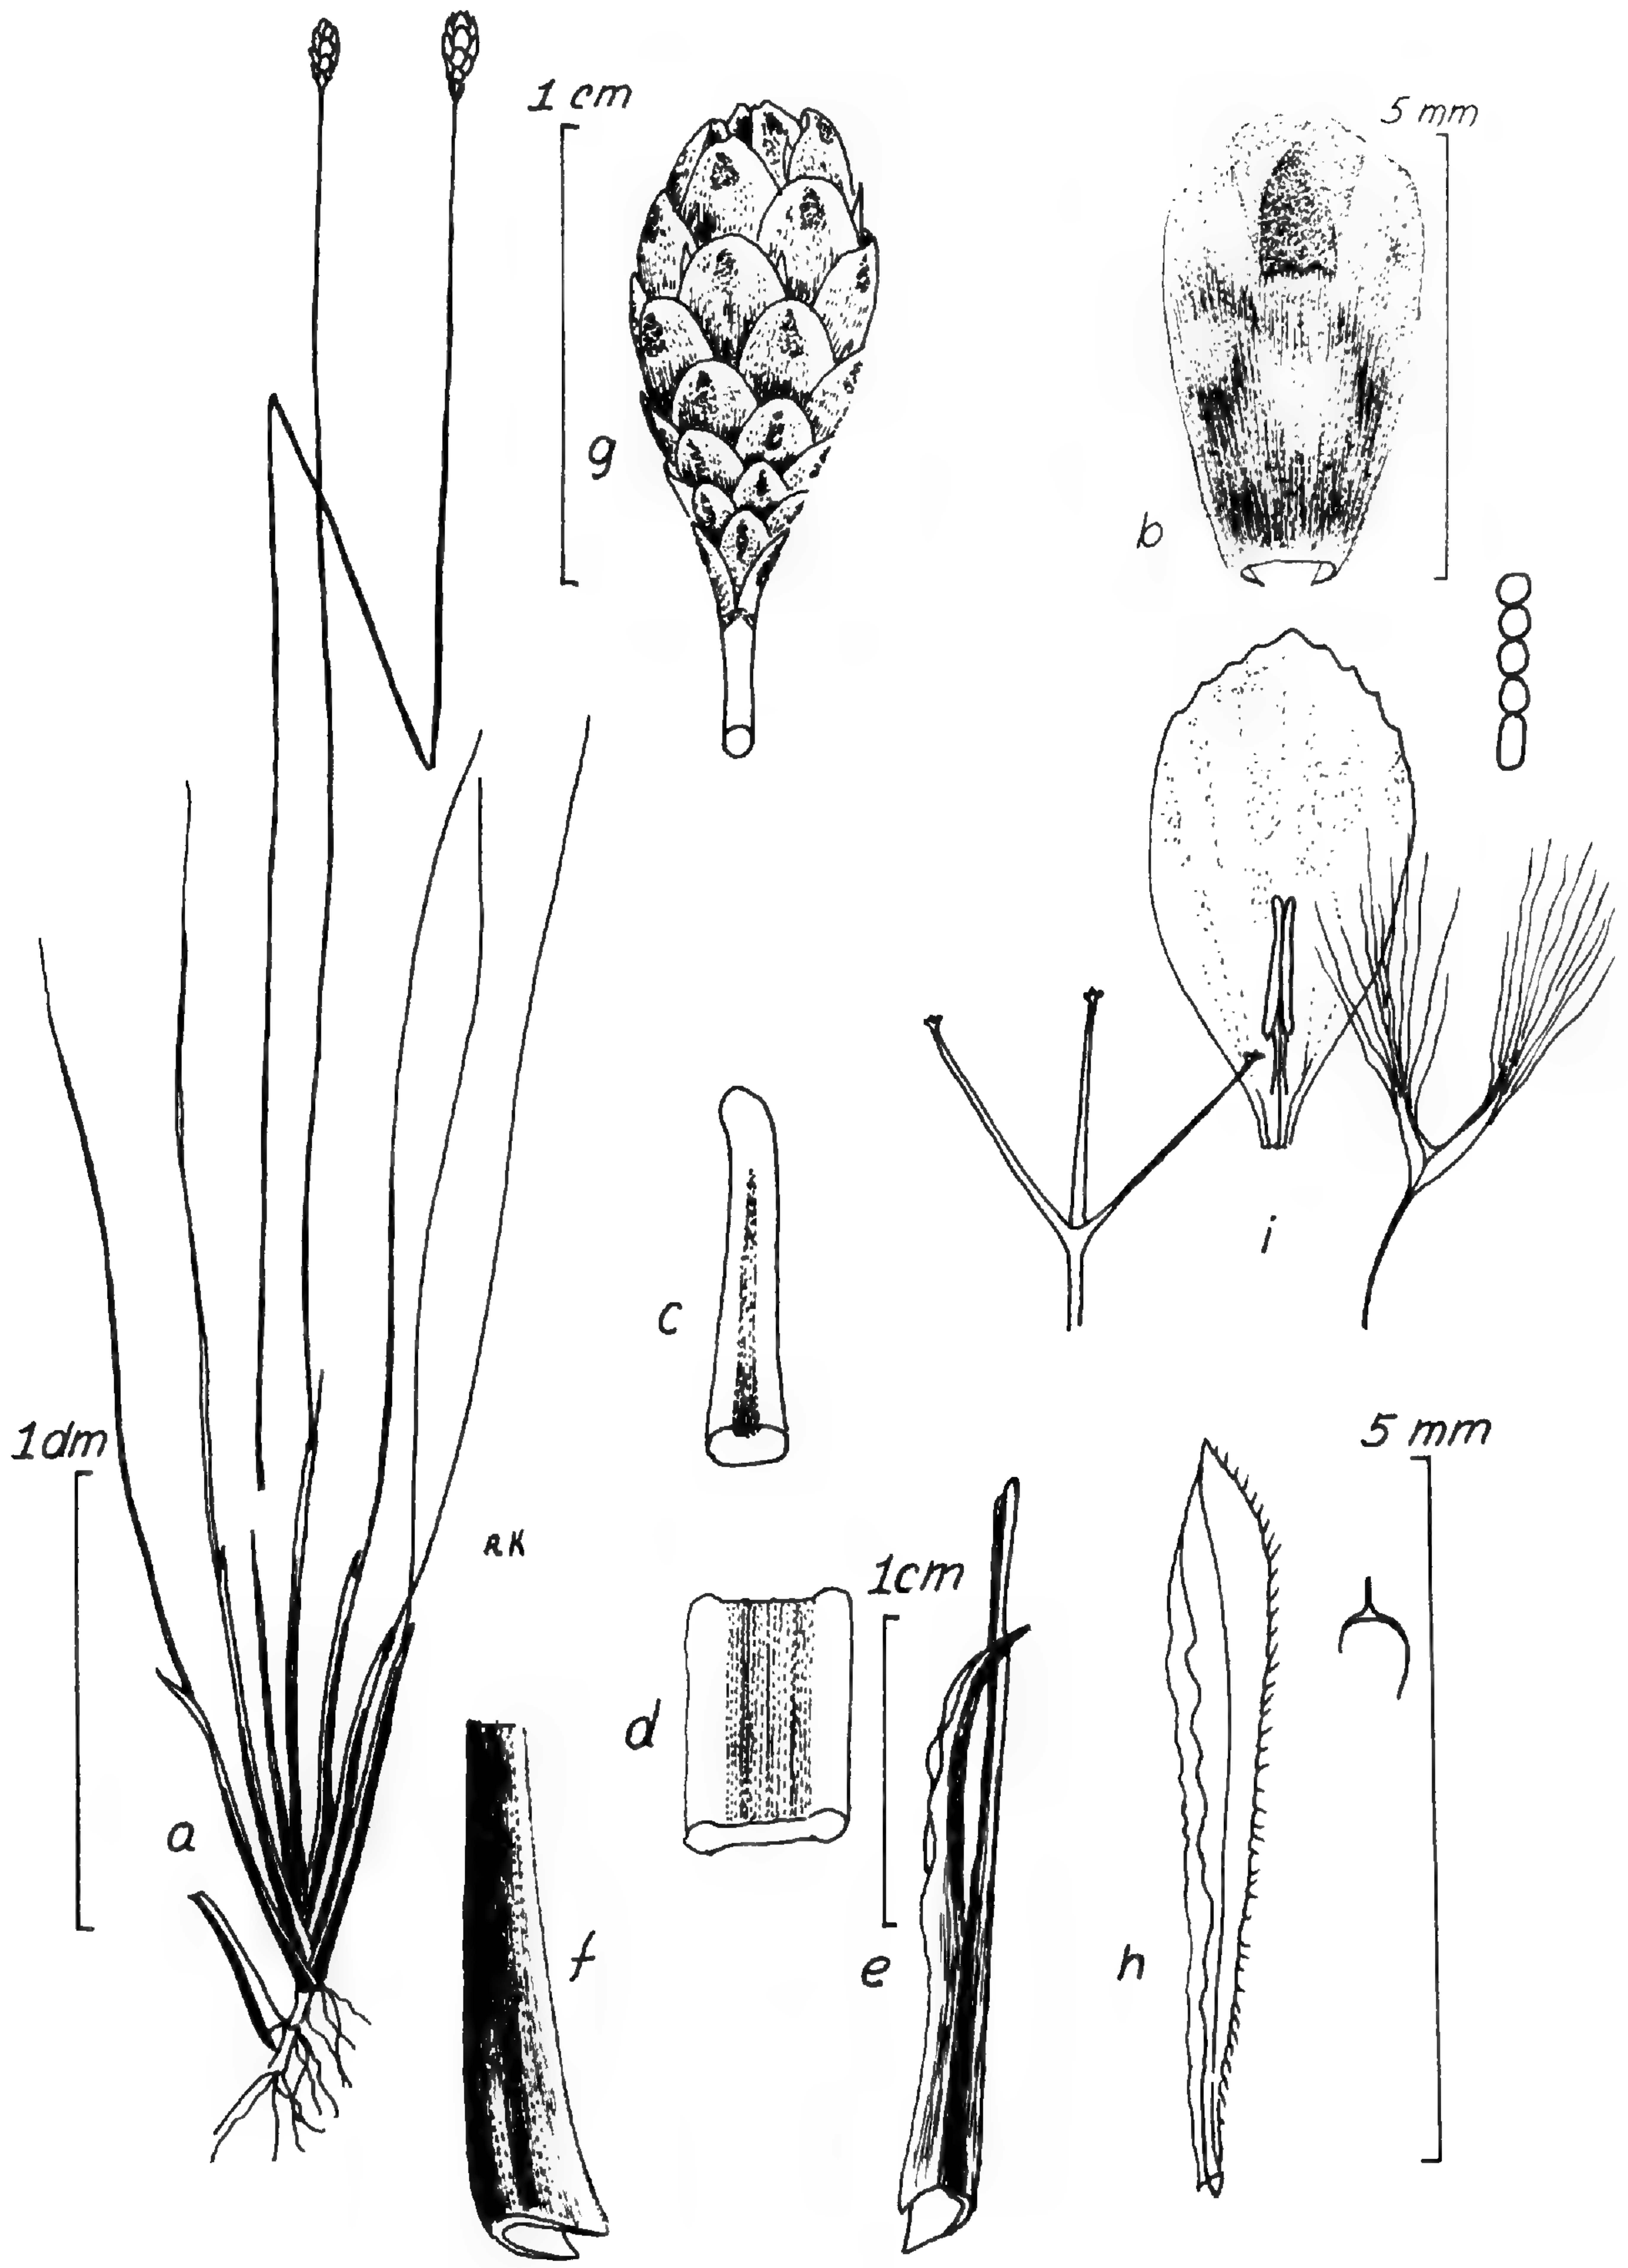

FIGURE 5. Xyris jataiana (Hatschbach 40060).—*a. Habit sketch.—b. Bract.—c. Leaf apex.—d. Sector of leaf at mid blade.—e. Upper part of leaf sheath at blade base.—f. Leaf base.—g. Spike.—h. Lateral sepal.—i. Petal blade, staminode, enlarged cells of staminode beard, stylar apex.*

ciliatis. Spicae multiflorae, late ovoideae, 7–9 mm longae, laxae, si prementes nunc compressae, 6–7 mm latae; bracteae ecarinatae, ovatae vel late obovatae aut suborbiculatae, obcordatae, laxe spiraliter imbricatae, tenues, pallide fulvae, marginibus amplis tenuissimis, friabilibus, ad apicem ferrugineis; bracteae steriles 5–6, 2–2.5 mm longae; bracteae fertiles usque ad 4.5 mm longae; area dorsalis late vel anguste elliptica, ca. ⅔ bracteis breviori, viridis. Sepala lateralia libera, spathulata, acuta, ca. 4 mm longa, tenuia, ala carinali tenuissima, subintegra.

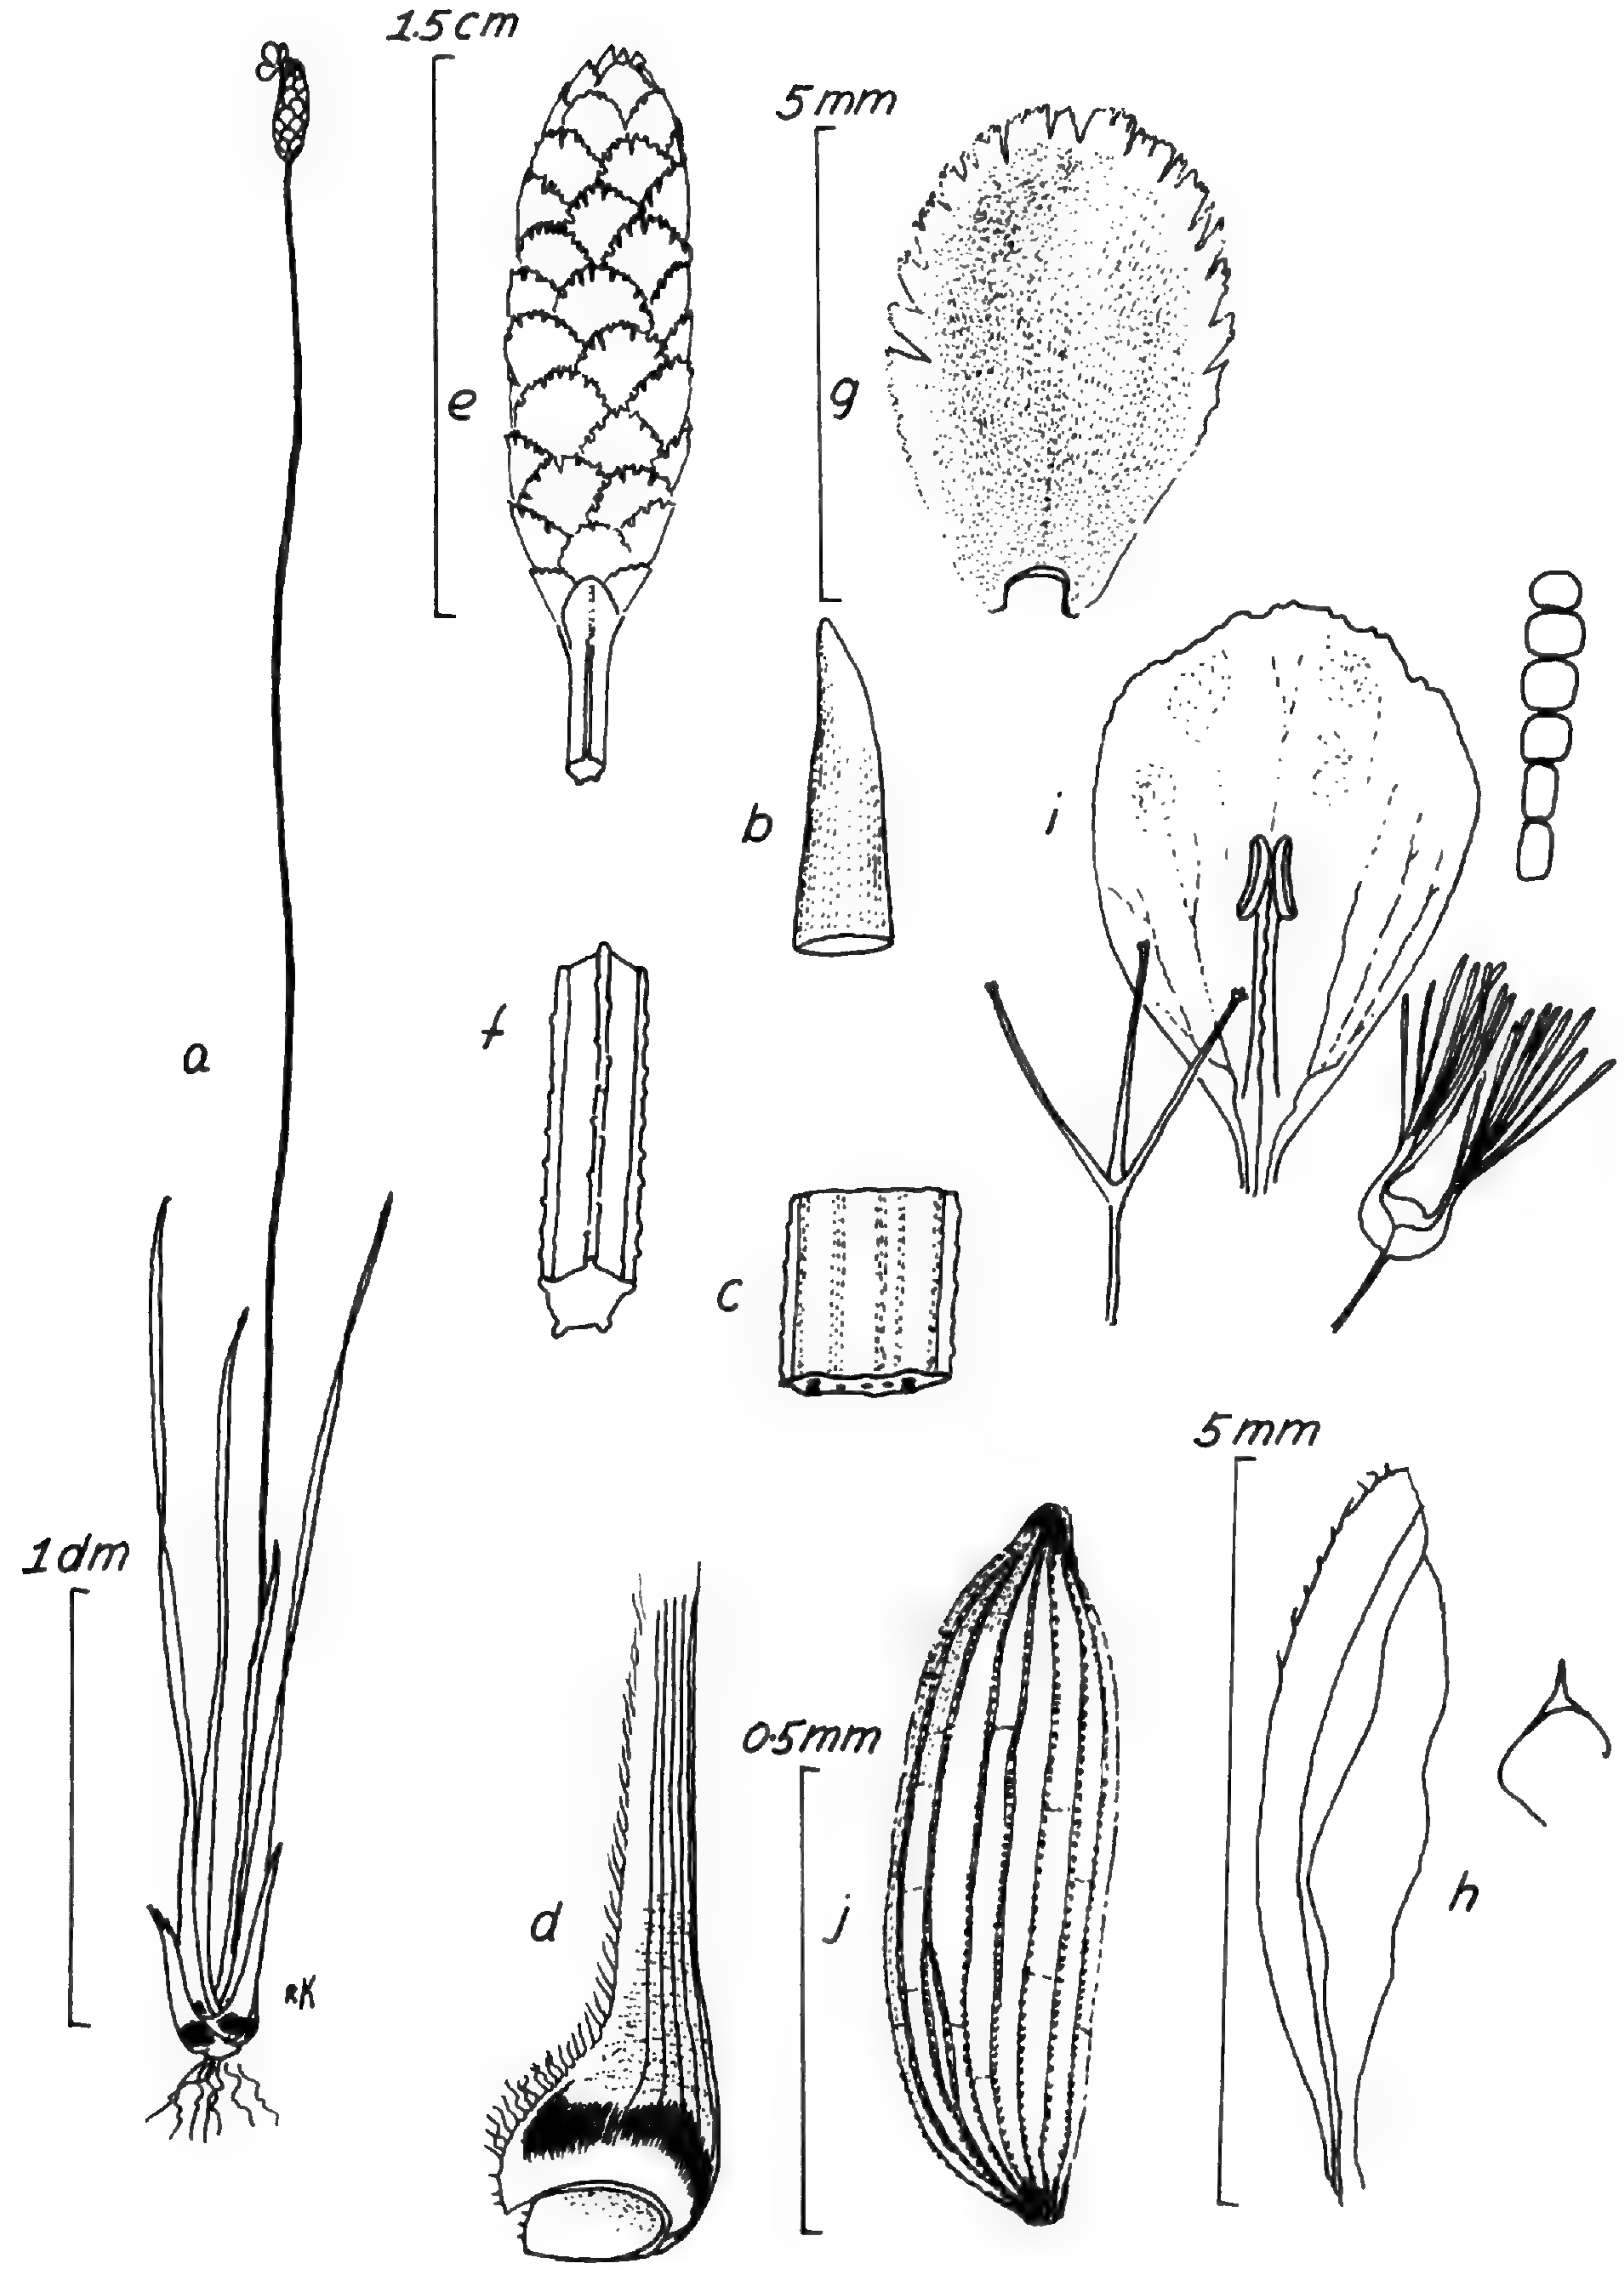

FIGURE 6. Xyris lutescens (Hatschbach 39021).—*a. Habit sketch.—b. Leaf tip.—c. Sector of mid blade.—d. Leaf sheath.—e. Spike.—f. Sector of mid scape.—g. Fertile bract.—h. Lateral sepal.—i. Floral parts.—j. Seed.*

Laminae petalorum obovatae, ca. 3 mm longae, rotundatae, luteolae. Staminodia bibrachiata, brachiis compressis, longipenicillatis. Antherae oblongo-lanceolatae, ca. 1.5 mm longae, valde emarginatae et sagittatae, filamentis longiores. Capsula obovoidea, ca. 2 mm longa, placenta centralis. Semina numerosa, turgide et late asymmetrice ovoidea, ca. 0.3 mm longa, atroferruginea, nitida, prominente longitudinaliter 14–16-costata.

Plants perennial, densely cespitose, the bases soft. Stems short. Roots slender. Leaves lax, 1–2 dm long, indistinctly distichous, smooth, longer than the scape sheaths; blades flat, strongly compressed, 1–2 times longer than the sheaths, 2–3.5 mm wide, longitudinally indistinctly multinerved, green; apices abruptly narrowed, narrowly acute, slightly thickened, incurved; margins thin, uniformly finely white ciliate; sheaths carinate (carinae entire), stramineous, the margins scarious and entire, narrowing gradually into the blades, gradually dilating toward base. Scape sheaths lax, twisted, low-costate, like leaves in color and with similar tips. Scapes slender, 2.5–4 dm high, ca. 1 mm broad, greenish, in cross section elliptic or narrowly elliptic, longitudinally finely and sharply striate-nerved, from middle to apex strongly bicostate and commonly ancipital, the costae compressed, wide, finely antrorsely white ciliate. Spikes many-flowered, broadly ovoid, 7–9 mm long, soft, if pressed then flattened, 6–7 mm wide; bracts ecarinate, ovate to broadly obovate or suborbicular, obcordate, loosely spirally imbricate, thin, pale tan except ferruginous apex, the ample margins very thin, friable; sterile bracts 5–6, 2–2.5 mm long; fertile bracts up to 4.5 mm long; dorsal area broadly to narrowly elliptic, about ⅔ as long as the bracts, green. Lateral sepals free, spathulate, acute, ca. 4 mm long, thin, the keel very thin, subentire. Petal blades obovate, ca. 3 mm long, rounded, yellowish. Staminodia bibrachiate, with branches flattened, long-penicillate. Anthers oblong-lanceolate, ca. 1.5 mm long, strongly emarginate and sagittate, longer than the filaments. Capsule obovoid, ca. 2 mm long, placentation central. Seeds numerous, turgidly and broadly asymmetrically ovoid, ca. 0.3 mm long, deep reddish brown, shining, prominently longitudinally 14–16-ribbed.

This soft-based, lax-leaved plant appears to be in the same complex as *X. mima* Smith & Downs and *X. moraesii* Smith & Downs; it is most similar in habit to the latter, differing mainly in the broader leaf blades, slightly narrower spikes, coloration of bract apex, and subentire sepal keels. *Xyris obcordata* is taller than the former and has broader spikes and entire (vs. ciliate) sepal keels. It is unlike either in its ancipital, broadly bicostate scape and reddish coloration of the thin, friable apex of the obcordate bracts.

7. **Xyris pranceana** Kral & Wanderley, sp. nov. TYPE: Brazil. Goiás: Chapada dos Veadeiros, 2 km from Veadeiros, Cerrado, common, 18 July 1964, *G. T. Prance & N. T. Silva 58195* (holotype, UB; isotypes, NY, US, VDB). Figure 8.

Planta perennis, densicaespitosa, glabra, basibus bulbosis, castaneis, rhizomate nullo vel brevi horizontali, per bases persistentes veternas foliorum obtecto. Radices graciles. Folia rigida, 1.5–3 dm longa, erecta, torta et leviter flexuosa, vaginis scaporum longiora; laminae teretes vel subteretes, vaginis 4–5-plo longiores, 0.3–0.5 mm crassae, vade multicostatae, saepe 1–2-sulcatae, ferrugineae vel brunneolae aut olivaceae; apices valde contracti, conice subulati; vaginae nitidae, integrae, ad basin ecarinatae, apicem versus carinatae, ferrugineae vel brunneolae, quam laminis multomagis latiores, valde ligulatae; ligula firma, plana, oblonga, 4–5 mm longa, ad apicem obtusa; margines tenues, integrae, infime gradatim expansae, tum abrupte ad basin dilatatae. Vaginae scaporum tortae, leviter multicostatae, lamproferrugineae, laminis brevibus, subulatis. Scapi vulgo 2.5–4.5 dm longi, recti, leviter torti, teretes, 0.5 mm crassi, inconspicue longitudine striati, olivacei. Spicae ellipsoideae, 8–10 mm longae, attenuatae, pluriflorae, bracteae convexae, ecarinatae, pallide ferrugineae vel brunneolae, nitidae, tenues, integrae, laxe spiraliter imbricatae; bracteae steriles 5–7, ellipticae vel ovatae, infimae ellipticae, fertilibus multo breviores et in eas gradatim transientes; bracteae fertiles ovatae vel late oblongae, ca. 5 mm longae, supernae magis plicatae et infernis tenuiores, ad apicem brevicarinatae; area dorsalis brevilinearis, ferruginea, apicalis. Sepala lateralia libera, valde inaequilatera, lineari-elliptica, curvata, 5–5.5 mm longa, acuta; ala carinali firma, a basi integra, a medio ad apicem ciliata, ad apicem alis et pilis ferrugineis. Laminae petalorum anguste obovatae, ca. 5.5 mm longae, luteolae, acutae, sparse erosae, cuneatae. Staminodia bibrachiata, brachiis longipenicillatis. Antherae lanceolato-oblongae, ca. 1.5 mm longae, sagittatae. Capsula lanceolata, ca. 4 mm longa, subulata; placenta centralis. Semina ovoidea vel ellipsoidea, ca. 0.5 mm longa, atroferruginea, minute sed acute multicostata.

Plants perennial, densely cespitose, smooth, the bases bulbous, castaneous, the rhizome none or short and horizontal, covered by chaffy bases of old leaves. Roots slender. Leaves stiff, 1.5–3 dm long, erect, twisted and somewhat flexuous, longer than the scape sheaths; blades terete or subterete, 4–5 times longer than the sheaths, 0.3–0.5 mm thick, shallowly several-ribbed, often 1–2-sulcate, reddish brown, or brownish, or greenish-brown; apices

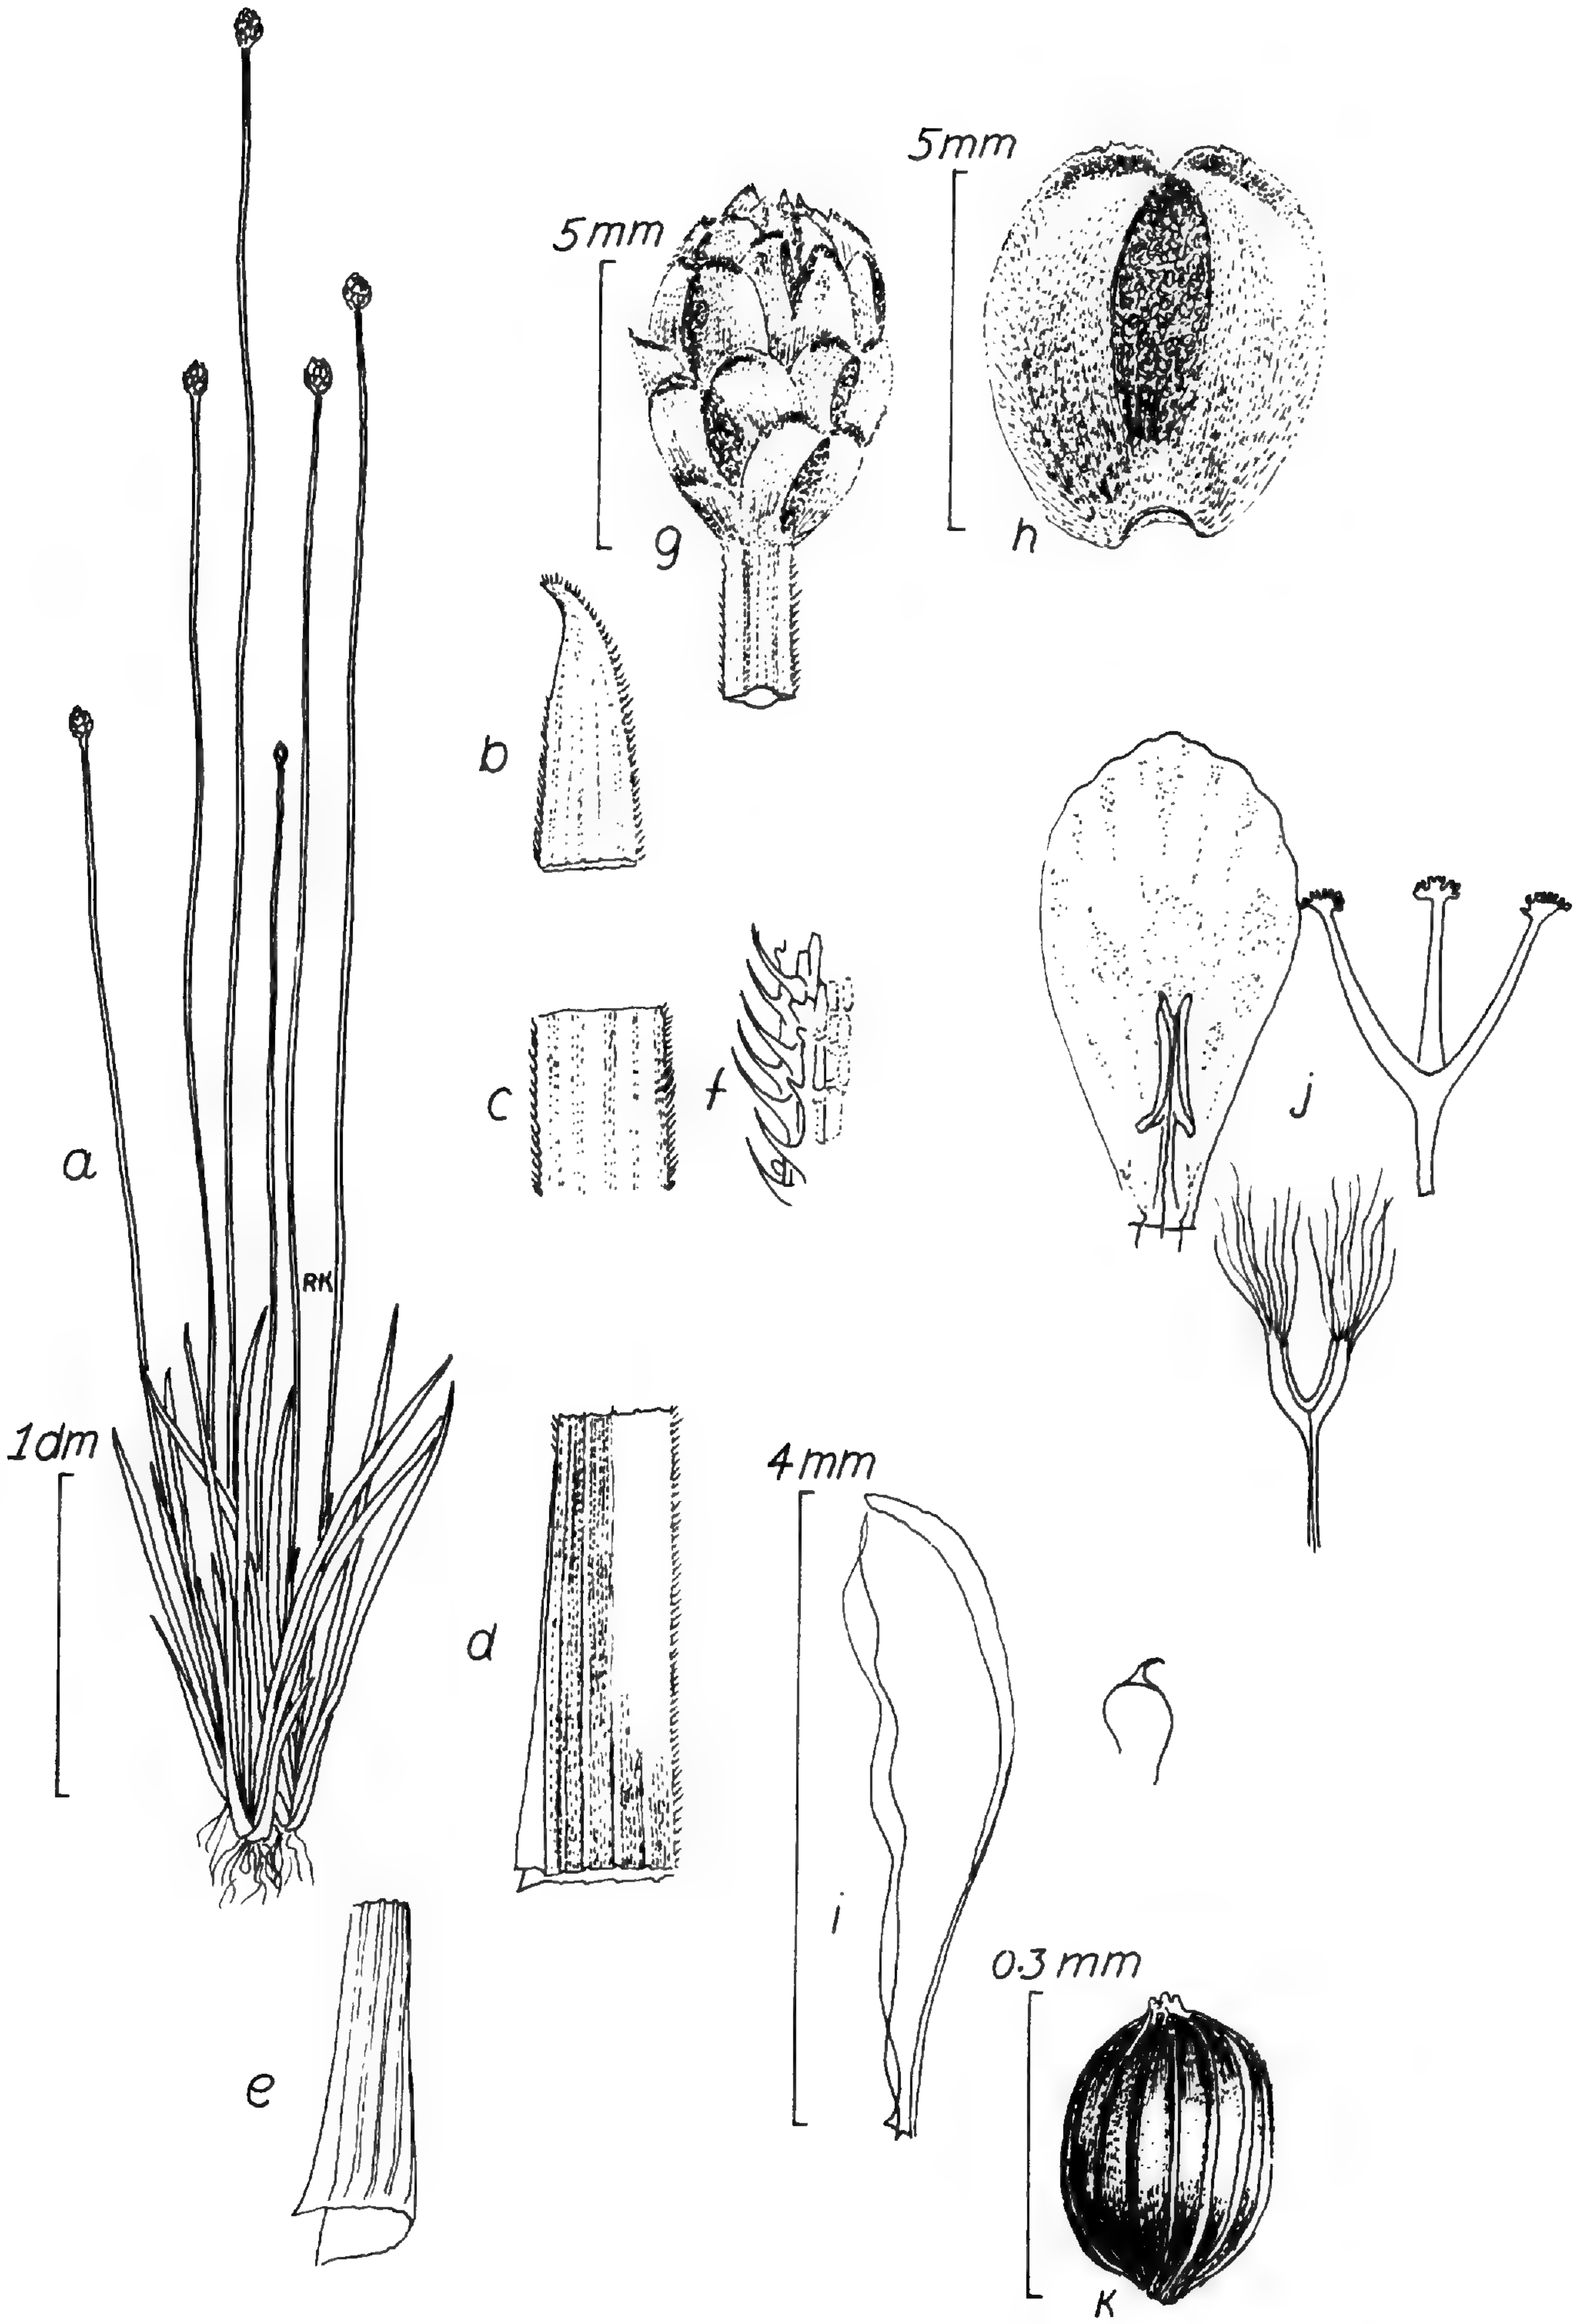

FIGURE 7. Xyris obcordata (Irwin et al. 27763).—*a. Habit sketch.—b. Leaf apex.—c. Sector of leaf at mid blade.—d. Sector of leaf at blade-sheath junction.—e. Leaf base.—f. Very enlarged small sector of leaf blade edge.—g. Spike.—h. Fertile bract.—i. Lateral sepal.—j. Petal blade and stamen, staminode, stylar apex.—k. Seed.*

strongly narrowed, conic-subulate; sheaths shining, ecarinate at base, carinate toward apex, reddish brown to brown, much wider than the blades, strongly ligulate, the ligule firm, flat, oblong, 4–5 mm long, apically obtuse, the margins thin, entire, gradually expanding downward, then abruptly dilating at base. Scape sheaths twisted, low-multicostate, lustrous reddish brown, with short, subulate blades. Scapes commonly 2.5–4.5 dm long, erect, somewhat twisted, terete, 0.5 mm thick, inconspicuously longitudinally striate, olivaceous. Spikes ellipsoid, 8–10 mm long, attenuate, many-flowered, the bracts convex, ecarinate, pale reddish brown or brownish, shining, thin, entire, loosely spirally imbricate; sterile bracts 5–7, elliptic to ovate, the lowest elliptic, much shorter than the fertile bracts and grading gradually into them; fertile bracts ovate to broadly oblong, ca. 5 mm long, the upper ones more folded and thinner than the lower ones, all short-carinate at apex; dorsal area short-linear, reddish brown, apical. Lateral sepals free, strongly inequilateral, linear-elliptic, curvate, 5–5.5 mm long, acute; keel firm, entire at base, sparsely (deciduously) ciliate from middle to apex, the keel and hairs at the sepal apex reddish brown. Petal blades narrowly obovate, ca. 5.5 mm long, yellow, acute, sparsely erose, the base cuneate. Staminodia bibrachiate, the branches long-penicillate. Anthers oblong-lanceolate, ca. 1.5 mm long, sagittate. Capsule ca. 4 mm long, lanceoloid, the tip subulate; placenta central. Seeds ovoid to ellipsoid, ca. 0.5 mm long, reddish brown, minutely but sharply multicostate.

While the dorsal areas of the bracts of this distinctive species are small, they are dark in contrast to the rest of the bract and are thus evident. The slender, terete leaf blades are much narrower than the dilated, strongly ligulate sheaths. The only hairs on the plant are those found scattered along the keel apex of the lateral sepals.

8. Xyris sceptrifera Kral & Wanderley, sp. nov. TYPE: Brazil. Goiás: Serra dos Cristais, 17°S, 48'W, creek margin ca. 5 km S. of Cristalina, Goiás, elev. 1,200 m, 3 Mar. 1966, *H. S. Irwin, J. W. Grear, Jr., R. Souza & R. Reis dos Santos 13410* (holotype, UB; isotypes, NY, US). Figure 9.

Planta perennis, caespitosa, basibus bulbosis castaneis; radices graciles. Folia rigida, glabra, solum basalia, valde torta et flexuosa, 5–6 dm longa, erecta vel leviter expansa aut excurvata, vaginis scaporum longiora; laminae subteretes vel angulatae, paucinervosae et sulcatae, 1–2 mm latae, flavovirentes, 3–4-plo vaginis longiores, glabrae; apices erecti, gradatim contracti, aristati, pagina superiore concava; margines (si evidentes) incrassati, glabri; vaginae basin versus rotundatae, longitudine multicostatae, atrocastaneae, nitidae, marginibus integris, in laminam gradatim convergentibus et ad apicem conduplicatis, infime gradatim expanse tum abrupte ad basin dilatatae. Vaginae scaporum laxe conduplicatae vel apertae, leviter carinatae, laminis subteretibus, erectis, acutis. Scapi lineares, recti, vade multicostati, valde torti et flexuosi, ca. 7–10 dm alti, teretes, 1–2 mm crassi, glabri, dilute virides. Spicae ovoideae, ellipsoideae, aut cylindricae, 1–2.5 cm longae, multibracteatae, bracteis spiraliter imbricatis, convexis ecarinatis, oblongis vel obovatis, brunneolis, vadose erosis vel integris; bracteae infimae paucae, oblongae, fertilibus leviter breviores et in eas transientes; bracteae fertiles 5–5.5 mm longae, convexe rotundatae, apicale late rotundatae vel truncatae, area dorsali anguste elliptica, pallide viridis. Sepala lateralia libera, valde inaequilatera, elliptica, ca. 5.5 mm longa, valde incurvata, leviter exserta; ala carinalis angusta, a basi ad medium integra, a medio retrorse fimbriata, ad apicem expanse vel antrorse dense fimbriata, trichomatibus ferrugineis. Laminae petalorum obovatae, ca. 4 mm longae, ad apicem anguste rotundatae, dentatae, luteolae. Staminodia bibrachiata, brachiis elongatis longipenicillatis. Antherae oblongae, ca. 2 mm longae, profunde sagittatae et retusae, filamentis longiores. Capsula cylindrica, ca. 2.5 mm longa; placenta centralis. Semina anguste oblongo-fusiformia, 1.2–1.3 mm longa, ferruginea, longitudine valde multicostata.

Plants perennial, cespitose, with castaneous bases, bulbous; roots slender. Leaves rigid, smooth, strictly basal, strongly twisted and flexuous, 5–6 dm long, erect or slightly spreading or excurved, longer than the scape sheaths; blades subterete or angulate, few-nerved and sulcate, 1–2 mm wide, yellow-green, 3–4 times longer than the sheaths; apices erect, gradually narrowed, aristate, with upper surface concave; margins (if evident) thickened, smooth; sheaths rounded toward base, longitudinally multicostate, dark castaneous, lustrous, entire-margined, narrowing gradually into the blade, conduplicate at apex, toward base gradually widening then abruptly dilating. Scape sheaths loosely conduplicate

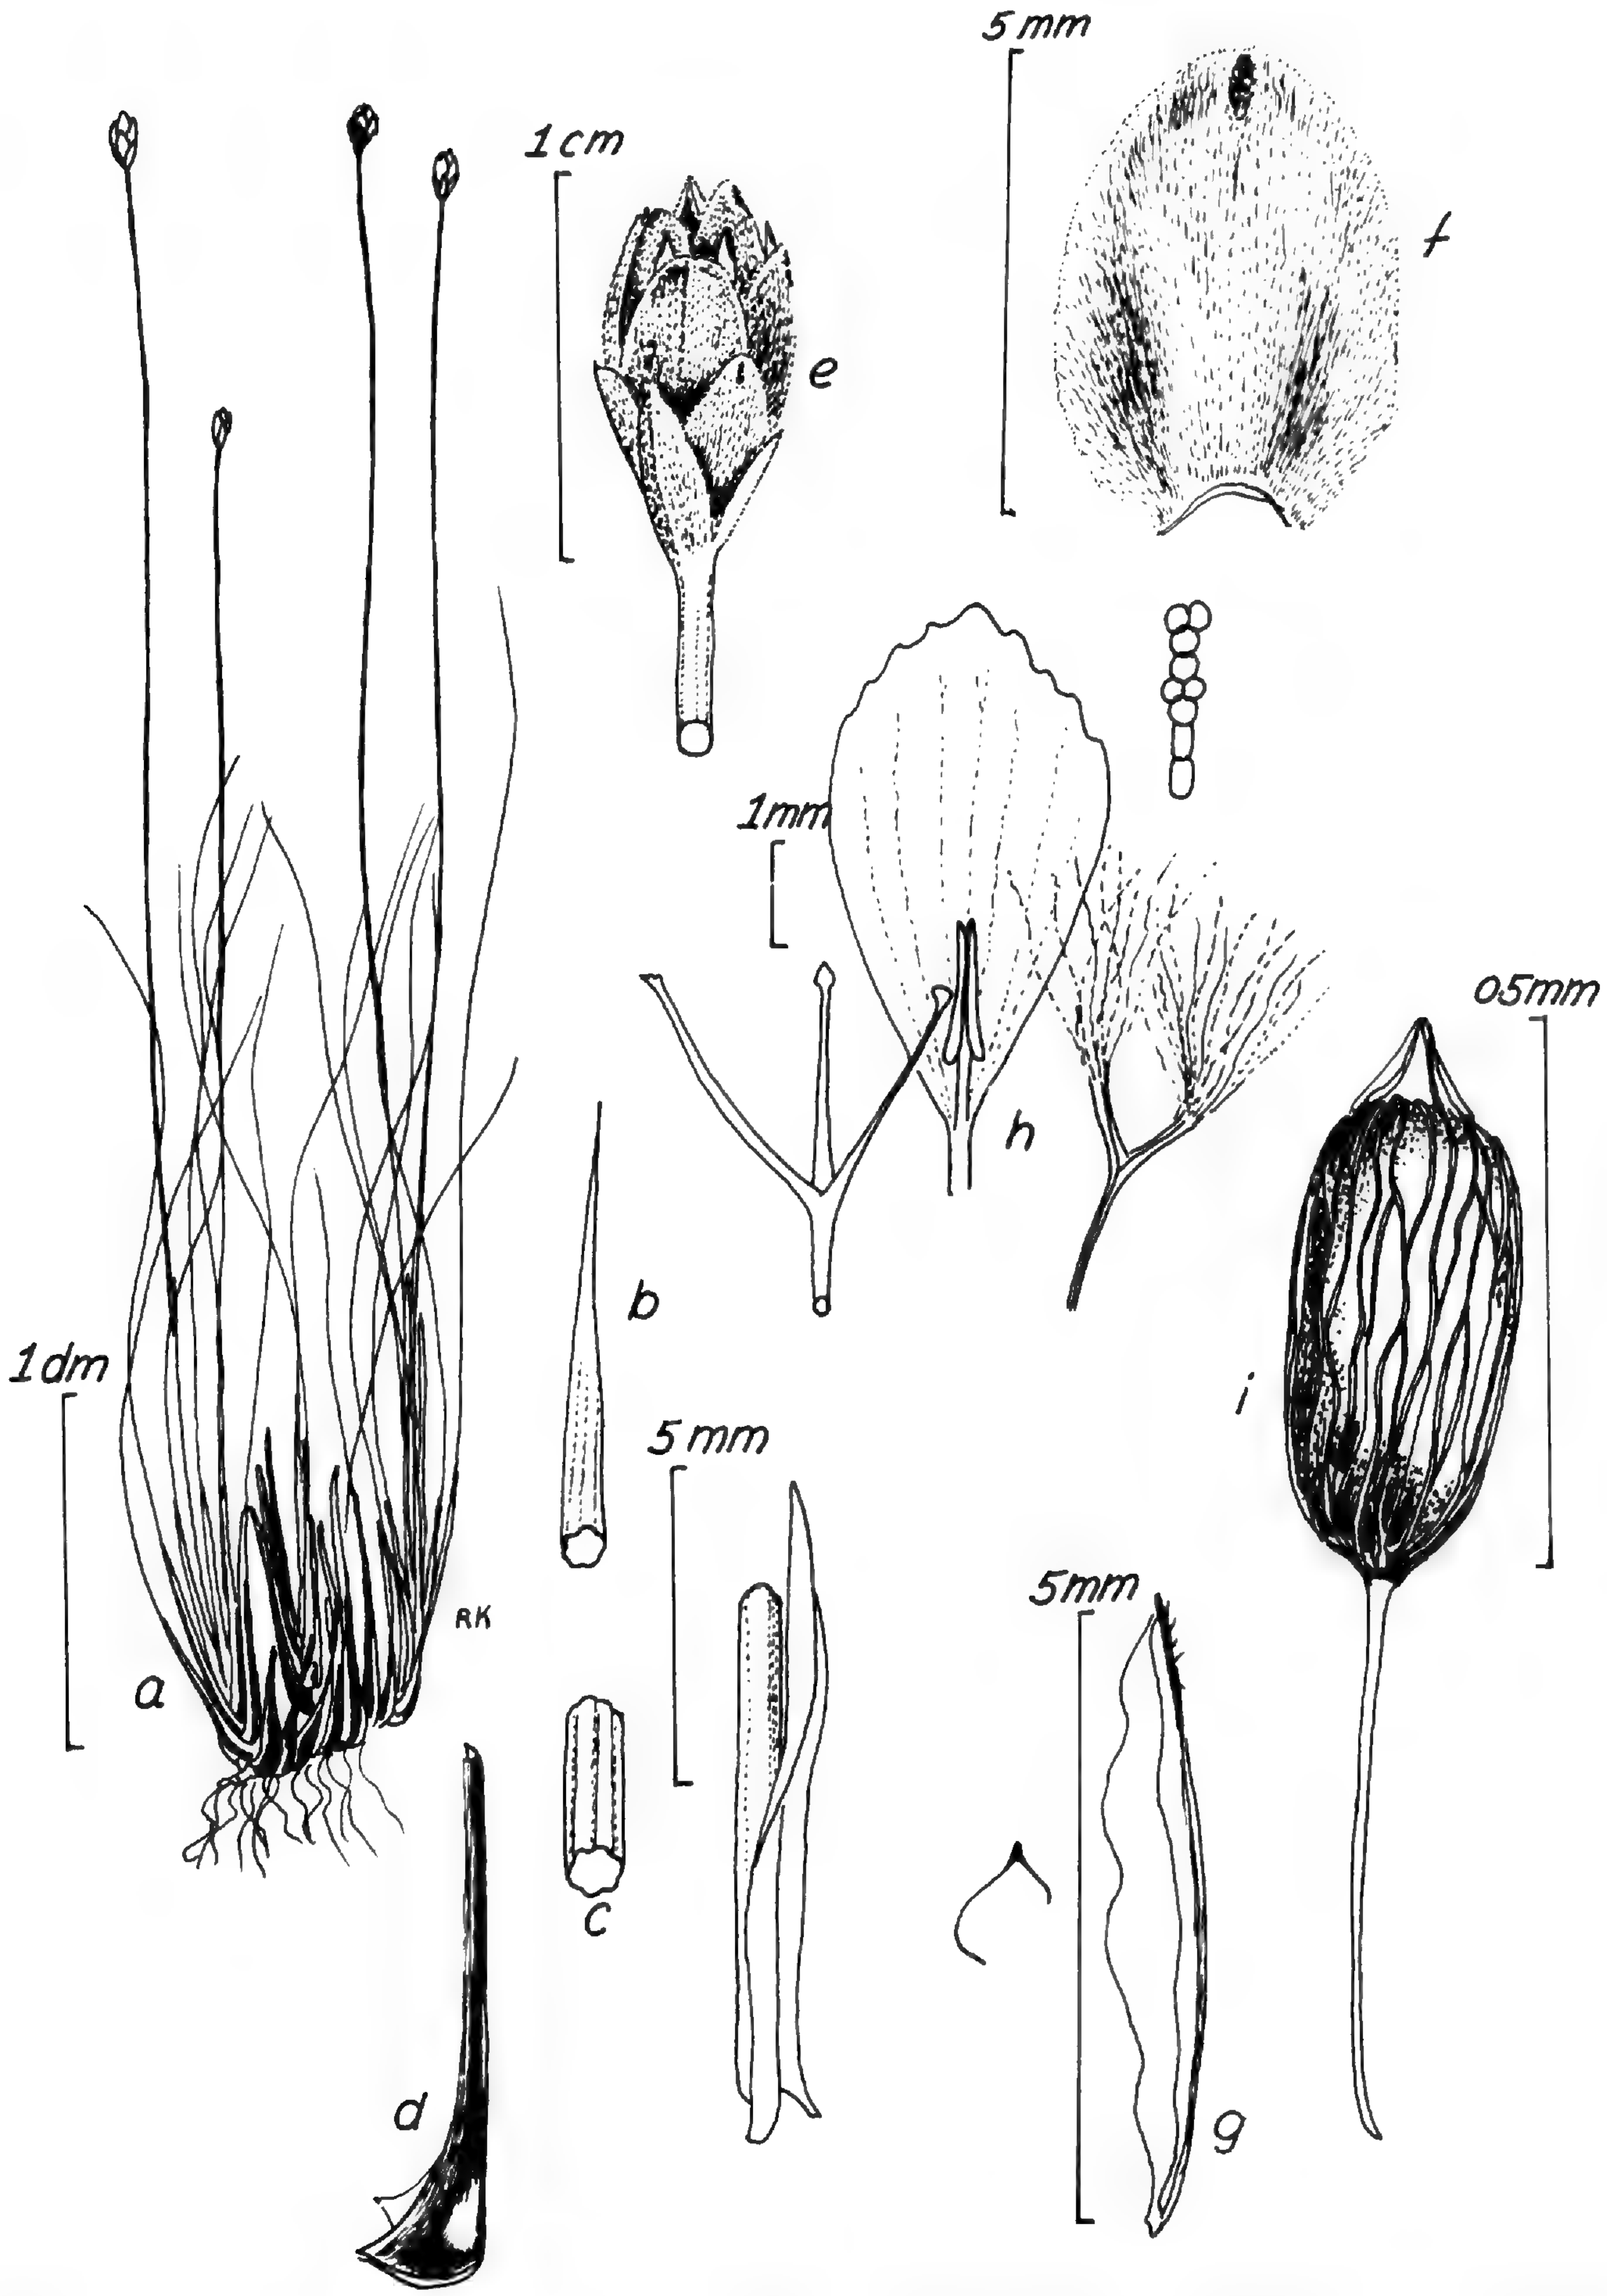

FIGURE 8. Xyris pranceana (Prance & Silva 58195).—*a. Habit sketch.—b. Leaf apex.—c. Sector of mid blade.—d. Leaf base.—e. Spike.—f. Fertile bract.—g. Lateral sepal.—h. Flower parts.—i. Seed with attached funicle.*

or open, slightly carinate, the blades subterete, erect, acute, short. Scapes linear, shallowly multicostate, strongly twisted and flexuous, ca. 7–10 dm high, terete, 1–2 mm thick, smooth, pale green. Spikes ovoid, ellipsoid or cylindric, 1–2.5 cm long, 5–7 mm thick, with many spirally imbricate bracts, convex-backed, oblong to obovate, brown, shallowly erose or entire; sterile bracts few, oblong, slightly shorter than the fertile bracts and grading into them; fertile bracts 5–5.5 mm long, convexly rounded, broadly rounded to truncate apically, the dorsal area elliptic, pale green. Lateral sepals free, strongly inequilateral, elliptic, ca. 5.5 mm long, strongly curvate; carinal keel narrow, entire from base to middle, retrorsely fimbriate at middle, spreadingly or antrorsely densely fimbriate at apex, the trichomes ferrugineous. Petal blades obovate, ca. 4 mm long, yellow, at apex narrowly rounded, toothed. Staminodia bibrachiate, the branches elongate, long-penicillate. Anthers oblong, ca. 2 mm long, deeply sagittate and retuse, longer than the filaments. Capsule cylindric, ca. 2.5 mm long; placentation central. Seeds narrowly oblong-fusiform, 1.2–1.3 mm long, reddish-brown, longitudinally strongly multiribbed.

Additional specimens examined. BRAZIL. GOIÁS: creek bank, ca. 6 mi. S of Cristalina, el. 1,175 m, 5 Nov. 1965, *H. S. Irwin, R. Souza & R. Reis dos Santos 9947* (NY, US). MINAS GERAIS: Morro das Pedras, wet campo, red clay, ca. 35 km NE of Patrocino, elev. 1,000 m, 29 Jan. 1970, *H. S. Irwin, E. Onishi, S. F. da Fonseca, R. Souza, R. Reis dos Santos & J. Ramos 25625* (NY, US).

This tall, bulbous-based species with twisted and flexuous leaves and scapes plainly relates to *Xyris goyazensis* Malme, and a full study may later reveal a varietal relationship. However, the fertile bracts, in addition to being more numerous in a larger spike, lack an apical tuft of villous hairs, and the lateral sepals, while fimbriate, have narrower keels which are entire toward the base. The apex of the leaf, unlike that of *X. goyazensis*, is spinulose. *Xyris sceptrifera* differs from the closely related *X. veruina* Malme by having fertile bracts with more obtuse tips, smaller and narrower dorsal areas, and narrower sepal keels which are less copiously fimbriate.

9. **Xyris seubertii** Nilsson var. **espinhacae** Kral & Wanderley, var. nov. TYPE: Brazil. Minas Gerais: Serra do Espinhaco, wet sand, sandstone precipices and adjacent cerrado, ca. 18 km west of Grão Mogol, elev. 950 m, 21 Feb. 1969, *H. S. Irwin, R. Reis dos Santos, R. Souza & S. F. da Fonseca 23667* (holotype, UB; isotypes, NY, US). Figure 3.

Planta perennis, caespitosa, basibus subbulbosis; caules breves; radices graciles. Folia flabellate expansa, anguste linearia, vulgo 5–7 cm longa, vaginis scaporum plerumque longiora; laminae 1–3-plo vaginis longiores, planae, 0.8–1.2 mm latae, glabrae, valde compressae, olivaceae, longitudine indistincte nervosae; apices gradatim tum abrupte contracti, anguste acuminati, scabri, erecti; margines tenues, antrorse scabrosi; vaginae praeter bases carinatae, carinis glabris, lateribus purpureis vel ferrugineis, glabris, valde multicostatis, basim versus papillosis, marginibus integris, in laminas gradatim convergentibus, infime gradatim expansis, tum abrupte ad basim dilatatis castaneis vel atroferrugineis. Scapi graciles, recti vel aliquantum torti, 2–3 dm alti, subteretes, olivacei, ecostati vel subtiliter 1–3-costati, costis glabris vel subtiliter scabrosis. Spicae pauciflorae, ovoideae vel ellipsoideae aut obovoideae, 5–7 mm longae, bracteae convexae, ecarinatae vel carinatae, subdecussatae, pallide brunneolae, marginibus scariosis, latis, integris, rotundatis, ad apicem ferrugineo-fimbriolatis; bracteae steriles 4, pari infimo oblongo vel anguste obovato, ca. 3 mm longo, carinato, areis dorsalibus linearibus, breviter excurrentibus, pari intimo latiores, obovato, ca. 3.5 mm longo; bracteae fertiles 4, oblongae, ca. 4.5–5 mm longae, rotundatae, plicatae, area dorsalis lanceolata, viridis, 3–4 mm longa. Sepala lateralia ⅓-connata, inaequilatera, curvata, ca. 5 mm longa, lobis oblongis, ala carinali angusta sed forte, a medio ad apicem dense ferrugineo-fimbriolata. Laminae petalorum ellipticae, ca. 5 mm longae, acutae, subintegrae, luteolae. Staminodia bibrachiata, brachiis linearibus compressis apicibus et lateribus longipenicillatis. Antherae lineari-oblongae, ca. 2 mm longae, refusae et sagittatae, filamentis 2-plo longiores. Capsula anguste ellipsoidea, ca. 3.5 mm longa; placenta centralis. Semina matura non visa.

Plants perennial, cespitose, with subbulbous base; stems short, the roots slender. Leaves flabellately spreading, narrowly linear, commonly 5–7 cm long, mostly longer than scape sheaths; blades 1–3 times longer than sheaths, flat, 0.8–1.2 mm wide, smooth, strongly flattened, olivaceous, longitudinally indistinctly nerved; apices gradually, then abruptly, narrowed, narrowly acuminate, scabrous, erect; margins thin, antrorsely scabrid; sheaths except for bases smooth-carinate, the

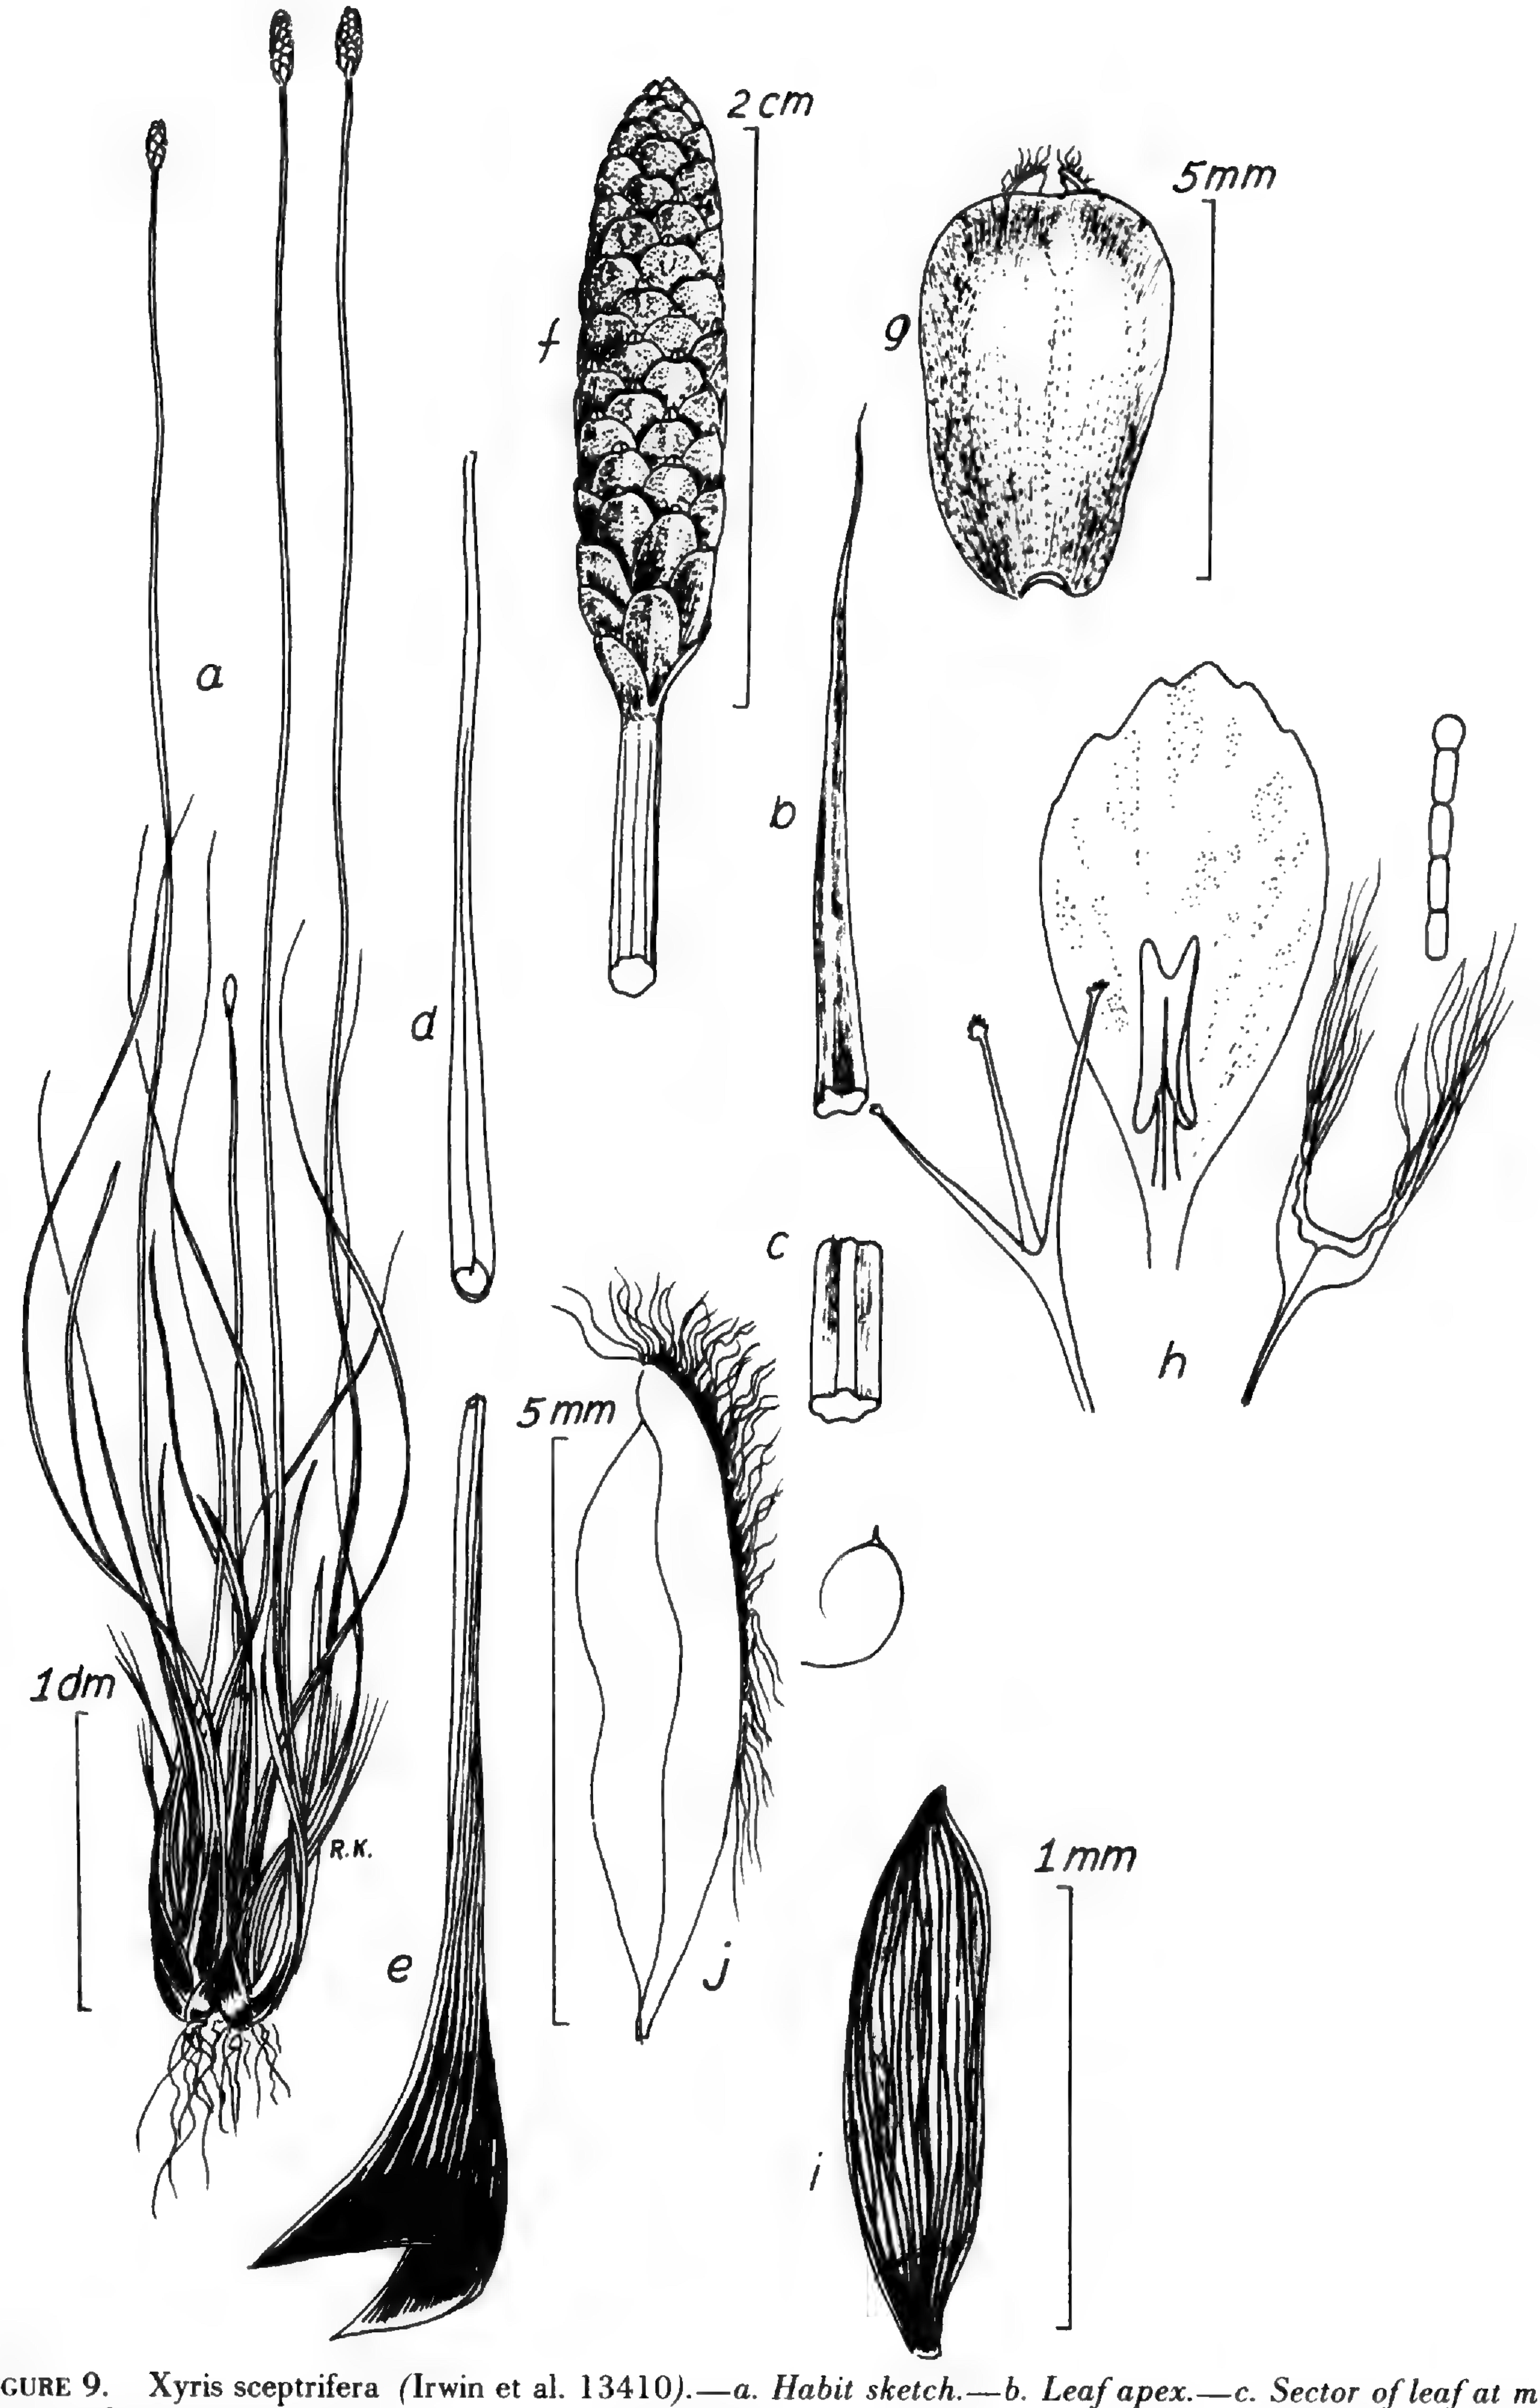

FIGURE 9. Xyris sceptrifera (Irwin et al. 13410).—*a. Habit sketch.—b. Leaf apex.—c. Sector of leaf at mid blade.—d. Sector of leaf showing sheath and blade junction.—e. Leaf base.—f. Spike.—g. Fertile bract showing exserted lateral sepal tips.—h. Petal, stamen, stylar apex, staminode.—i. Seed.—j. Lateral sepal.*

sides purplish or ferruginous, smooth, strongly multicostate, papillose toward base, the margins gradually narrowing into the blades, below gradually widening then dilating abruptly at base, castaneous or deep red-brown. Sheaths of scapes lax, twisted toward base, multicostate, brown, toward apex open, green, with margins broadly scarious, with blades as on foliage leaves but short. Scapes slender, straight or somewhat twisted, 2–3 dm high, subterete, olivaceous, ecostate or finely 1–3-costate, the costae smooth or finely scabrid. Spikes few-flowered, ovoid or ellipsoid or obovoid, 5–7 mm long, the bracts convex, ecarinate or carinate, subdecussate, pale brown, the margins broad, entire, scarious, rusty fimbriolate at apex; sterile bracts 4, the lower pair oblong or narrowly obovate, ca. 3 mm long, carinate, with linear, short-excurrent dorsal areas; inner pair wider, obovate, ca. 3.5 mm long; fertile bracts 4, oblong, ca. 4.5–5 mm long, rounded-plicate, the dorsal area lanceolate, greenish, 3–4 mm long. Lateral sepals ca. ⅓ connate, inequilateral, curvate, ca. 5 mm long with lobes oblong, acute, the keel narrow but strong, densely rusty fimbriolate from middle to apex. Petal blades elliptic, ca. 5 mm long, acute, subentire, yellow. Staminodia bibrachiate, the branches linear, flattened, apically and laterally long-penicillate. Anthers linear-oblong, ca. 2 mm long, retuse and sagittate, 2 times as long as filaments. Capsule narrowly ellipsoid, ca. 3.5 mm long, the placentas central. Mature seeds not seen.

The new variety appears to be a small variant of *X. seubertii,* agreeing with that species by having greenish, excurrent dorsal areas and connate lateral sepals with densely rusty-pubescent keels. The bracts are sparsely but definitely villosulous (vs. glabrous) apically; the placentation is definitely free-central rather than basal as in the type variety.

10. Xyris villosicarinata Kral & Wanderley, sp. nov. TYPE: Brazil. Minas Gerais: wet depression near creek, grazed campo and cerrado, upland valley, Serro do Itabirito, Minas Gerais, ca. 45 km SE of Belo Horizonte, ca. 1,500 m elev., 8 Feb. 1968, *H. S. Irwin, H. Maxwell & D. C. Wasshausen 19570.* (holotype, UB; isotypes, NY, US). Figure 10.

Planta perennis, caespitosa, basibus leviter bulbosis, fuscis. Caules breves, per bases persistentes veternas foliorum obtecti. Radices graciles. Folia rigida, erecta, 0.8–1.5 dm longa, solum basalia, vaginis scaporum longiora; laminae vaginis 4–5-plo longiora, tortae, 1–1.3 mm latae, compressae, flavovirentes vel ferrugineofuscae, transverse rugulosae, distincte longitudine 3–4-nervosae; apices anguste acuti, interdum aristulati; aciebus crassiusculi; vaginae ad basim leviter dilatatae, ecarinatae, in laminas gradatim decrescentes, transverse rugulosae, apicem versus carinatae, lateribus fuscis, aciebus pallide longiciliatis. Vaginae scaporum fuscae vel ferrugineae, transverse rugulosae, multicostatae, apicem versus carinatae, laminis brevibus incurvatis. Scapi teretes vel subteretes, plus minus spiraliter torti, flexuosi, 2–3 dm alti, ca. 1 mm crassi, transverse rugulosae, virides, bicostati vel ecostati. Spicae anguste ovoideae vel ellipsoidales, 0.7–1 cm longae, pauciflorae, bracteae convexae, leviter carinatae, costales, pallide lamproferrugineae, integrae vel leviter laceratae, dorsis papillosis; bracteae steriles 4, subdecussatae, pari infimo oblongo, ca. 3 mm longo, pari intimo obovato, ca. 5 mm longo; bracteae fertiles obovatae, rotundatae, plicatae, usque ad 7 mm longae, tenues, area dorsali indistincta. Sepala lateralia libera, subaequilateralia, lineari-oblonga, ca. 6 mm longa, obtusa; ala carinali apicem versus irregulariter ciliata vel fimbriolata, lateribus villosulis. Laminae petalorum ellipticae, 6–7 mm longae, acutae, integrae, flavae. Staminodia bibrachiata, brachiis compressis, longipenicillatis. Antherae lanceolatae, ca. 2 mm longae, sagittatae, filamentis longiores. Placenta basalis. Semina non visa.

Plants perennial, cespitose, with bases slightly bulbous, brown. Stems short, covered by bases of old foliage leaves. Roots slender. Leaves rigid, erect, 0.8–1.5 dm long, strictly basal, longer than the scape sheaths; blades 4–5 times longer than sheaths, twisted, 1–1.3 mm wide, flattened, yellow-green to reddish brown, transversely rugulose, distinctly longitudinally 3–4-nerved; apices narrowly acute, sometimes aristulate; edges thickened; sheaths slightly dilated toward base, ecarinate, gradually narrowing above into blades, transversely rugulose, carinate toward apex, the sides brownish, the edges ciliate with long pale hairs. Scape sheaths brownish to reddish brown, transversely rugulose, multicostate, carinate toward apex, with short, incurved blades. Scapes terete or subterete, ± spirally twisted, flexuous, 2–3 dm high, ca. 1 mm

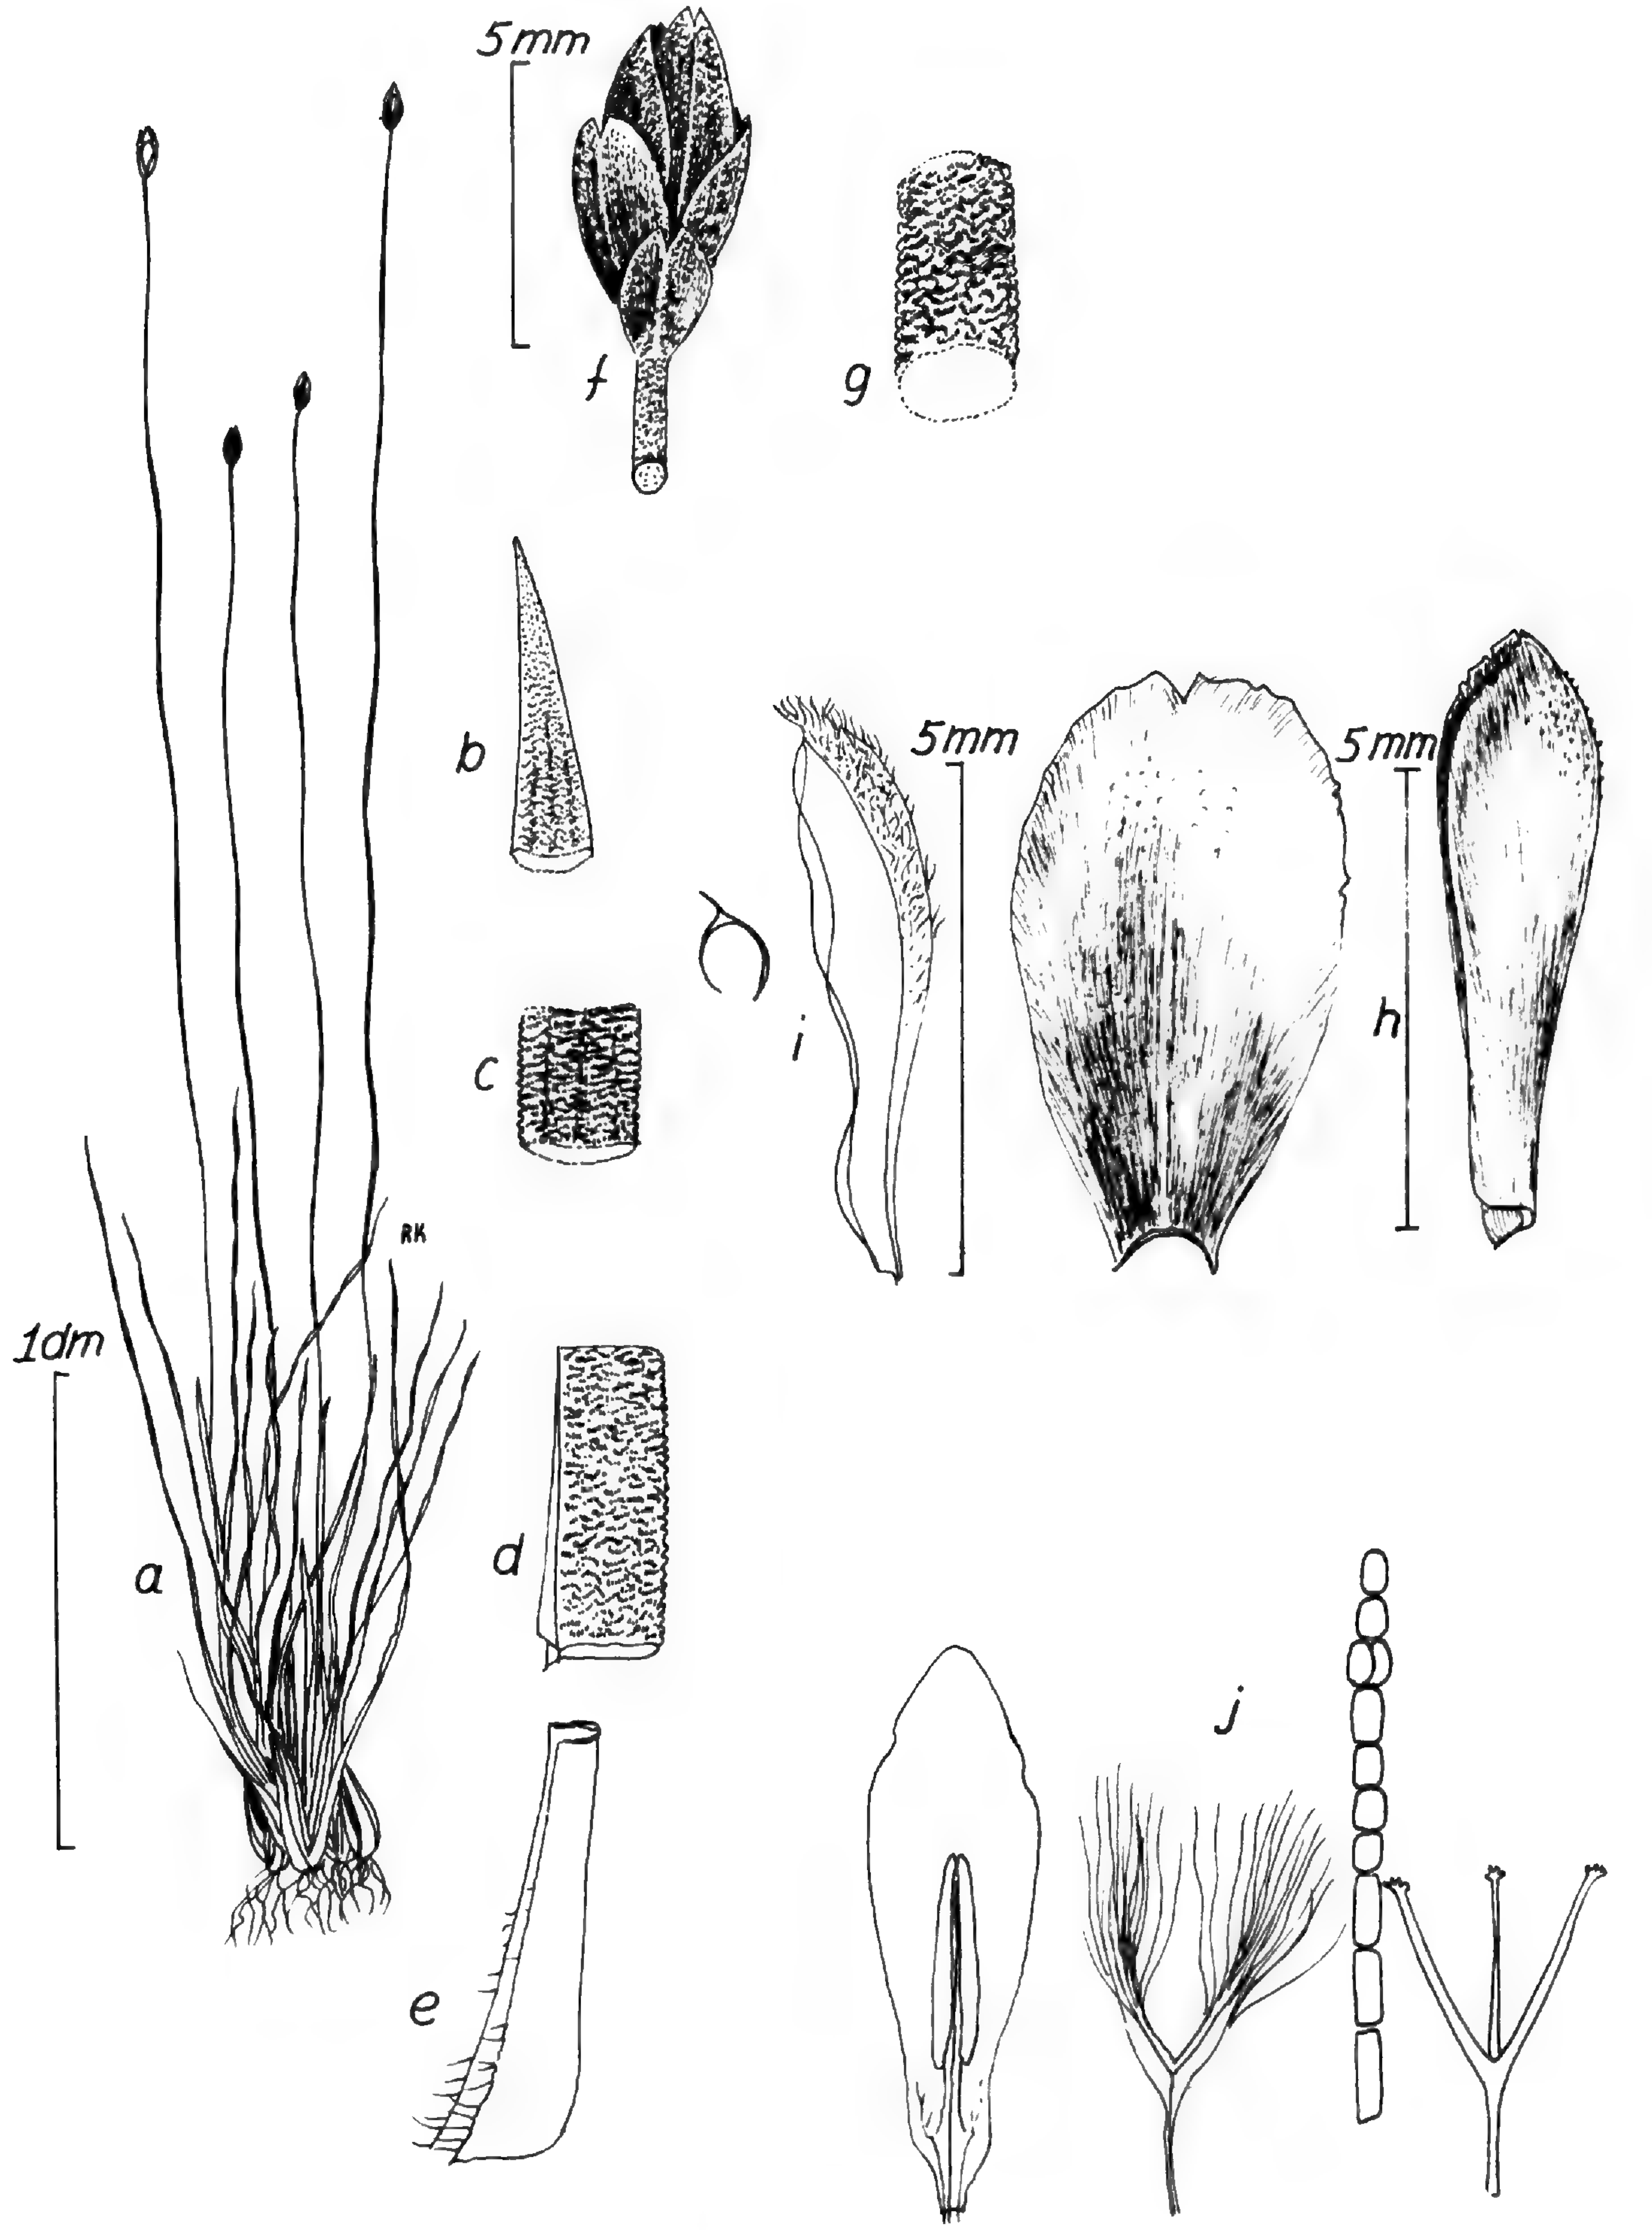

FIGURE 10. Xyris villosicarinata (Irwin et al. 19570).—*a. Habit sketch.—b. Leaf apex.—c. Sector of mid blade.—d. Sector at leaf blade–sheath junction.—e. Leaf base.—f. Spike.—g. Sector of scape at mid scape.—h. Two views of fertile bract.—i. Lateral sepal.—j. Petal and stamen, staminode, staminodial beard hair, stylar apex.*

thick, transversely rugulose, green, bicostate to ecostate. Spikes narrowly ovoid or ellipsoid, 0.7–1 cm long, few-flowered, the bracts convex, slightly carinate, with midrib, pale shining reddish brown, entire or slightly lacerate, the backs papillose; sterile bracts 4, subdecussate, the lowest pair oblong, ca. 3 mm long, the inner pair obovate, ca. 5 mm long; fertile bracts obovate, rounded, plicate, up to 7 mm long, thin, the dorsal area indistinct. Lateral sepals free, subequilateral, linear-oblong, ca. 6 mm long, obtuse; keel irregularly ciliate or fimbriolate toward apex, the sides villosulous. Petal blades elliptic, 6–7 mm long, acute, entire, yellow. Staminodia bibrachiate, the branches flattened, long-penicillate. Anthers lanceolate, ca. 2 mm long, sagittate, longer than the filaments. Placenta basal. Seeds not seen.

This bears several of the characters of *Xyris tortula* Martius, but the foliage is rugulose throughout (not smooth), the margins of the narrow, twisted leaf blades are not cartilaginous as in *X. tortula*, and the sides of the lateral sepal keel toward its apex are densely villosulous with pale hairs, rather than confined to the keel only as in *X. tortula*.

NEW AND NOTEWORTHY TAXA FROM PANAMA[1]

Gordon McPherson[2]

ABSTRACT

Three new species, Prunus fortunensis *(Rosaceae),* Symplocos panamensis *(Symplocaceae) and* Angostura kunorum *(Rutaceae), as well as four new generic records for Panama are described.*

Botanical exploration of Panama has been going on for decades and yet many species still remain undiscovered. Collecting trips made in 1986 to such western Panamanian sites as the Fortuna Dam area, the Bocas del Toro slope above Chiriquí Grande, and Cerro Colorado could be counted on to yield new species as well as new records, some of them generic, for the Panamanian flora. Moreover, other rich but long-accessible areas such as the El Llano to Carti strip, Santa Rita Ridge, and Cerro Jefe continue to yield novelties. For the most part these are not fully appreciated until they reach the hands of appropriate specialists and then, typically, are published only after some delay. In some cases, however, it is possible to readily evaluate the collections of special interest, and the following three species are here described as new.

Prunus fortunensis McPherson, sp. nov. (Rosaceae). TYPE: Panama. Bocas del Toro: Fortuna Dam region, 1,250–1,300 m, 11 Feb. 1986, *McPherson 8404* (holotype, PMA; isotypes, CAS, CR, DUKE, K, MEXU, MICH, MO, US, UTD). Figure 1.

Species combinatione foliorum parvorum integrorum glabrorum cum inflorescentia racemosa et floribus parvis circa 10-stamineis a congeneribus regionis diversa.

Tree 14 m; branchlets glabrous, somewhat longitudinally striate in older portions, the slightly raised lenticels 0.5–1 mm long; nodes marked by raised leaf scars, these pubescent along their adaxial margin when newly exposed, glabrescent. Leaf blades elliptic to slightly ovate, 3.5–6 cm long, 1.4–3 cm wide; base obtuse; apex acuminate, ultimately narrowly obtuse; margin entire; both surfaces glabrous, the laminar glands usually 1 pair, intramarginal, basal; secondary veins 5–6(–7) on each side of the midrib, all of the venation slightly impressed on the upper surface, the midrib alone raised on the lower surface. Petioles 5–8 mm long, caniculate, glabrous. Stipules triangular, 1.5–2 mm long, 1 mm wide at base, caducous. Inflorescences in the axils of leaves of the current season, racemose, 3–5.5 cm long, glabrous; peduncle 6–10 mm long, bearing 14–20 flowers; pedicels 2–4 mm long; bracts small, absent at anthesis. Hypanthium campanulate at anthesis, glabrous, 1–1.5 mm long from base to rim; lobes

ANN. MISSOURI BOT. GARD. 75: 373–378. 1988.

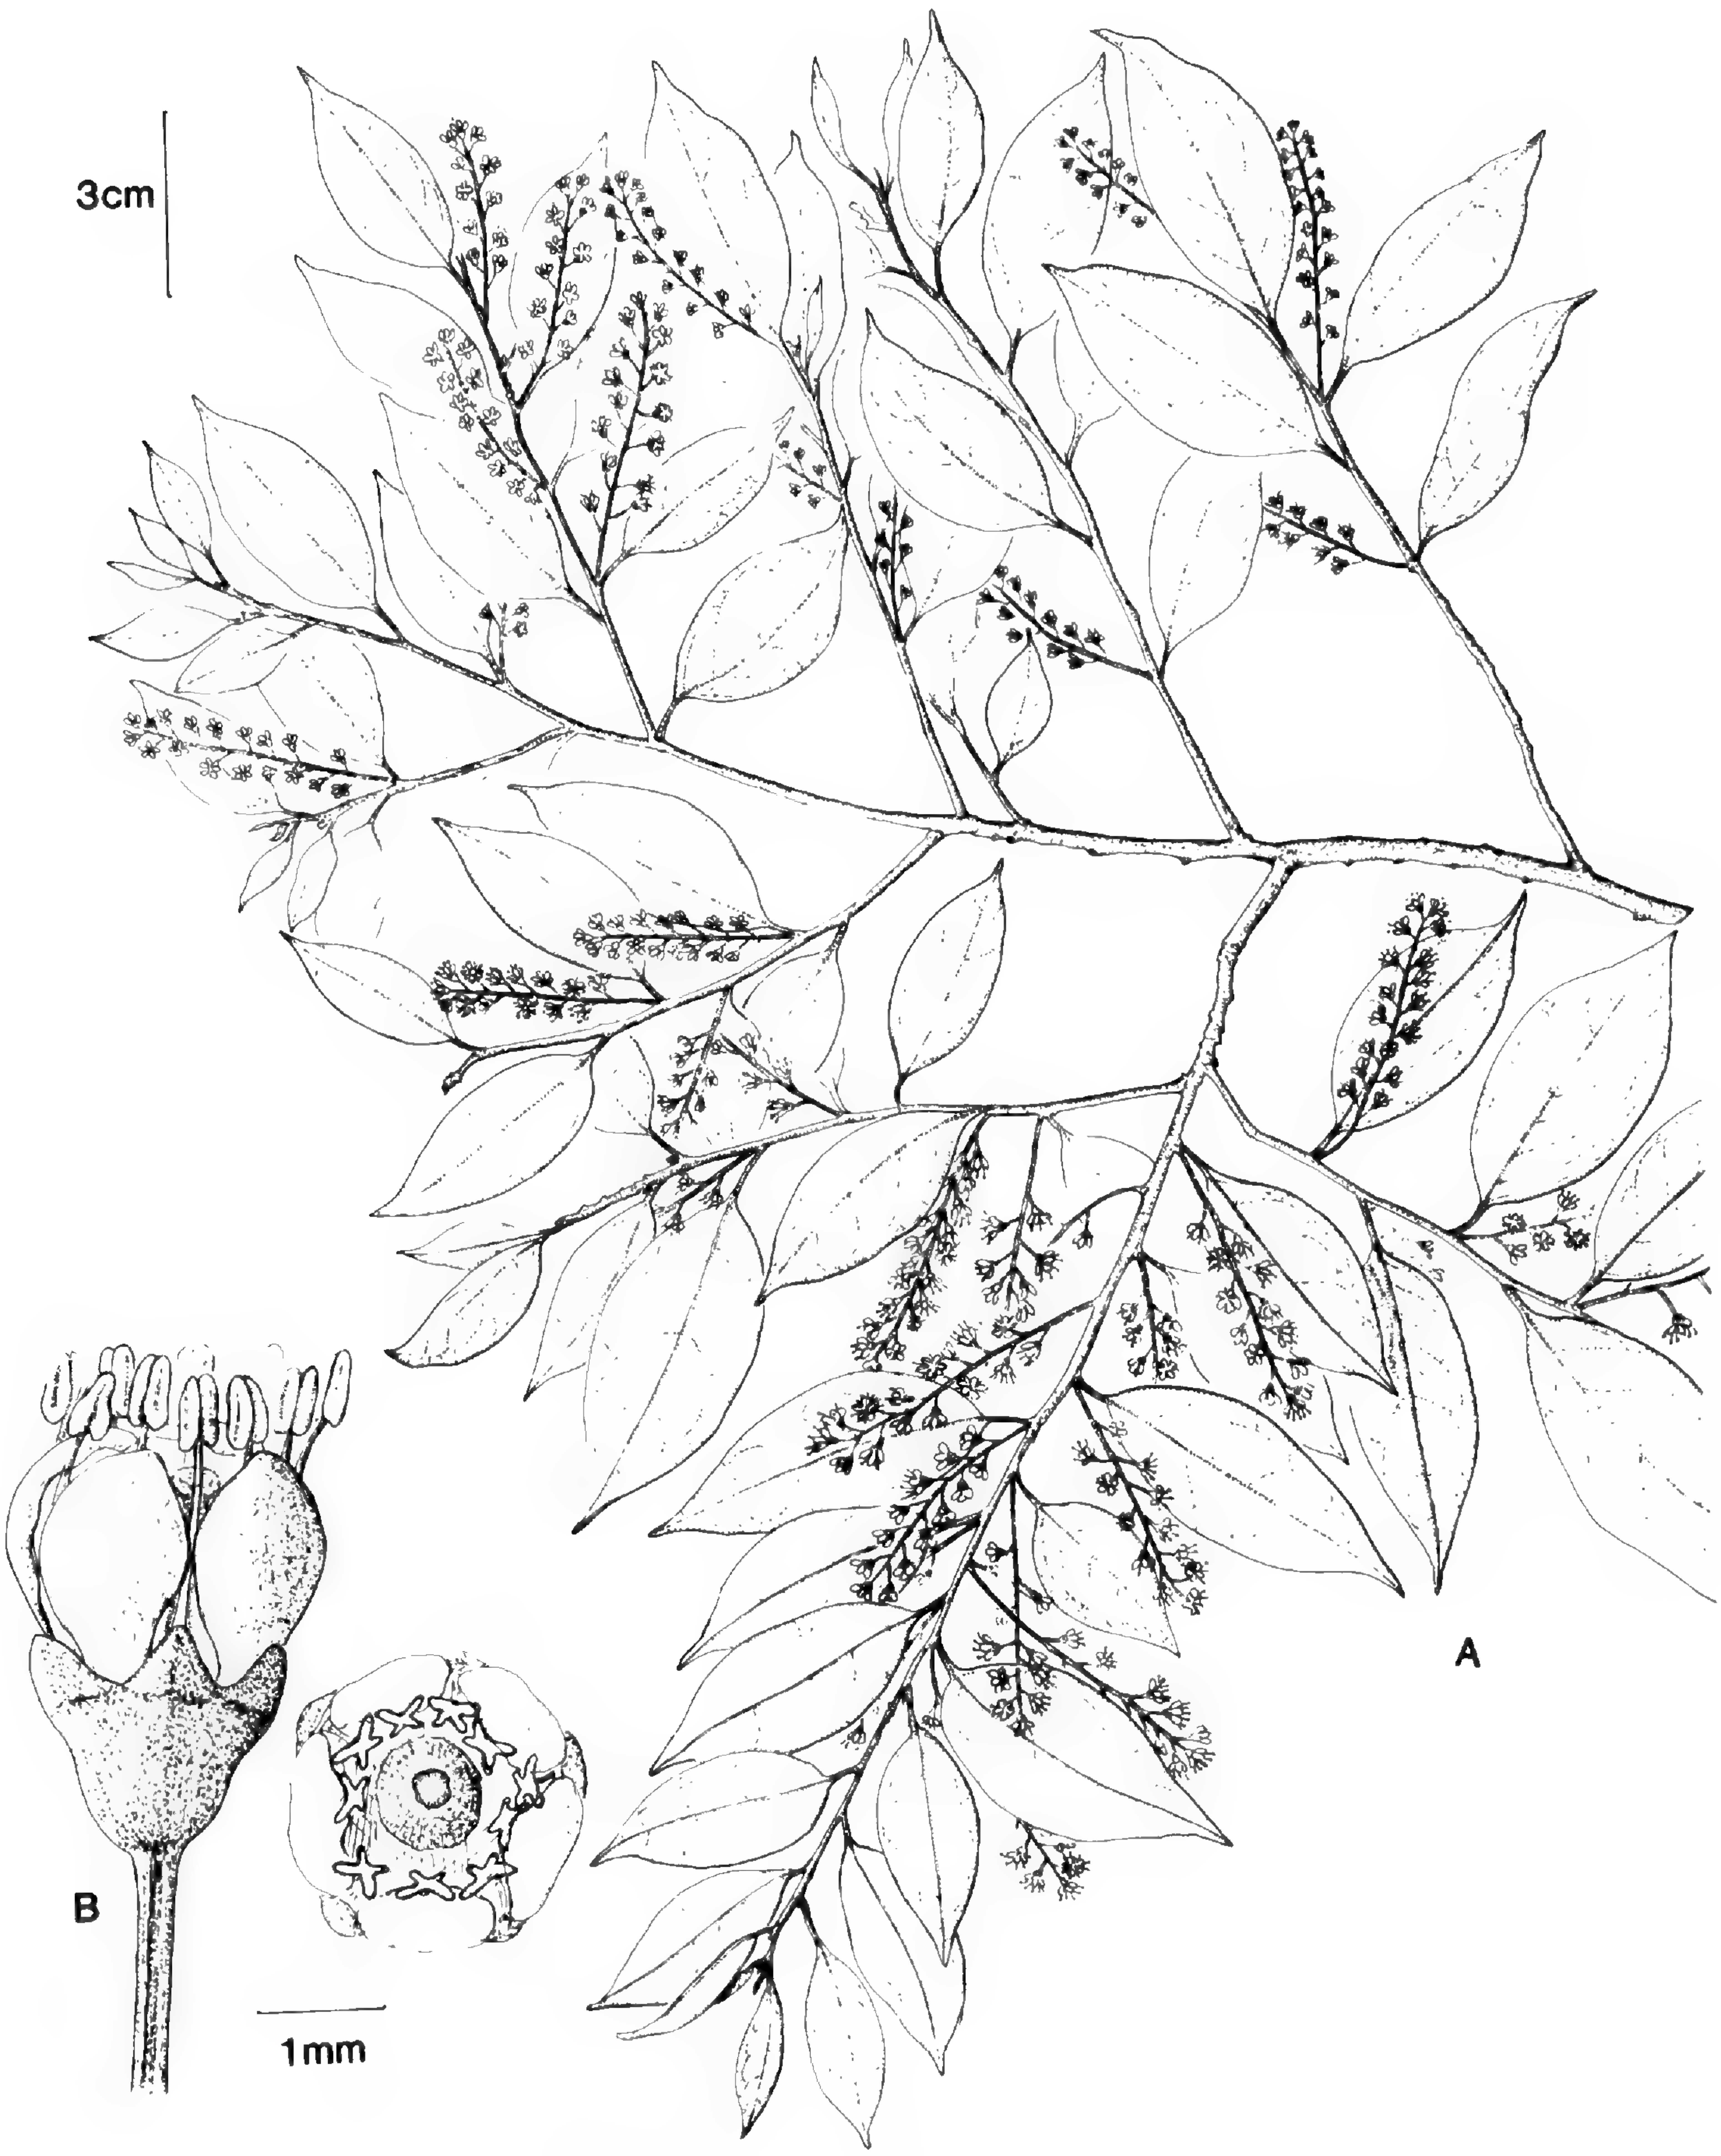

FIGURE 1. Prunus fortunensis (McPherson 8404).—*A. Flowering branchlet.—B. Flower, lateral and top views.*

ca. 0.6 mm long, 1 mm wide at the base, obtuse, somewhat cucullate. Petals white, roughly circular, 1–1.5 mm diam., entire. Stamens 9–11(–15), 1.8–2 mm long, the anthers ca. 0.5 mm long. Ovary ca. 1 mm diam., glabrous; style 1.5–2 mm long, glabrous; stigma flattened, 0.5–0.8 mm wide. Fruit unknown.

This species is distinguished from its congeners in the region (*P. annularis* Koehne, *P. brachybotrya* Zucc.) by its combination of small, entire, glabrous leaves, racemose inflorescence, and small flowers with ca. 10 stamens.

Symplocos panamensis McPherson, sp. nov. (Symplocaceae). TYPE: Panama. Colón: Santa Rita Ridge, ca. 500 m, 16 Feb. 1986, *McPherson 8447* (holotype, PMA; isotypes, BM, CAS, COL, CR, DUKE, K, L, MEXU, MICH, MO, NYBG, US, UTD). Figure 2.

Species pilis appressis, foliis chartaceis fere glabris dentatis a paucis nervis, petiolis brevibus, sepalis partim pubescentibus, corollis 11–16 mm fere glabris, floris 40–45-stamineis, stylis aliquantum pubescentibus omnino a congeneribus regionis diversa.

Tree 10–12 m; twigs pale in color, somewhat flattened, the youngest often channeled (at least on drying); young stems and buds white pubescent, the buds densely so, the hairs strongly appressed, those of the stem not dense, ± persistent but becoming sparse on older stems. Leaf blades obovate-elliptic to elliptic, 7–21 cm long, 2.7–7.2 cm wide, thinly chartaceous; base usually somewhat attenuate and narrowly obtuse, sometimes acute; apex acuminate; margin entire proximally, denticulate to dentate distally, often pubescent; upper surface glabrous, the lower surface pubescent while immature but glabrous or nearly so at maturity, a few hairs sometimes remaining near the base; midrib adaxially sunken over most of its length, raised abaxially, pubescent with white, appressed hairs; secondaries 5–6(–8) on each side of the midrib, somewhat arcuate, puberulent. Petiole 2–5(–7) mm long, channeled and glabrous adaxially, appressed-pubescent abaxially. Inflorescences axillary, the subtending leaf often fallen; axis 1–5 mm long, pubescent, bearing (1–)3–7 flowers; bracts several, the peduncular bracts densely pubescent abaxially, the pedicellar bracts less so, all glabrous adaxially. Hypanthium 1 mm long, glabrous or sparsely pubescent. Calyx lobes white, 5, 1.5–2 mm long, 1.5–2 mm wide at the base, obtuse, pubescent abaxially along the midline with white, appressed, somewhat flexuous hairs; margins pubescent. Corolla white, of 4–6 partly fused petals 11–16 mm in length and connate near the base, adnate to androecium about halfway up, the spreading portion of the lobes typically ca. 4 mm long, 2–5 mm wide, glabrous or sparsely puberulent with appressed hairs, occasionally bearing a misshapen anther apically. Stamens 40–45, exserted, the filaments straplike, the free portions of the outer ones up to 5 mm long, 0.7 mm wide, the inner stamens shorter, narrower, and somewhat inflexed. Ovary 3-locular; ovules 4 per locule, the superior portion of the ovary ca. 1 mm long, pubescent; style 9–11 mm long, at least sparsely pubescent over its entire length; stigma capitate, ca. 1 mm diam. Fruit unknown.

This species differs from other *Symplocos* species of the region (*S. austin-smithii* Standley, *S. chiriquensis* Pittier, *S. serrulata* Humb. & Bonpl., *inter alia*) in its appressed hairs, thin, nearly glabrous, distally dentate leaf blades with few secondaries, short petioles, only partially pubescent sepals, nearly or quite glabrous, rather long corolla, 40–45 stamens, and styles pubescent their entire length.

Additional specimen examined. PANAMA. DARIÉN: Cuasi-Cana trail on Cerro Campamineto, east of Tres Bocas, headwaters of Río Cuasi, 29 Apr. 1968, *Kirkbride & Duke 1246* (MO).

Angostura kunorum McPherson, sp. nov. (Rutaceae). TYPE: Panama. San Blas: along El Llano–Carti road, ca. 14.5 mi. from Interamerican Highway, ca. 350 m, 17 June 1986, *McPherson 9525* (holotype, PMA). Figure 3.

Species 5–7-foliolatis, foliolis grandibus latis, inflorescentia anguste paniculata, alabastris rectis petalis valvatis, androeciis omnino fertilibus a congeneribus diversa.

Slender tree 4 m tall; young, leaf-bearing stems ca. 1 cm diam., roughened by many small ridges (at least on drying), conspicuously lenticellate, brown puberulent with a mixture of erect, curved, whitish hairs and minute,

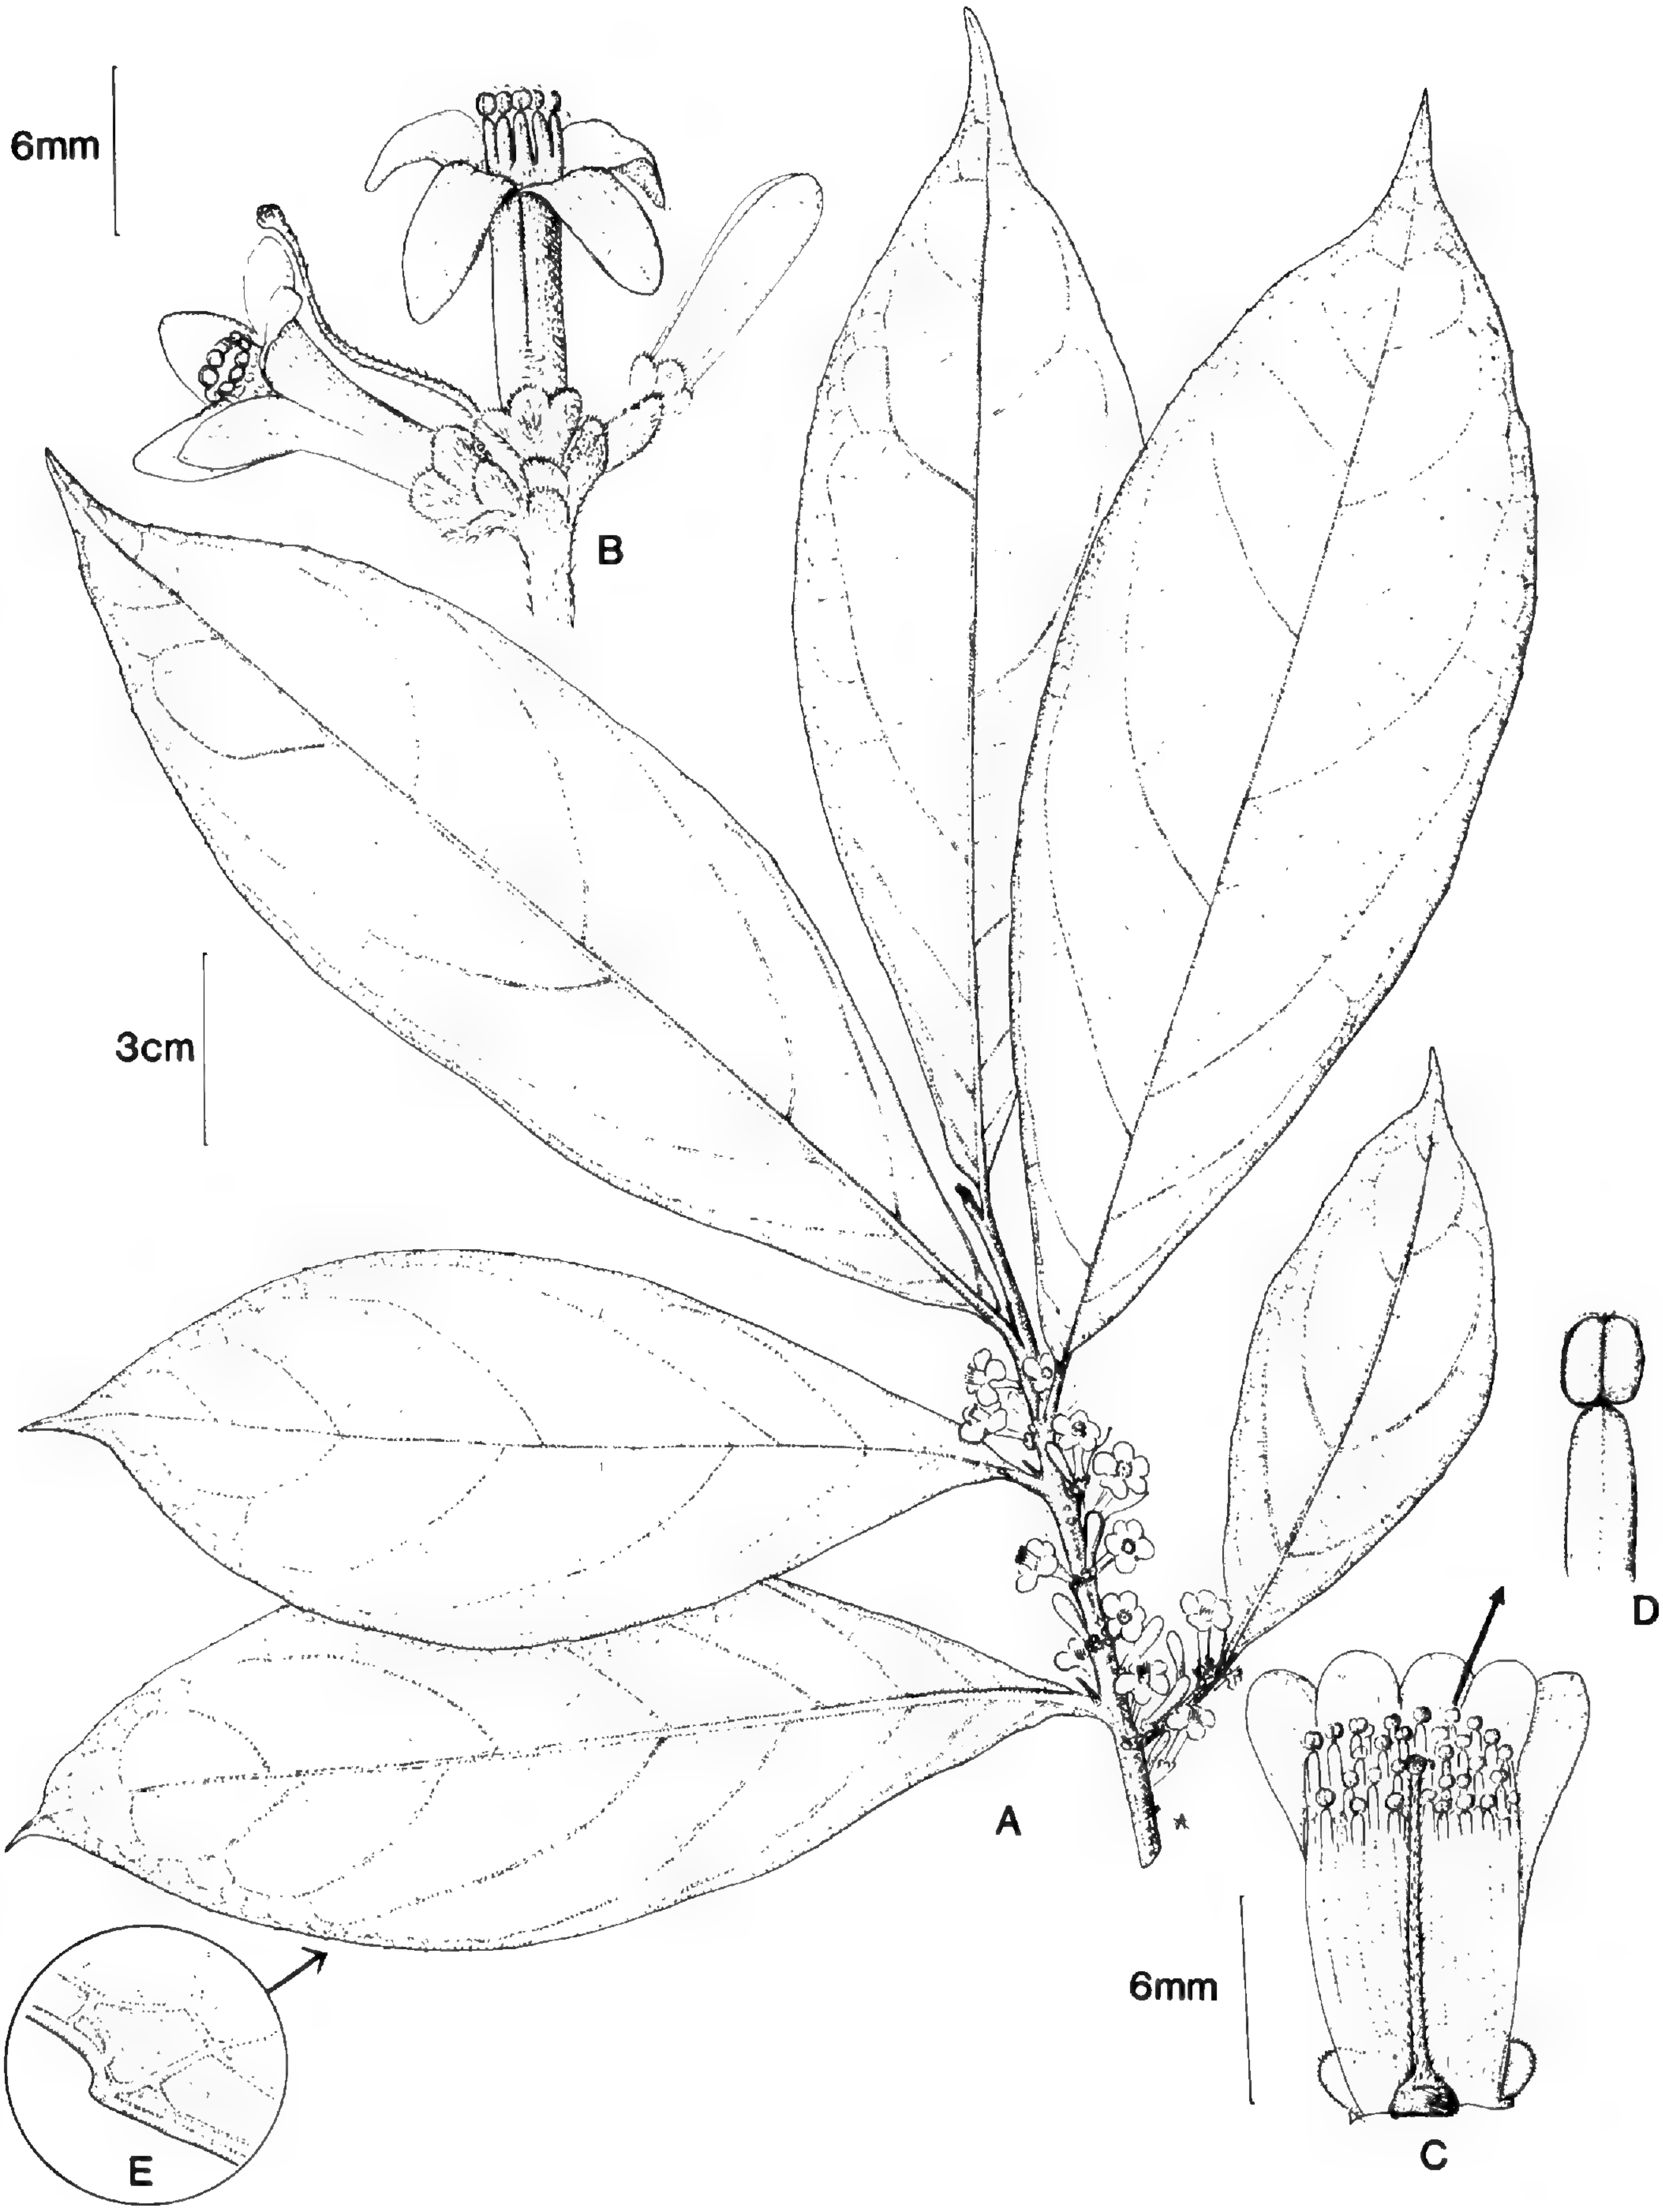

FIGURE 2. Symplocos panamensis (McPherson 8447).—*A. Flowering branchlet.—B. Inflorescence.—C. Opened flower.—D. Stamen.—E. Detail of leaf margin.*

brown, spherical, sessile granulations as well as with intermediates; leaf buds with a similar but denser indument; leaf scars ca. 1 cm long, ca. 1 cm wide. Leaves alternate; blades palmately compound, 5- or 7-foliolate, the leaflets diverging through ½–⅔ of a circle, elliptic, the central and largest leaflet ca. 37 cm long, 12–13 cm wide, the outermost and

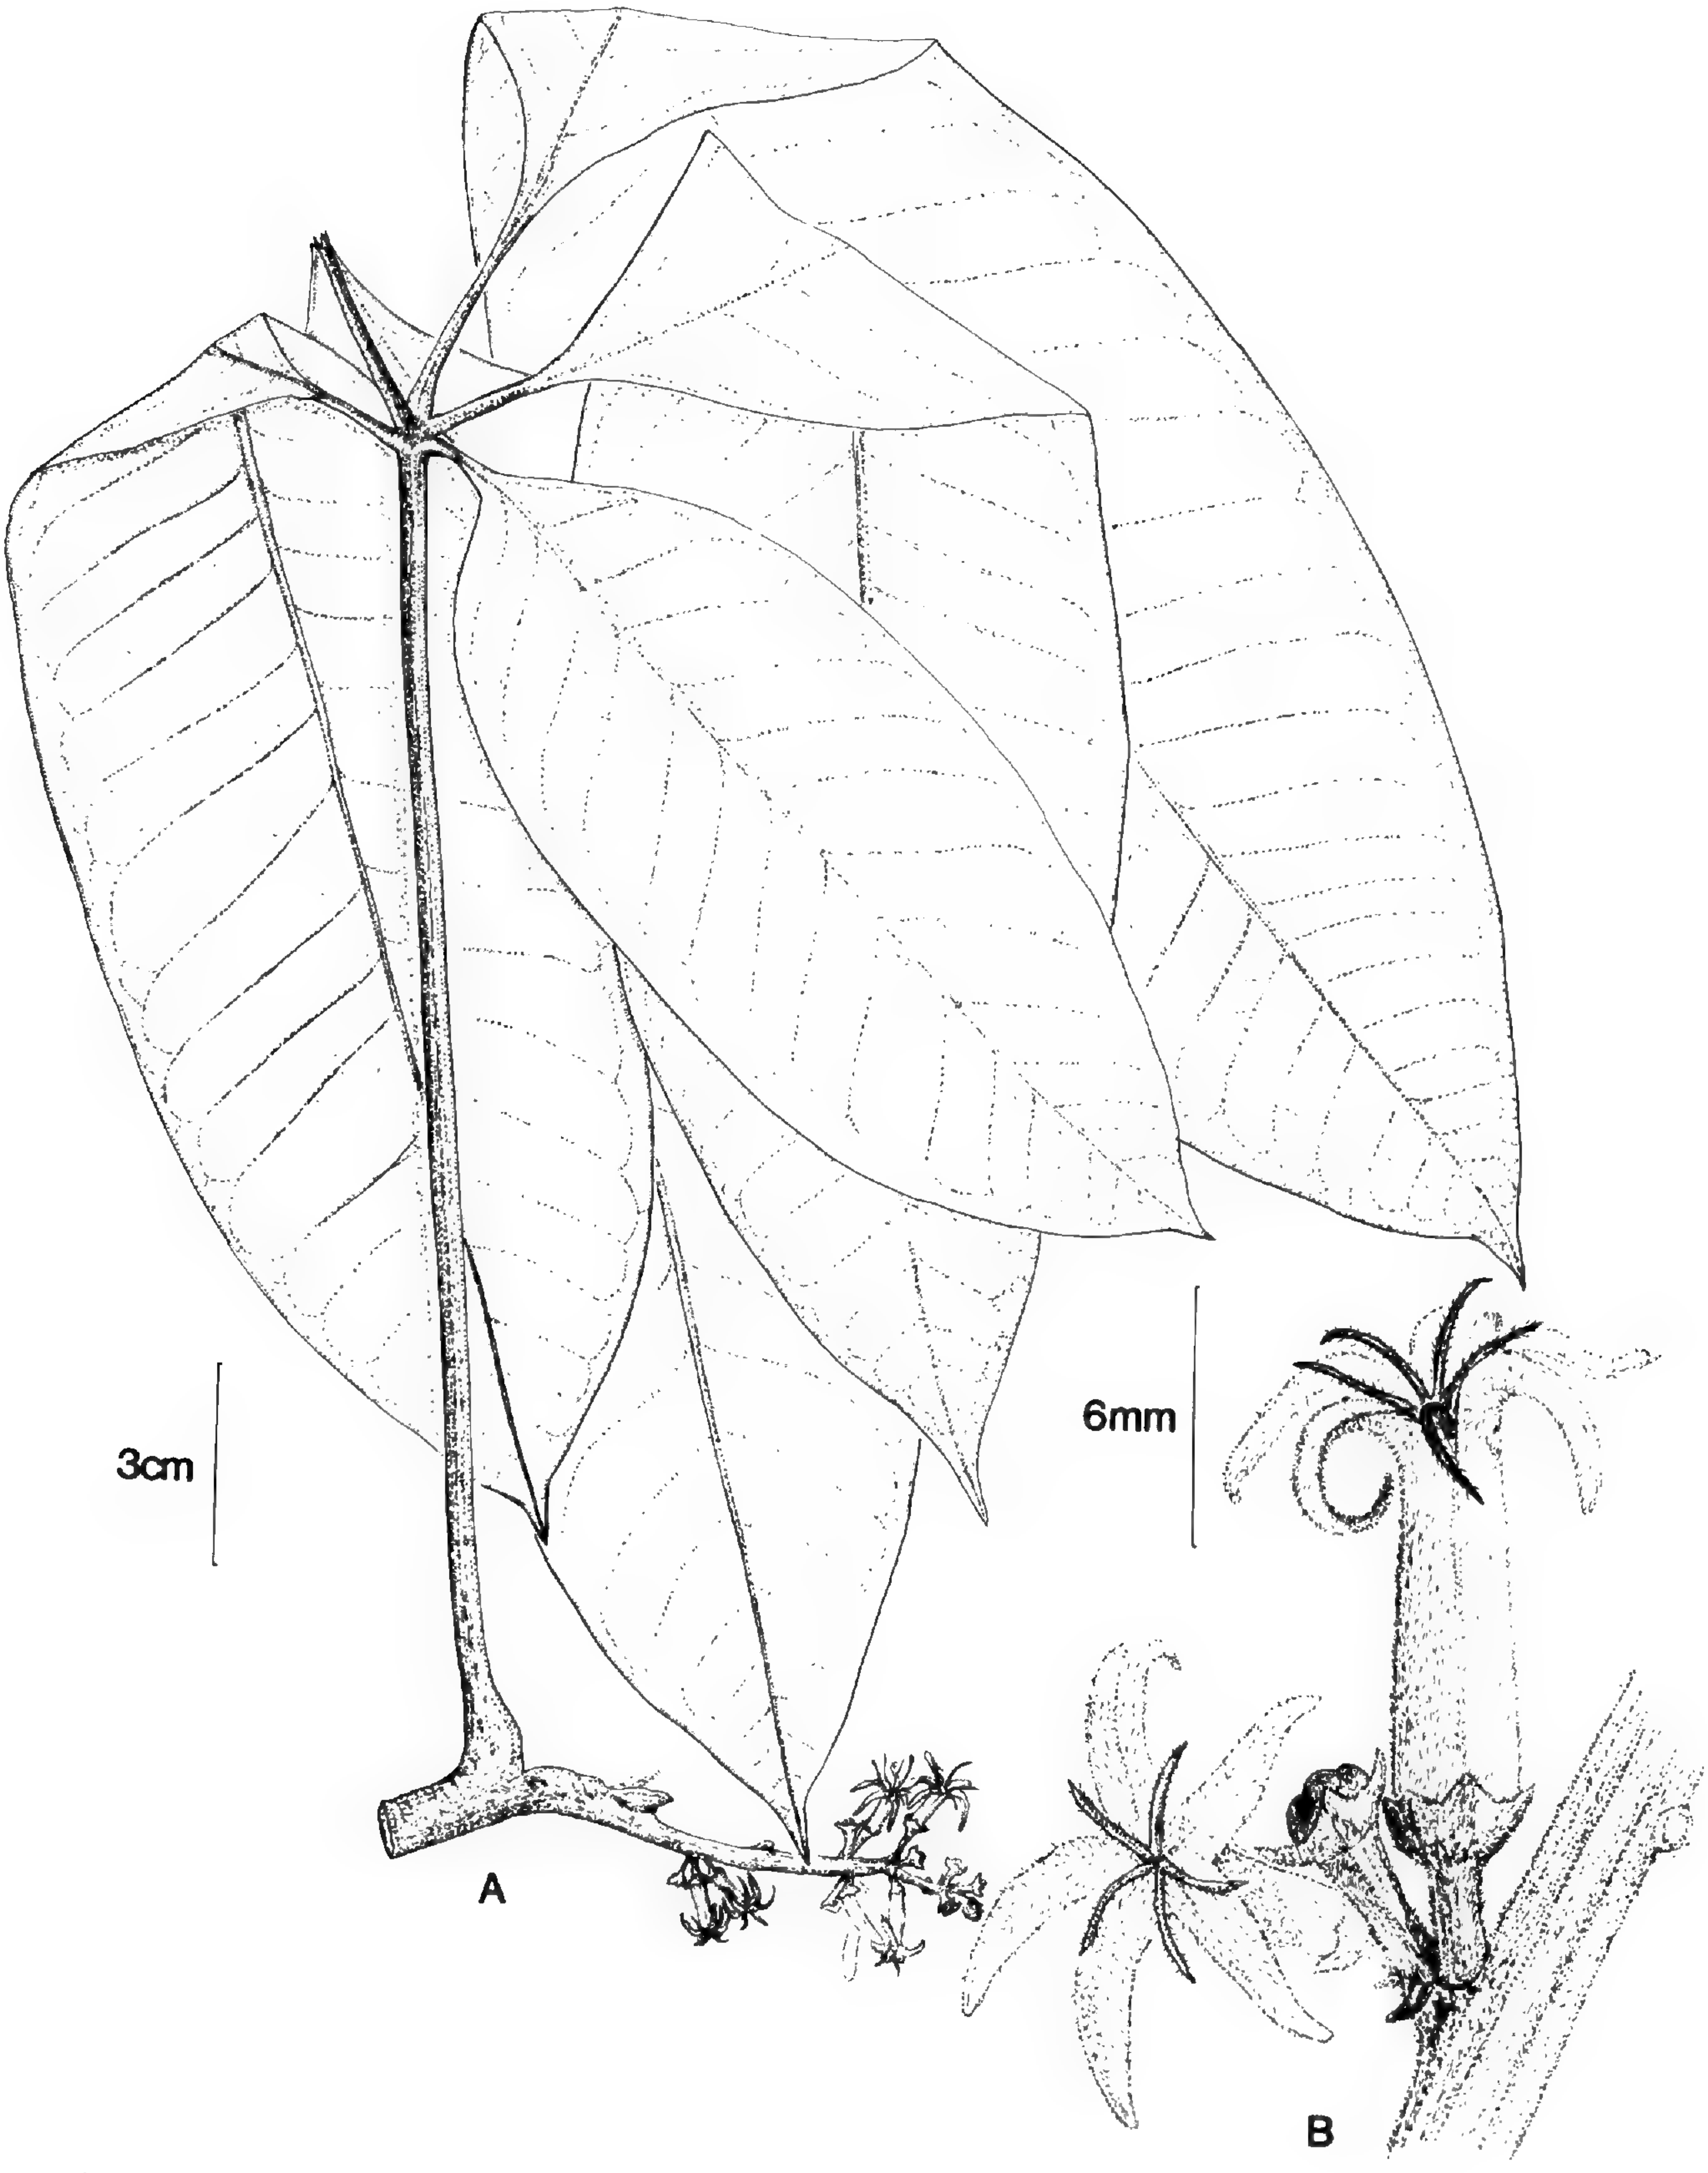

FIGURE 3. Angostura kunorum (McPherson 9525).—*A. Flowering branchlet.*—*B. Flowers.*

smallest 19–29 cm long, 7–11.5 cm wide, attenuate at base, shortly and sharply acuminate at apex, chartaceous, the margins entire, the surfaces densely punctate, glabrous at least at maturity (except for the midrib, this puberulent like the stem and reddish brown when dry), the secondaries slightly impressed on the adaxial surface, ca. 27–30 in number on each side of the largest leaflets and ca. 18 on each side of the smallest leaflets; petiolules canaliculate, puberulent like the stem but glabrescent, pulvinate basally, the central one ca. 3.5 cm long, the outermost 0.8–1.5 cm long, all ca. 3 mm diam.; petiole ca. 28–31.5 cm long, ca. 5 mm diam. near mid length, broadly caniculate, conspicuously lenticellate, pubescent like the stem but partially glabrescent, pulvinate basally, the apex of the petiole flattened, ca. 1 cm diam. Inflorescence appearing pseudoterminal but perhaps truly terminal, very narrowly paniculate (the lateral dichasia subsessile), the axis of the single known inflorescence 8 cm long (further collections may be significantly longer), ca. 4 mm diam. near mid length, puberulent like the stem; stalks of the lateral dichasia 1–2 mm long; bracts triangular, ca. 2 mm long, 2 mm wide at base, stout, acute, puberulent; pedicels 3–5 mm long, puberulent. Buds straight. Calyx cupular, white, 5–6-lobed, 2 mm long, 4–5 mm diam.; lobes shallow, acute, densely puberulent, densely beset with swollen surficial glands ca. 0.2 mm diam. Corolla of 4–6 petals, white, valvate (or very nearly so) in bud, up to 2 cm long in bud, 1.2–1.5 cm long when open (the recurved portion not included); petals linear, connate by marginal tomentum, separating and recurving at anthesis and eventually ¾ to completely unattached to one another, tomentose on both surfaces, the hairs longer and curlier than those of the calyx and unaccompanied by brown granulations, the swollen surficial glands obvious, clear to brownish (at least on drying). Stamens all fertile, 5 or 6; filaments adnate to petal bases, 8–9 mm long, ca. 1.5 mm wide near base, somewhat flattened, tomentose; anthers 11–13 mm long, ca. 0.8 mm wide, introrse, pubescent with long, straight, ± erect hairs, abaxially densely beset with swollen surficial glands. Disk cupular, sometimes bearing impressions of the petal bases and hence ridged, 1 mm high, 2–3 mm diam. Ovary 5-carpellate, 1 mm long, glabrous; style ca. 2 mm long, glabrous; stigma ca. 2 mm long, cylindric, slightly thicker than style, glandular. Fruit unknown.

Angostura kunorum differs from other species of this varied genus in its 5–7 large, broad leaflets, narrowly paniculate inflorescence, straight buds with essentially valvately arranged petals, and entirely fertile androecium.

Among the genera recently added to the known flora of Panama are *Sparattanthelium* of the Hernandiaceae (*S. amazonum* Mart., *McPherson 9643*), *Etaballia* of the Leguminosae (*E.* cf. *guianensis* Benth., *McPherson 9513*), *Metteniusa* of the Icacinaceae (*M. tessmanniana* (Sleumer) Sleumer, *Gentry 13829A*, *McPherson 7364*), and *Plinia* of the Myrtaceae (*P.* spp.; *McPherson 7341*, *9089*). These four genera are primarily South American in their distributions.

NOTES

TWO NEW RUSHES (*JUNCUS*, JUNCACEAE) FROM CHIAPAS, MEXICO

This note describes a new species and a new variety of *Juncus* from the state of Chiapas in Mexico.

Juncus chiapasensis Balslev, sp. nov. TYPE: Mexico. Chiapas: Lagunas de Montebello near Guatemala border, 30 km (air) E of La Trinitaria, 1,200 m, *Roe, Roe & Mori 966* (holotype, DS-584358; isotypes, F, WIS). Figure 1A, B.

Planta perennis, caespitosa; folia linearia, teretia, septata; inflorescentia anthela, 10–20 × 5–12 cm, 8–17-capitulata; capitula 10–35-flora; tepala 2.5–3 mm longa, castanea; stamina 3, 1.8–2.5 mm longa; capsula 4–4.5 × 1–1.2 mm, obclavata, castanea, tepalis longior.

Perennial, caespitose herbs 60–90 cm tall. Rhizome 3 mm diam. Culms erect, 2–3 mm diam., terete, smooth or finely striate. Basal sheathing bladeless leaves absent or one to each culm, up to 7 cm long. Foliar leaves 1–2 basal and 1–2 cauline to each culm, 10–45 cm long; sheaths 4–8 cm long with membranaceous margins, terminally biauriculate, the auricles 2–3 mm long and rounded; blades 1.5–3 mm diam., round in cross section, conspicuously cross septate. Inflorescence a decompound anthela, 10–20 × 5–12 cm, of 8–17 flower heads, these globose, 10–13 mm diam., 10–35 flowered, castaneous, the ultimate head-bearing branches ca. 0.5 mm thick. Lower inflorescence bract 3–7 cm long, much shorter than the inflorescence, resembling basal and cauline leaves; upper bracts progressively shorter, the floral bracts acuminate, ca. 0.2 mm long, membranaceous. Tepals subequal, 2.5–3 mm long, lanceolate, acute, the outer ones V-shaped in cross section, the inner ones flat. Stamens three, 1.8–2.5 mm long; filaments linear; anthers oblong, 0.6–0.8 mm long, about half as long as the filaments. Capsule 4–4.5 × 1–1.2 mm, conspicuously longer than the tepals, obclavate, trigonous, acute, gradually tapering towards the apex, castaneous, unilocular. Seeds 1 × 0.2 mm, ellipsoid, apiculate, reticulate, yellow-brown, with a thick, hyaline outer seed coat.

This new species is known only from a few localities in the state of Chiapas, Mexico, near the Guatemalan border. It has been collected at elevations of 1,200–2,200 meters in marshes along lake shores. It belongs to *Juncus* subg. *Septati* Buchenau (1875), as evidenced by its terete, hollow, and cross-septate leaf blades. This subgenus, with some 80 species distributed worldwide, is the largest in the genus. In the neotropical region, some 15 species belong to subg. *Septati.* The inflorescence of this new species is also typical of that subgenus: the flowers are congested into heads arranged in an anthela of which the proximal branches overtop the distal branches. *Juncus chiapasensis* differs from the closely related *J. guadeloupensis* Buchenau by having globose flower heads and obclavate, castaneous capsules much longer than the tepals. *Juncus guadeloupensis* has golden brown capsules and is endemic to the Caribbean island of Guadeloupe. *Juncus debilis* A. Gray likewise occurs in Chiapas and has longer capsules than tepals, but it is much smaller than *J. chiapasensis* in all dimensions.

Additional specimens examined. MEXICO. CHIAPAS: La Trinitaria, Lagunas de Montebello, 1,300 m, *Breedlove & Thorne 21247* (DS); San Cristóbal valley, 2,200 m, *Breedlove & Thorne 21285* (DS, mixed with *J. ebracteatus* E. Meyer; MICH).

FIGURE 1. A, B. Juncus chiapasensis (Roe, Roe & Mori 966).—*A. Habit.—B. Flower with protruding capsule. C, D.* Juncus liebmannii *var.* polycephalus (Breedlove 15065).—*C. Habit.—D. Flower with capsule and floral bract.*

Juncus liebmannii Macbride, Field Mus. Nat. Hist., Bot. Ser. 11(1): 9. 1931 (as *J. liebmannii*). Replaced synonym: *Juncus brevifolius* Liebm. (1850), non Hoffsgg. & Link in Rostkov (1801).

This species has one variety in the Andes of Ecuador and Colombia (var. *quitensis* (Buchenau) Balslev, 1979), and two varieties in Mexico and Central America, one of which is described here as new. *Juncus liebmannii* was first collected in Puebla, Mexico by Liebmann in 1841 and described as *J. brevifolius* (Liebmann, 1850). Liebmann was aware that Hoffmannsegg & Link in Rostkov (1801) had used the name *J. brevifolius* before, but since the entity bearing the first application of the name was a synonym of a species of *Luzula*, he felt free to use the name again for a species of *Juncus*. This was accepted by Buchenau (1873, 1886, 1890, 1906), who called the typical variety *J. brevifolius* var. *mexicanus*. Macbride (1931) renamed the species according to current nomenclatural rules.

Juncus liebmannii Macbride var. **polycephalus** Balslev, var. nov. TYPE: Mexico. Chiapas: southern city limits of Tepisca, 1,800 m, *Breedlove 15065* (holotype, DS-609015; isotypes, MICH, NY). Figure 1C, D.

Planta perennis; rhizoma repens, internodiis 1 cm longis. Folia linearia, teretia vel aliquantum compressa, septata; auriculae involutae; inflorescentia anthela 3–8 × 2–4 cm, 10–30-capitulata; capitula 4–6 mm lata, 10–15-flora.

Perennial herbs 60–70 cm tall. Rhizome horizontally creeping, 2–3 mm diam. Culms erect, 1–2 mm diam., terete, finely striate. Cataphylls 1–2 to each culm, up to 12 cm long. Foliar leaves 2–3 to each culm, inserted along the whole culm, 10–25 cm long, the basal and upper foliar leaves with shorter blades than the middle ones; sheaths 5–15 cm long, with a distinct membranaceous margin terminating in two involute auricles; blades 1–1.5 mm diam., round or slightly flattened in cross section, hollow and cross septate. Inflorescence a decompound anthela, 3–8 × 2–4 cm, of 10–30 flower heads, these semiglobose or conical, 4–6 mm diam., 10–15 flowered, castaneous, the ultimate head-bearing branches 0.2–0.3 mm thick. Lower inflorescence bract up to 8 cm long, with a foliar blade, this round in cross section and with transverse septa, or only 3–4 cm long and with the blade reduced to a small acicular appendage; upper bracts much smaller; floral bracts 1–2 mm long, membranaceous. Tepals subequal, 2–2.5 mm long, lanceolate, acute, the outer ones V-shaped in cross section, inner ones flat. Stamens six, 1–1.5 mm long; filaments linear; anthers oblong, ca. 0.3 mm long, about ⅓ as long as the filaments. Capsules 2–2.5 × 1–1.5 mm, obovoid, acuminate to short-beaked, about as long as the tepals, keeled along the sutures, castaneous, unilocular. Seeds 0.4 × 0.2 mm, ellipsoid, apiculate, reticulate, yellow-brown.

This new variety agrees with *J. liebmannii* var. *liebmannii* in all characters except for the inflorescence, which is divided into 10–30 distinct flower heads. In the typical variety the inflorescence is divided in two subequal parts with the flowers arranged diffusely in 2–3-flowered glomerules but not in distinct heads.

I thank Kirsten Tind for the beautiful and illustrative plate and Rupert Barneby for linguistic assistance.

A NEW SPECIES OF *STRYCHNOS* (LOGANIACEAE) FROM NICARAGUA

While preparing treatments of Loganiaceae for the forthcoming *Flora de Nicaragua* and *Flora Mesoamericana*, I encountered a new species of *Strychnos* from the Caribbean lowlands of Nicaragua. *Strychnos* is a pantropical genus of some 200 species. Of the approximately 90 species of the American tropics, only nine, including the one described here, occur in Mexico or Central America. In the most recent treatments of the American species of *Strychnos* (Krukoff & Barneby, 1969; Krukoff, 1972), *S. nicaraguensis* would be assigned to sect. *Breviflorae* Progel subsect. *Eriospermae* Krukoff & Barneby on the basis of its recurved spines, terminal inflorescences, short styles, and seeds with testa composed of soft fibers. Unfortunately, the corolla of *S. nicaraguensis* remains unknown, so that the length of the corolla tube in relation to the calyx, one of the important sectional characters in *Strychnos* (equaling or shorter than the calyx in sect. *Breviflorae*, much longer in the other sections), cannot be positively ascertained. Nevertheless, other characters, principally the recurved spines and fibrous testa, assure its placement in subsect. *Eriospermae* of sect. *Breviflorae*.

Strychnos nicaraguensis Huft, sp. nov. TYPE: Nicaragua. Zelaya: N of Talolinga in gallery forest, 19 Aug. 1983, *J. C. Sandino 4509* (holotype, F-1988116, F neg. no. 62188; isotype, MO, not seen).

Frutex volubilis; caules non conspicue lenticellis praediti, spinis recurvatis. Folia glabra rhombeo-ovata, apice longiacuminata, basi acuta vel acuminata, costa supra non impressa, nervis lateralibus obscuris. Flores 4–7, cymis terminalibus compactis; sepala 5 discreta deltato-lanceolata ciliata aliter glabra; corolla staminaque non visa. Fructus laevis, ca. 1.5 mm diametro, luteus, pericarpio tenui; semina 1 vel 2, depresso-globosa, testa fibrosa.

Liana; stems not conspicuously lenticellate, with recurved spines to 2 cm long; branchlets wandlike, flexuous, densely puberulous, soon glabrate. *Leaves* with petioles 1–2 mm long, puberulous; blades rhombic-ovate, 3–5(–5.5) cm long, 1.4–2.2 cm wide, (1.7–)2–2.9(–3.2) times as long as wide, glabrous, dull green above, pale below, triplinerved, the midvein scarcely or not at all impressed above, the secondary veins obscure; apex long-acuminate; base acute to acuminate; margin entire. *Flowers* 4–7 in compact, terminal, slender-pedunculate cymes 5–7 cm diam., the peduncles 1–1.5 cm long; bracts lanceolate, 1.5–3 mm long, ciliate; pedicels 1–2 mm long; calyx segments 5, free, slightly unequal, deltate-lanceolate, navicular, long-acuminate, ciliate, otherwise glabrous, 1.2–1.8(–2) mm long; corolla not seen; stamens not seen; style ca. 0.8 mm long. *Fruits* globose, smooth, ca. 1.5 cm diam., the shell ca. 0.5 mm thick, yellow; seeds 1 or 2, depressed globose, ca. 5 mm long, ca. 7 mm diam., the testa fibrous.

Subsection *Eriospermae* is distinguished from subsect. *Breviflorae* Krukoff & Barneby, which comprises the rest of sect. *Breviflorae*, solely by the characteristic soft fibrous testa of the seeds, which breaks away from the dry, shrunken endosperm of old seeds and encloses the endosperm like a sac. *Strychnos nicaraguensis* belongs to a group of species of subsect. *Eriospermae* that are characterized by conspicuously lenticellate branchlets, recurved spines, midveins impressed above, faint or obscure foliar reticulations, distinctly pedicellate flowers, and sparingly ciliate calyx lobes. It is distinguished from all species in this group by the absence of conspicuous lenticels and by its distinctive small rhombic-ovate leaves without an impressed midvein. The only other species of this group in Central America, *S. brachi-*

ANN. MISSOURI BOT. GARD. 75: 383–384. 1988.

stantha Standley, further differs by its much larger fruits (to 9 cm in diameter) with thick shells, as does *S. nigricans* Progel of southeastern Brazil. The species most closely related to *S. nicaraguensis* appears to be *S. mattogrossensis* S. Moore, a species widely distributed in the Amazon basin. Both species have small fruits with thin shells ca. 0.5 mm thick, but *S. mattogrossensis* differs in having ovate, obovate, or elliptic leaves that are not at all rhombic-ovate and larger, more highly branched cymes 7–25 mm in diameter. Other species in this group include *S. cerradoensis* Krukoff & Barneby, native to the state of Minas Gerais, Brazil, which differs from *S. nicaraguensis* by its thick-shelled fruit, and *S. alvimiana* Krukoff & Barneby (Phytologia 27: 105. 1973), of the state of Bahia, Brazil, which has larger leaves that are dull on both surfaces and rounded or obtuse at the base.

Additional specimens examined. NICARAGUA. ZELAYA: Municipio de Siuna, Comarca El Hormiguero, Trocha El Hormiguero, 7 Jan. 1983, *Ortiz 586* (F); Municipio de Siuna, "Calera," 13°46′N, 84°46′W, 300–345 m, 12 Mar. 1984, *Ortiz 1790* (F).

TWO NEW SPECIES OF *INGA* (LEGUMINOSAE) FROM PANAMA

This paper describes two species of *Inga* from Panama, bringing the total number of *Inga* species known from that country to 29 (D'Arcy, 1987). The two species are unrelated within the genus, apparently belonging to different sections. Both are from areas where endemism is reported in other groups.

Inga jefensis Liesner & D'Arcy, sp nov. TYPE: Panama. Panamá: 1 mi. upstream from Frizzel's Finca Indio, slopes of Cerro Jefe, flower & fruit, 9 Sep., *Foster & Kennedy 1828* (holotype, PMA; isotype, MO). Figure 1.

Arbor parva, differt Ingis aliis panamensibus foliolis glabris concoloribus, rhachibus non alatis, inflorescentia umbellata, pedicellis gracilibus longioribus, fructibus longioribus.

Tree 15 m tall, the branchlets copiously lenticellate, nearly glabrous but with occasional minute trichomes. Leaves with petiole 5–10 cm long, terete, slender, unwinged, drying olive green; rachis ca. 15 cm long, resembling the petiole, the glands ca. 2 mm across; petiolules (*Gentry 8854*) ca. 6 mm long, thick, drying olive green; leaflets 4–5 pairs, elliptic to obovate, acuminate, basally obtuse, 6.3–19 cm long, drying concolorous, olive green (emerging growth drying reddish brown), glabrous, the lateral veins 9–10 on each side; stipules oblong or obovate, ca. 15 mm long, 6 mm wide, drying enervate, membranaceous. Inflorescence umbellate; peduncle ca. 7 cm long, slender; pedicels slender, 7–12 mm long. Flowers ca. 23; calyx tubular, ca. 2 mm long, glabrate, the lobes short, rounded; corolla tubular, 13–14 mm long, lobed $\frac{1}{5}$–$\frac{1}{3}$ its length, the lobes ca. 3 mm long, ca. 3 mm wide at the base; stamens ca. 3 cm long, exserted ca. 1.5 cm, the exserted portion longer than the corolla. Fruit linear, compressed around the seeds, the margins slightly sinuate between the seeds, ca. 30 cm long, 18–25 mm wide, 8 mm thick (dried).

The fruit of this species is similar to but longer than that of *Inga portobellensis* Beurling (sect. *Leptinga* fide León, 1966) from the Caribbean coast north of the localities for the new species. *Inga jefensis* differs in its smaller calyx (2 mm vs. 20–25 mm long) and notably in having an unwinged leaf rachis. This species is also somewhat similar to *Inga paterno* Harms (also in sect. *Leptinga*), which ranges from Costa Rica to Mexico, but *I. paterno* has sessile florets and a short, massive fruit 4–7 mm wide and 2–3 cm thick.

Inga jefensis is known only from Central Panama. The two locations, Cerro Jefe, a mountain ridge behind Panama City with elevations up to 900 m, and Santa Rita Ridge, another mountain ridge paralleling the Caribbean coast, are both areas known to have many endemic species. The collection from Cerro Jefe was taken in flower and fruit in September, and the collection from Santa Rita Ridge was taken in December in flower.

Paratypes. PANAMA. COLÓN: Santa Rita Ridge road 4 mi. from Transisthmian Highway to Agua Clara weather station, 500 m, flower, 11 Dec., *Gentry et al. 8854* (MO).

Inga spiralis Liesner & D'Arcy. TYPE: Panama. Panamá: 23.4 km from Panamerican Highway, fruiting, 13 Apr., *Mori & Kallunki 5577* (holotype, PMA; isotype, MO). Figure 2.

Arbor parva, differt Ingis aliis panamensibus foliis grandibus, foliolis grandibus discoloribus rigidis, rhachibus non alatis, calyce lato, fructu solido spiraliter 1½-plo superposito puberulenti.

Tree 15 m tall (*Dressler 4325*), the branchlets drying reddish with scattered minute simple hairs, prominently lenticellulate when young, glabrescent, becoming grayish.

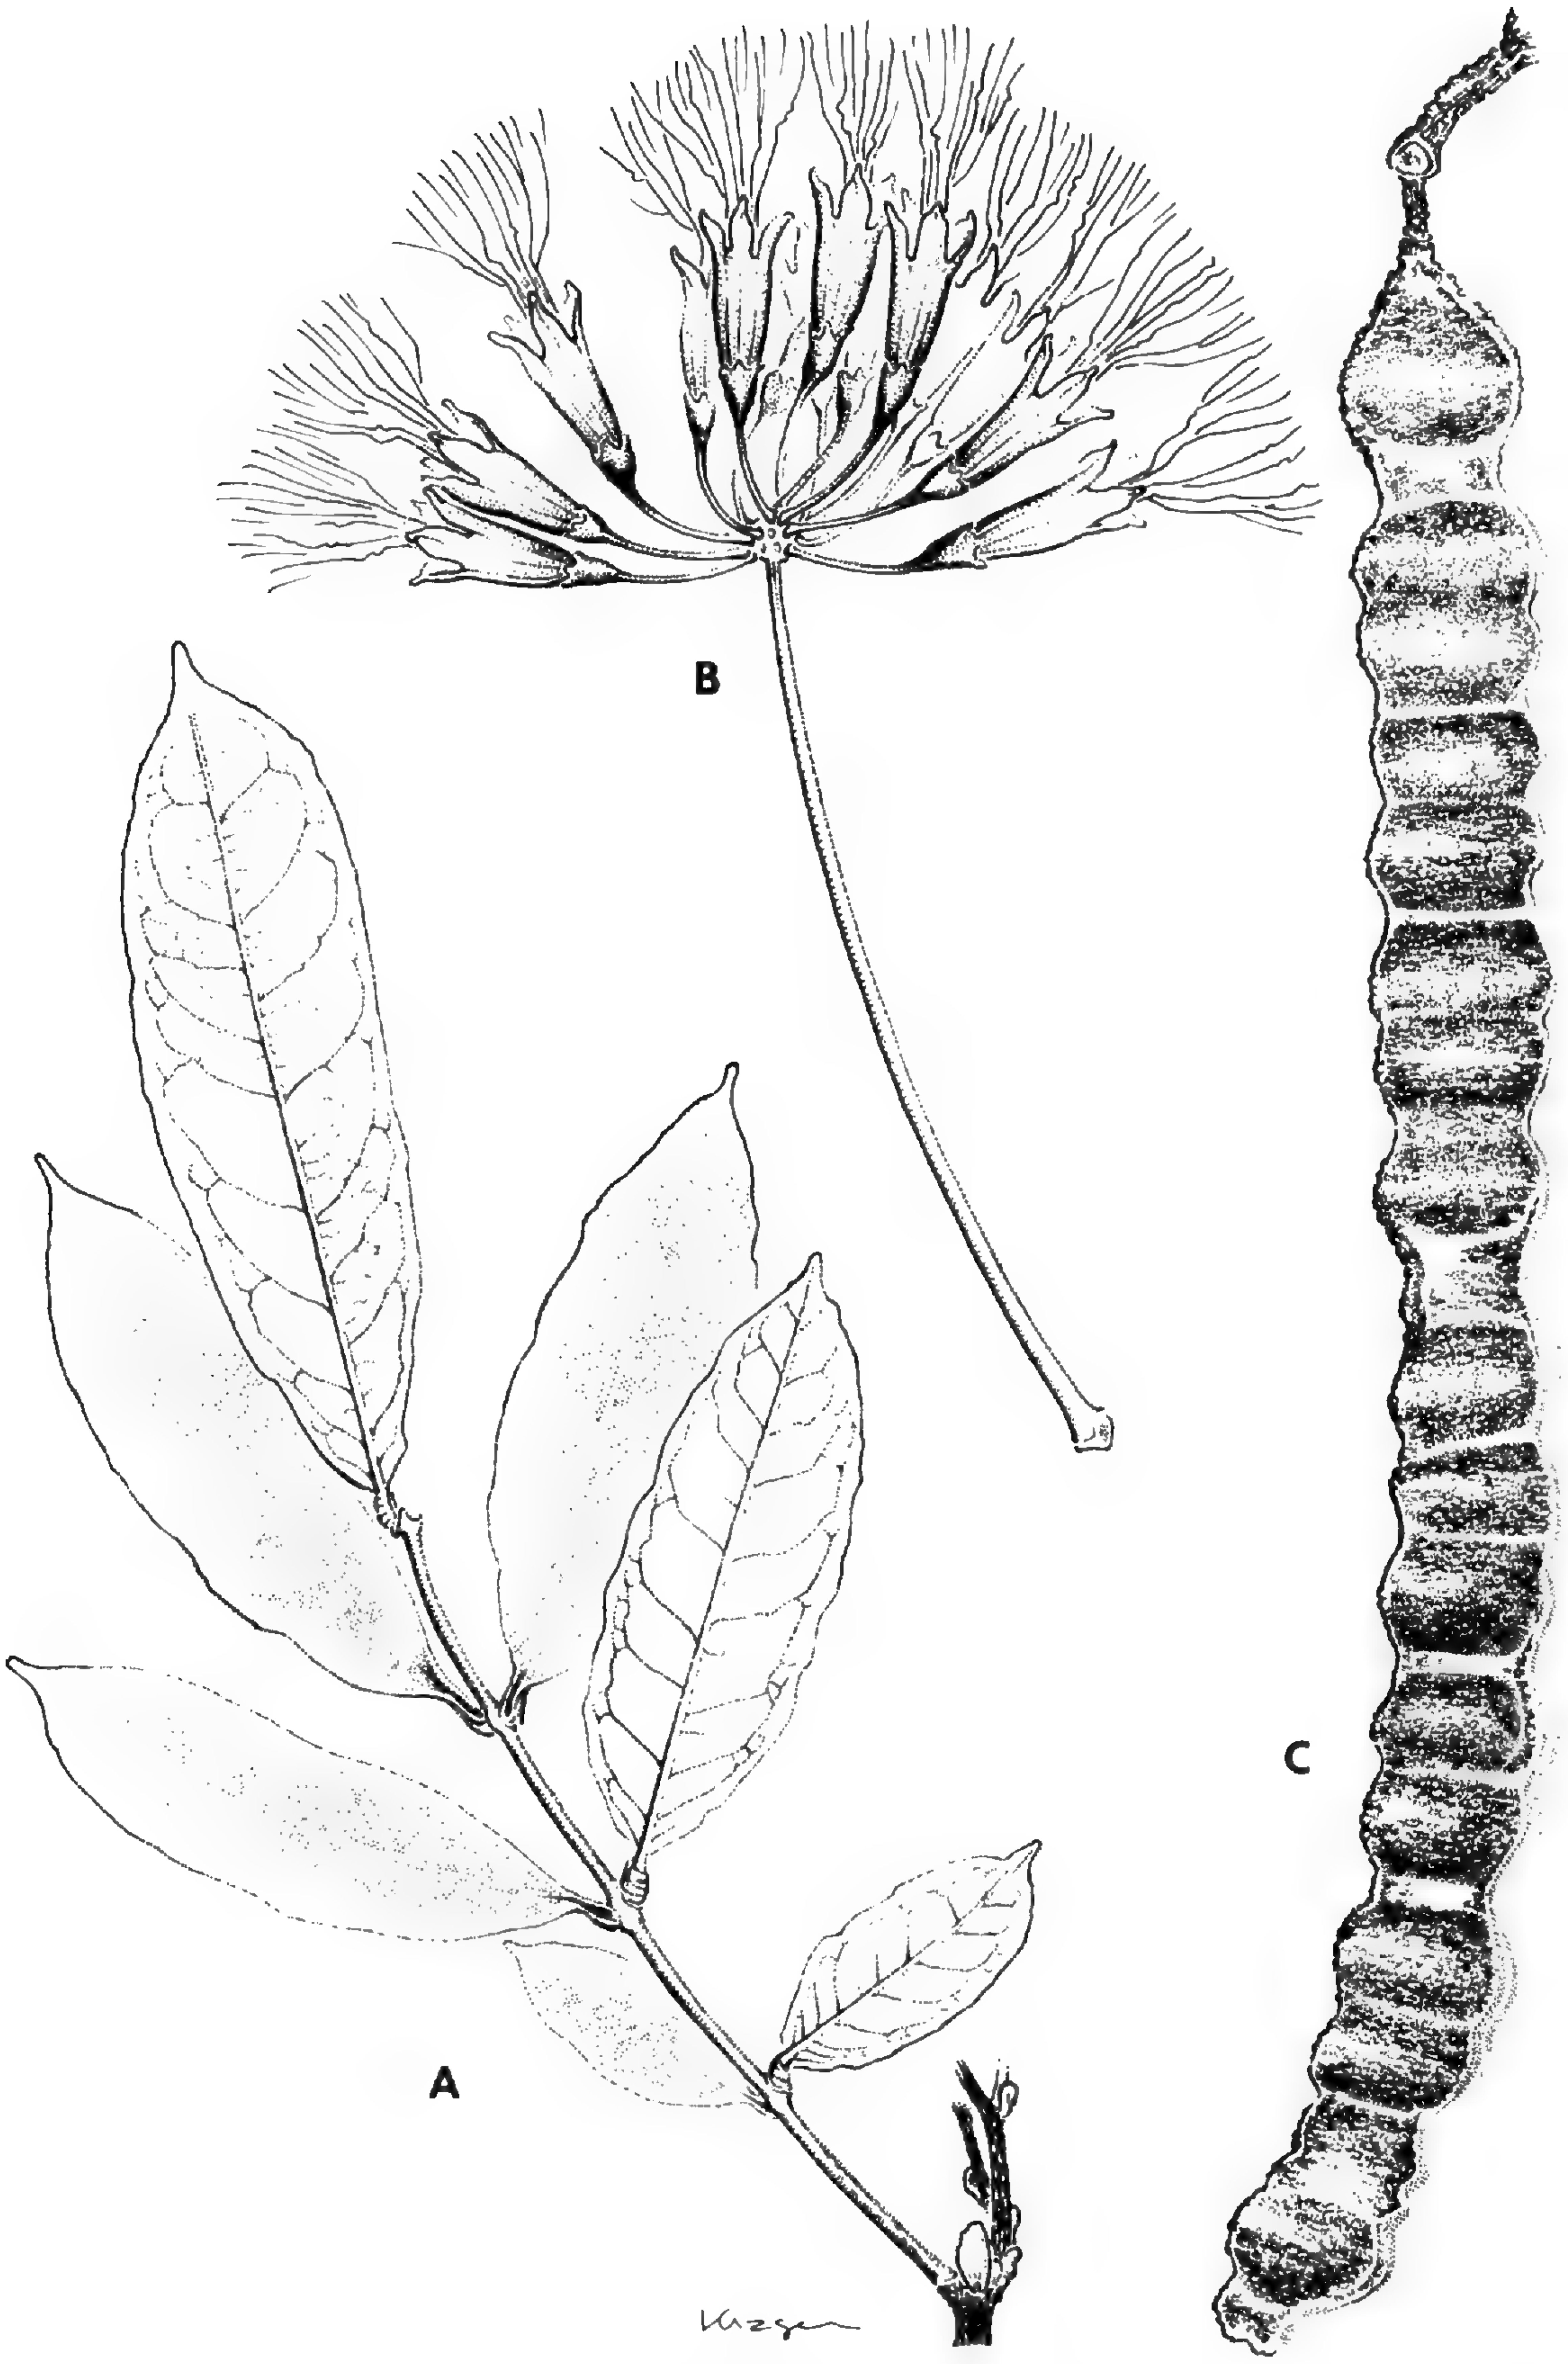

FIGURE 1. Inga jefensis (Foster & Kennedy 1828 *(MO)).—A. Leaf and twig with stipule (×0.5).—B. Inflorescence (×1).—C. Fruit (×0.5).*

Leaves with the petiole 10–21 cm long, subterete, slightly angled basally, unwinged, drying reddish, with sparse minute simple hairs; rachis 15–30 cm long, nonwinged, resembling the petiole, the glands subcupulate, ca. 3 mm across; petiolules ca. 4 mm long, stout; leaflets elliptic to obovate, apically rounded and short apiculate, basally obtuse, 20–30 cm long, 16 cm broad, drying discolorous, slate-colored above, reddish be-

FIGURE 2. Inga spiralis.—*A. Flower (× ⅓).—B. Fruit and pedicel borne on branch (× 0.5).—C. Leaf (× ⅓).—D. Stipule and old inflorescence (× 0.5). (A, C, from* Dressler 4325 *(MO); B, from* Mori & Kallunki 5577 *(MO); D, from* Liesner 1314 *(MO).)*

neath, glabrous above, softly puberulent beneath with short hairs; lateral veins 16–18 on each side; stipules conspicuous, subfoliaceous, subcircular, ca. 5 cm long, drying prominently nerved, persistent. Inflorescence (*Dressler 4325*) umbellate, the peduncle 7 cm long, straight, ca. 4 mm thick, borne "on branches ca. 3 cm diam.," pedicels 3–4 mm long, broadening upwards. Flowers 40–50; calyx 1 cm long, lobed ⅓–½ way down, the lobes oblong, 5–6 mm long, 4–5 mm wide at the base; corolla 2 cm long, deeply lobed, the lobes ca. 10 mm long, 4 mm wide, apically acute; filaments 3–4 cm long, exserted 2–3 cm. Fruit flattened, circinnate, coiled 1½ times, 3–4 cm across, conspicuously rugose nervate, forming a massive spiral 7–9 cm diam., softly puberulent with dense, short, whitish hairs.

This species is distinct in its massive, tightly coiled fruit. It is known only from the El Llano–Carti road in Panamá Province, not far south of Nusigandi. The fruit somewhat resembles that of *Inga davidsoniae* Standl. (sect. *Inga* ser. *Densiflorae* according to León, 1966) of Chiriquí Province, which is also short and thick, but that fruit is not coiled, and the leaflets of *Inga davidsoniae* are small in contrast to the unusually large leaves of the new species. Specimens in flower were collected in March and April and fruiting specimens in April.

Paratypes. PANAMA. PANAMÁ: El Llano–Carti highway ca. 20 km N of El Llano, 300–350 m, flowering, 6 Apr. *Dressler 4325* (MO). SAN BLAS: El Llano–Carti road, continental divide to 1 km N of divide, flowering, 30 Mar., *Liesner 1314* (MO).

NOTES ON THE FIJIAN ENDEMIC *MERYTA TENUIFOLIA* (ARALIACEAE)

Meryta J. R. & G. Forst. comprises about 30 species of dioecious, simple-leaved araliaceous trees and shrubs, nearly all of which are endemic to one or a few Pacific islands. The genus is centered in New Caledonia, where 11 species occur (Lowry, unpubl. data), and four species are recognized in Samoa and Tonga (Cox, 1985), one of which also appears to have been collected recently on Alofi (Morat & Veillon, 1985). *Meryta* reaches its western limit in Micronesia on Yap and has one species each in Vanuatu (formerly New Hebrides), Norfolk Island, New Zealand, and Rarotonga (Cook Islands). In Polynesia, perhaps three to five species occur on Tahiti, where they form a polymorphic and taxonomically difficult complex; two species have been described from Raiatea, and one species, *M. brachypoda* Harms, occurs on Raiavavae and on Tubuai. One endemic species of *Meryta* is found on Rapa to the south, and an undescribed species has been collected in the Marquesas.

Until recently, *Meryta* was thought to be lacking from Fiji (Smith & Stone, 1968). In December 1968, however, a single pistillate collection with mature fruit was made in the mountainous interior of Viti Levu and was described as *M. tenuifolia* by Smith (1971). This material is somewhat fragmentary and the descriptive notes that accompany it are sketchy. Nevertheless, it is clear that *M. tenuifolia* is very distinctive within the genus and is remarkable in being a large, highly branched canopy tree to nearly 25 m tall.

During a visit to Fiji in November 1985, I was able to re-collect *Meryta tenuifolia* near the village of Vanualevu, at the edge of the Rairaimatuku Plateau. A small population comprising several individuals of this tree, known locally as "lutulutu," was found on a gentle slope in dense, undisturbed forest at 980 m elevation, less than one km to the east of Vanualevu, perhaps two km to the north-northeast of the type locality. We located staminate plants in bud and flower as well as pistillate individuals with flowers and nearly mature fruits. Pressed specimens supplemented with FAA-preserved material and color photographs permit the following amended description.

Meryta tenuifolia A. C. Smith, Pacific Sci. 25: 499. 1971, *emend.* Lowry. TYPE: Fiji. Viti Levu: Nandronga & Navosa (now Navosa) Prov., rocky bank of Nggalivava Creek, a northward flowing stream joining Lumunda Creek (Singatoka River tributary), ca. 1.5 km S of Vanualevu, 750–800 m, 4 Dec. 1968 (fr), *M. J. Berry* (coll. *E. Damanu*) *97* (holotype, BISH; isotype, K). Figure 1.

Dioecious, branched, glabrous trees to ca. 25 m tall; trunk to ca. 70 cm dbh, fluted to ca. 1 m; stems robust, covered with numerous leaf scars. Leaves simple, alternate, clustered at the ends of branches; blades medium green above, lighter below, chartaceous, broadly elliptic, (9–)11–22 × (5–)7–12(–13) cm, the venation light yellow green, the midvein raised but without prominent bulges below, the secondary veins 8–11, diverging from the midvein at 50–60° angles, arcuate at the ends, the higher-order veins evidently raised above and below, forming a dense network, the apex rounded to obtuse or broadly acute, the margin entire, minutely thickened and revolute, the base obtuse to rounded and often shortly decurrent; petiole slender, 1.5–2 mm diam., with an expanded, clasping, brownish base with scarious margins. Inflorescence a panicle of racemules (or sometimes umbellules), terminal, erect, light green, occasionally tinged

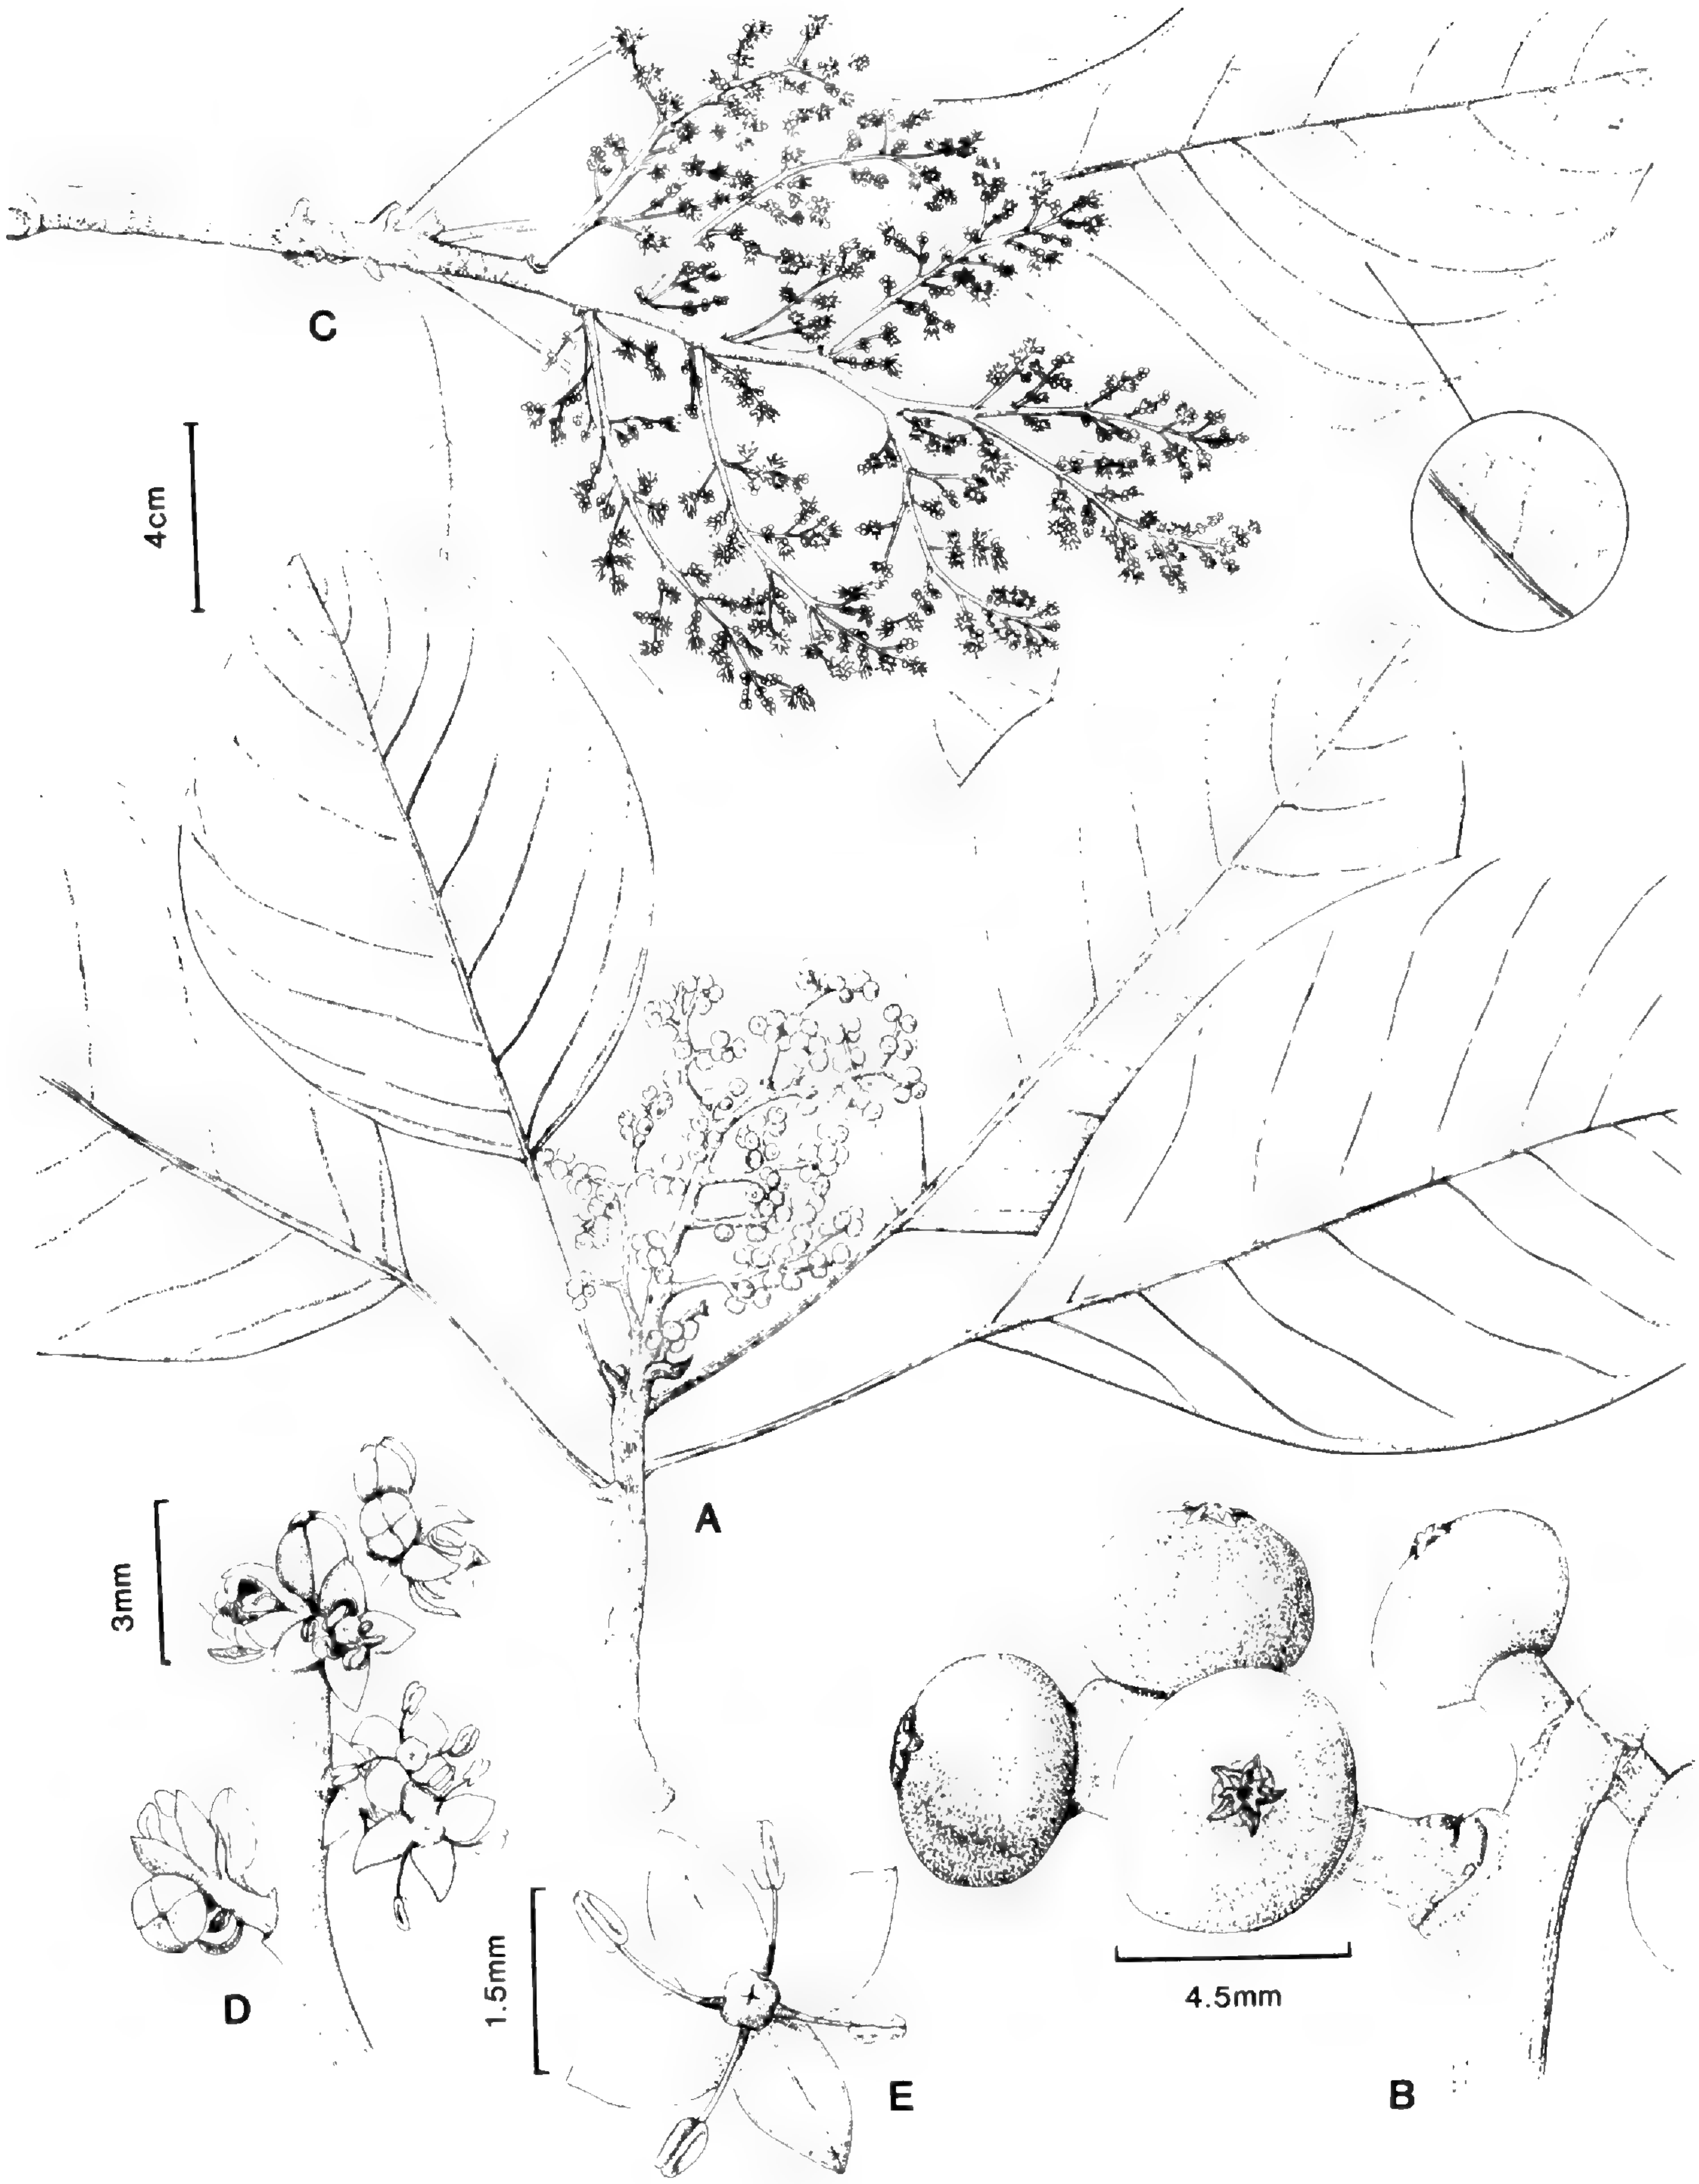

FIGURE 1. Meryta tenuifolia.—*A. Branch of pistillate plant with infructescence.—B. Nearly mature fruit.—C. Branch of staminate plant with inflorescence.—D. Tertiary axis with staminate flowers.—E. Staminate flower at anthesis (top view).*

orangish; primary axis slender, in staminate plants to 20 cm long, in pistillate plants to 10 cm long; the secondary axes 6–8, scattered, ascending, on staminate plants 6–9 cm long, on pistillate plants 3–4 cm long, each subtended by an early-caducous, ovate, cupulate, scarious, strongly adaxially concave cataphyll 12–15 mm long; tertiary axes subtended by small, scarious, caducous bractlets, the axes on staminate plants 6–12, ascending, 12–25 mm long, each with 3–6 racemules (sometimes reduced to umbellules) of (3–)4–6 sessile flowers, the axes on pistillate plants 4–6, ascending to spreading, 4–12 mm long, each with 4–6(–7) racemosely arranged sessile flowers. Staminate flowers ovate in bud; sepals wanting; petals 4, ovate, spreading at anthesis, ca. 1.5 mm long; stamens 4, inflexed in bud, ascending at anthesis, cream white, the filaments slender, 1.5–2 mm long, the anthers with 4 thecae, dorsifixed; the rounded nectar disk yellowish, weakly 4-sided. Pistillate flowers ovate-pyriform in bud; sepals wanting; petals 4 or 5, narrowly deltoid, subacute, recurved after anthesis, ca. 0.5 mm long, expanding to 0.6–0.9 × 0.9–1.3 mm in fruit; stamens vestigial, 0.5–0.8 mm long, caducous, the anthers sterile; ovary inferior, (5–)6–10-carpellate, ca. 1.5–2 mm high at anthesis, the flattened nectar disk 1–1.5 mm diam., expanding to ca. 2 mm in fruit; styles (5–)6–10, united basally, the free arms erect to ascending at anthesis, 0.3–0.6 mm long, in fruit expanding to 0.5–1 mm long, becoming divergent. Fruit a drupe, olive green when nearly mature, subglobose-oblate, 2–3.5(–4.5) × (3.5–)4–5.5 mm, smooth and plump when fresh, turning strongly and acutely (5–)6–10-costate when dry.

Additional specimens examined. FIJI. VITI LEVU: Navosa Prov., edge of Rairaimatuku Plateau, E and above Vanualevu village, dense forest on slight slope, 980 m, 18 Nov. 1985 (staminate bud, fl), *P. P. Lowry 3838* (BISH, MO (3 sheets), P, US); (pistillate fl, fr), *3839* (BISH, MO (3 sheets), P, US).

As Smith (1985) indicated, *Meryta tenuifolia* does not appear to be closely related to the very distinctive species occurring in Vanuatu and Samoa. Furthermore, it does not show strong affinities with species of *Meryta* on Rarotonga, Norfolk Island, and New Zealand. However, until my upcoming detailed revision of the genus has been completed, it will not be possible to determine whether *M. tenuifolia* is closest to Polynesian species such as *M. choristantha* Harms of Rapa, as suggested by Smith (1985), or to New Caledonian species such as *M. balansae* Baill.

I am grateful to A. C. Smith for providing locality information and a map of the original collection, and for valuable suggestions on the manuscript. Thanks are also due to J. M. Miller and S. Vodonaivalu for assistance in the field, to C. A. Todzia and B. C. Stone for additional comments, and to J. K. Myers for preparing the illustration. This work was supported in part by NSF Doctoral Dissertation Improvement Grant BSR83-14691, the Missouri Botanical Garden, the W. Alton Jones Foundation, and the Division of Biology and Biomedical Sciences of Washington University, St. Louis, Missouri.

PASSIFLORA PUSILLA (PASSIFLORACEAE), A NEW SPECIES FROM CENTRAL AMERICA

During the course of an ongoing study of Central American Passifloraceae, the following distinctive new species has been found in collections generated by the *Flora de Nicaragua* project and from older Costa Rican collections.

Passiflora pusilla MacDougal, sp. nov. TYPE: Nicaragua. Chontales: Hacienda Corpus, W of Juigalpa, ca. 100 m, 12°07′N, 85°28′W, 14 June 1984, *Stevens 22968* (holotype, MO; isotype, HMNH). Figure 1.

Passiflora hirsuta nana, scandens vel decumbens; caulis 12–55 cm longus, triqueter vel subtriqueter; petioli eglandulosi; folia trilobata, basi cordati, lobis obtusis vel truncatis, marginibus integris; pedunculi singulares uniflori; bracteae nulli; coronae filamenta biseriata, filamentis interioribus submicroscopicis, 0.2–1.5 mm longis; operculum plicatum; ovarium dense puberulum; fructus 3.5–4 cm longus, 0.5–0.7 cm latus, anguste fusiformis, sexangularis; semina dentibus seriebus 2 longitudinalis dispositus.

Diminutive, weakly climbing or often decumbent herb, 12–55 cm long, often fertile within 10–15 cm of its base. Roots perennial, the primary root 2.5–4 mm diam.; 1–5 annual stems arising from axillary buds at base of stem. Plant hirsutellous throughout with cylindrical, straight or slightly antrorsely bent, unicellular but often many-septate pelucid trichomes (0.1–)0.4–1.4(–1.8) mm long, these generally intermixed with microscopic, appressed trichomes 0.06–0.08(–0.1) mm long. Stem triangular or subtriangular (drying sulcate), 3-carinate, nearly glabrous below, becoming puberulent above with microscopic, appressed trichomes, and conspicuously hirsute on the carinae with trichomes (0.1–)0.4–0.6(–0.8) mm long. Stipules (2.5–)3–4(–5) × 0.4–0.5 mm, narrowly lanceolate to linear-triangular, subfalcate, hirsute, greenish, the apices not necrescent. Petioles 1–2.5(–3.6) cm, eglandular, canaliculate, sometimes tinged purplish. Laminae 1–2.4 × 2–4.5 cm at fertile nodes, depressed obovate in general outline, cordate at base, very shallowly 3-lobed (and in one collection, very rarely the lateral lobes shallowly and obscurely lobed at base), the lateral lobes obtuse, ± rounded, the central lobe broadly obtuse or nearly truncate, the angle between lateral lobes (80–)85–100(–108)°, ratio of lateral to central lobe lengths 1.1–1.4, ratio of laminar width to length 1.6–2.2, the margins entire and minutely setose to strigose; laminar nectaries absent. Tendrils absent, or present at distal nodes and then capillary and nonlignified; posture of developing tendrils and shoot apex unknown. Prophyll of vegetative ramifying bud 1, narrowly ovate, caudate. Peduncles solitary at nodes, 4.5–15(–21) mm, uniflorous, ebracteate. Flower ca. 1 cm diam., with 1–1.7 mm stipe (elongating to 1.7–3 mm in fruit), the hypanthium 3.5–4 mm diam., hirsute, the longer trichomes often borne 0.1–0.2 mm above the surface of the epidermis on cylindrical, slightly raised bases; sepals 7 × 1.8–2.2 mm, lanceolate, pale yellowish green; petals 2.7–3.5 × 1–1.3 mm, narrowly ovate or oblong, pale yellowish green; filamentous corona in 2 series, the outer 5–6 mm long, yellow toward apex, yellowish green to greenish below and sometimes with 1–3 narrow purplish bands at base or in lower half; inner series rudimentary, the members few, borne at base of operculum, 0.2–1.5 mm, capillary, slightly clavate; operculum 0.7–1 mm, membranous, the margin erose, plicate; nectary with annulus or nectar ring adjacent to limen; limen (disk) cupuliform, closely surrounding base of androgynophore, its edge ± erect and 0.7–0.8 mm high; staminal filaments connate

ANN. MISSOURI BOT. GARD. 75: 392–395. 1988.

4.2–6 mm along androgynophore, the free portions ca. 2 mm long; anthers 1.8–2.1 mm long, ovary 1.4–1.8 × 0.7–1 mm, narrowly obovoid or ellipsoid, 6-ridged or hexagonal in cross section, densely puberulent with appressed trichomes 0.05–0.1 mm long; styles ca. 3 mm?; stigmas capitellate. Fruit 3.5–4 × 0.5–0.7 cm, narrowly fusiform or fusiform, the stipe often indistinct, distally caudate, hexagonal and 6-carinate, sparsely and minutely puberulent, dehiscent; arils whitish, scanty, shorter than seed; seeds 3.1–3.4 × 1.7–1.8 mm, obovate, obliquely beaked at chalazal end, the short beak sharply angled toward the raphe, with 2 longitudinal rows of teeth (or 5–6 transversely sulcate, the ridges traversed by a broad longitudinal furrow).

Phenology. This is a species of strongly seasonally dry habitats, and it apparently dies back to the ground each dry season. The small size of the plant suggests that it may flower and set seed within only a few months of germination; nevertheless, nearly all of the specimens studied were collected with roots intact and show remnants of dead shoots from previous seasons. The short herbaceous shoots may be expected to emerge after the spring rains in April. Flowering from May through the summer and into the end of the rainy season, *Passiflora pusilla* has been found in fruit from late June to November.

Habitat and distribution. In the low tropical dry and gallery forests in the general vicinity of Lake Nicaragua, this passionflower is associated with the distinctive soil type called "sonsocuite" in Nahuatl. This sticky black soil is alkaline, poorly drained, and is seasonally inundated. It supports a forest of low stature, with *Crescentia*, *Cordia*, and mimosoids like *Acacia*, but has been mostly converted to pasture or intensive cultivation of cotton, rice, or sesame. This small passionflower has been found mainly below 300 m elevation in partial shade at the edges of the "sonsocuite," on banks at the edges of roads and pastures, or in the shade of associated gallery forest. There are two records from a disturbed area at 800 m on the Meseta Central of Costa Rica.

The specific epithet refers to the very small size of this plant.

Paratypes. COSTA RICA. GUANACASTE: Santa Rosa National Park, 30 km W of Liberia, 0–320 m, 10°50′N, 85°35′W, 18 Aug. 1984 (fr), *Janzen 12412* (MO); 5 km NE of Bagaces, 95 m, 22 July 1964 (fl, fr), *Jiménez M. 2136* (F); W of airport, 10 km W of Liberia, 0–100 m, 10°30′N, 85°34′W, 25 June 1977 (fl), *Liesner & Rockwood 2516* (MO); 23 km SW of Liberia, 10°24′N, 85°34′W, 1–200 m, 23 July 1964 (fl, fr), *Tessene 1424* (WIS). SAN JOSÉ: Santa Ana [9°56′N, 84°11′W], 800 m, 25 Nov. 1963 (fl, fr), *Jiménez M. 1319* (F); Brasil de Santa Ana [9°56′N, 84°13′W], 800 m, 2 June 1957 (fl), *Rodríguez C. 464* (UC). NICARAGUA. CHONTALES: Hacienda Corpus, W of Juigalpa, ca. 100 m, 12°07′N, 85°28′W, 20 May 1984 (fl), *Stevens 22898* (MO, HMNH).

Passiflora pusilla is referred to subg. *Plectostemma* Masters sect. *Xerogona* (Rafinesque) Killip on account of the small flower with a plicate operculum, subtriangular carinate stem, absence of either floral bracts or extrafloral nectaries, dehiscent fusiform fruit, and testal architecture of a chalazal beak sharply angled towards the raphe with a fundamentally transversely grooved sclerotesta. The dehiscent, hexagonal, fusiform fruit of *P. pusilla*, characteristic of sect. *Xerogona*, is known in its fully mature state only from *Jiménez M. 2136*.

Passiflora pusilla is perhaps most similar vegetatively to *P. tenella* Killip. *Passiflora tenella* is endemic to the Pacific tropical deciduous forests of Ecuador and Peru (Holm-Nielsen et al., in press). The two species share a very reduced size, similar eglandular leaves, and solitary peduncles. The laminae of *P. tenella* differ, however, in being less pubescent (especially abaxially), with the apices of the lateral lobes acute and the angle between them broader. The ovary of *P. tenella* is nearly glabrous. Its fruit, although also fusiform, is shorter and relatively broader, lacking the caudate apex seen in *P. pusilla*; whether it dehisces is unknown. The seed of the South American species differs greatly by being transversely sulcate with five rugulose ridges. Killip (1938) placed *P. tenella* in sect.

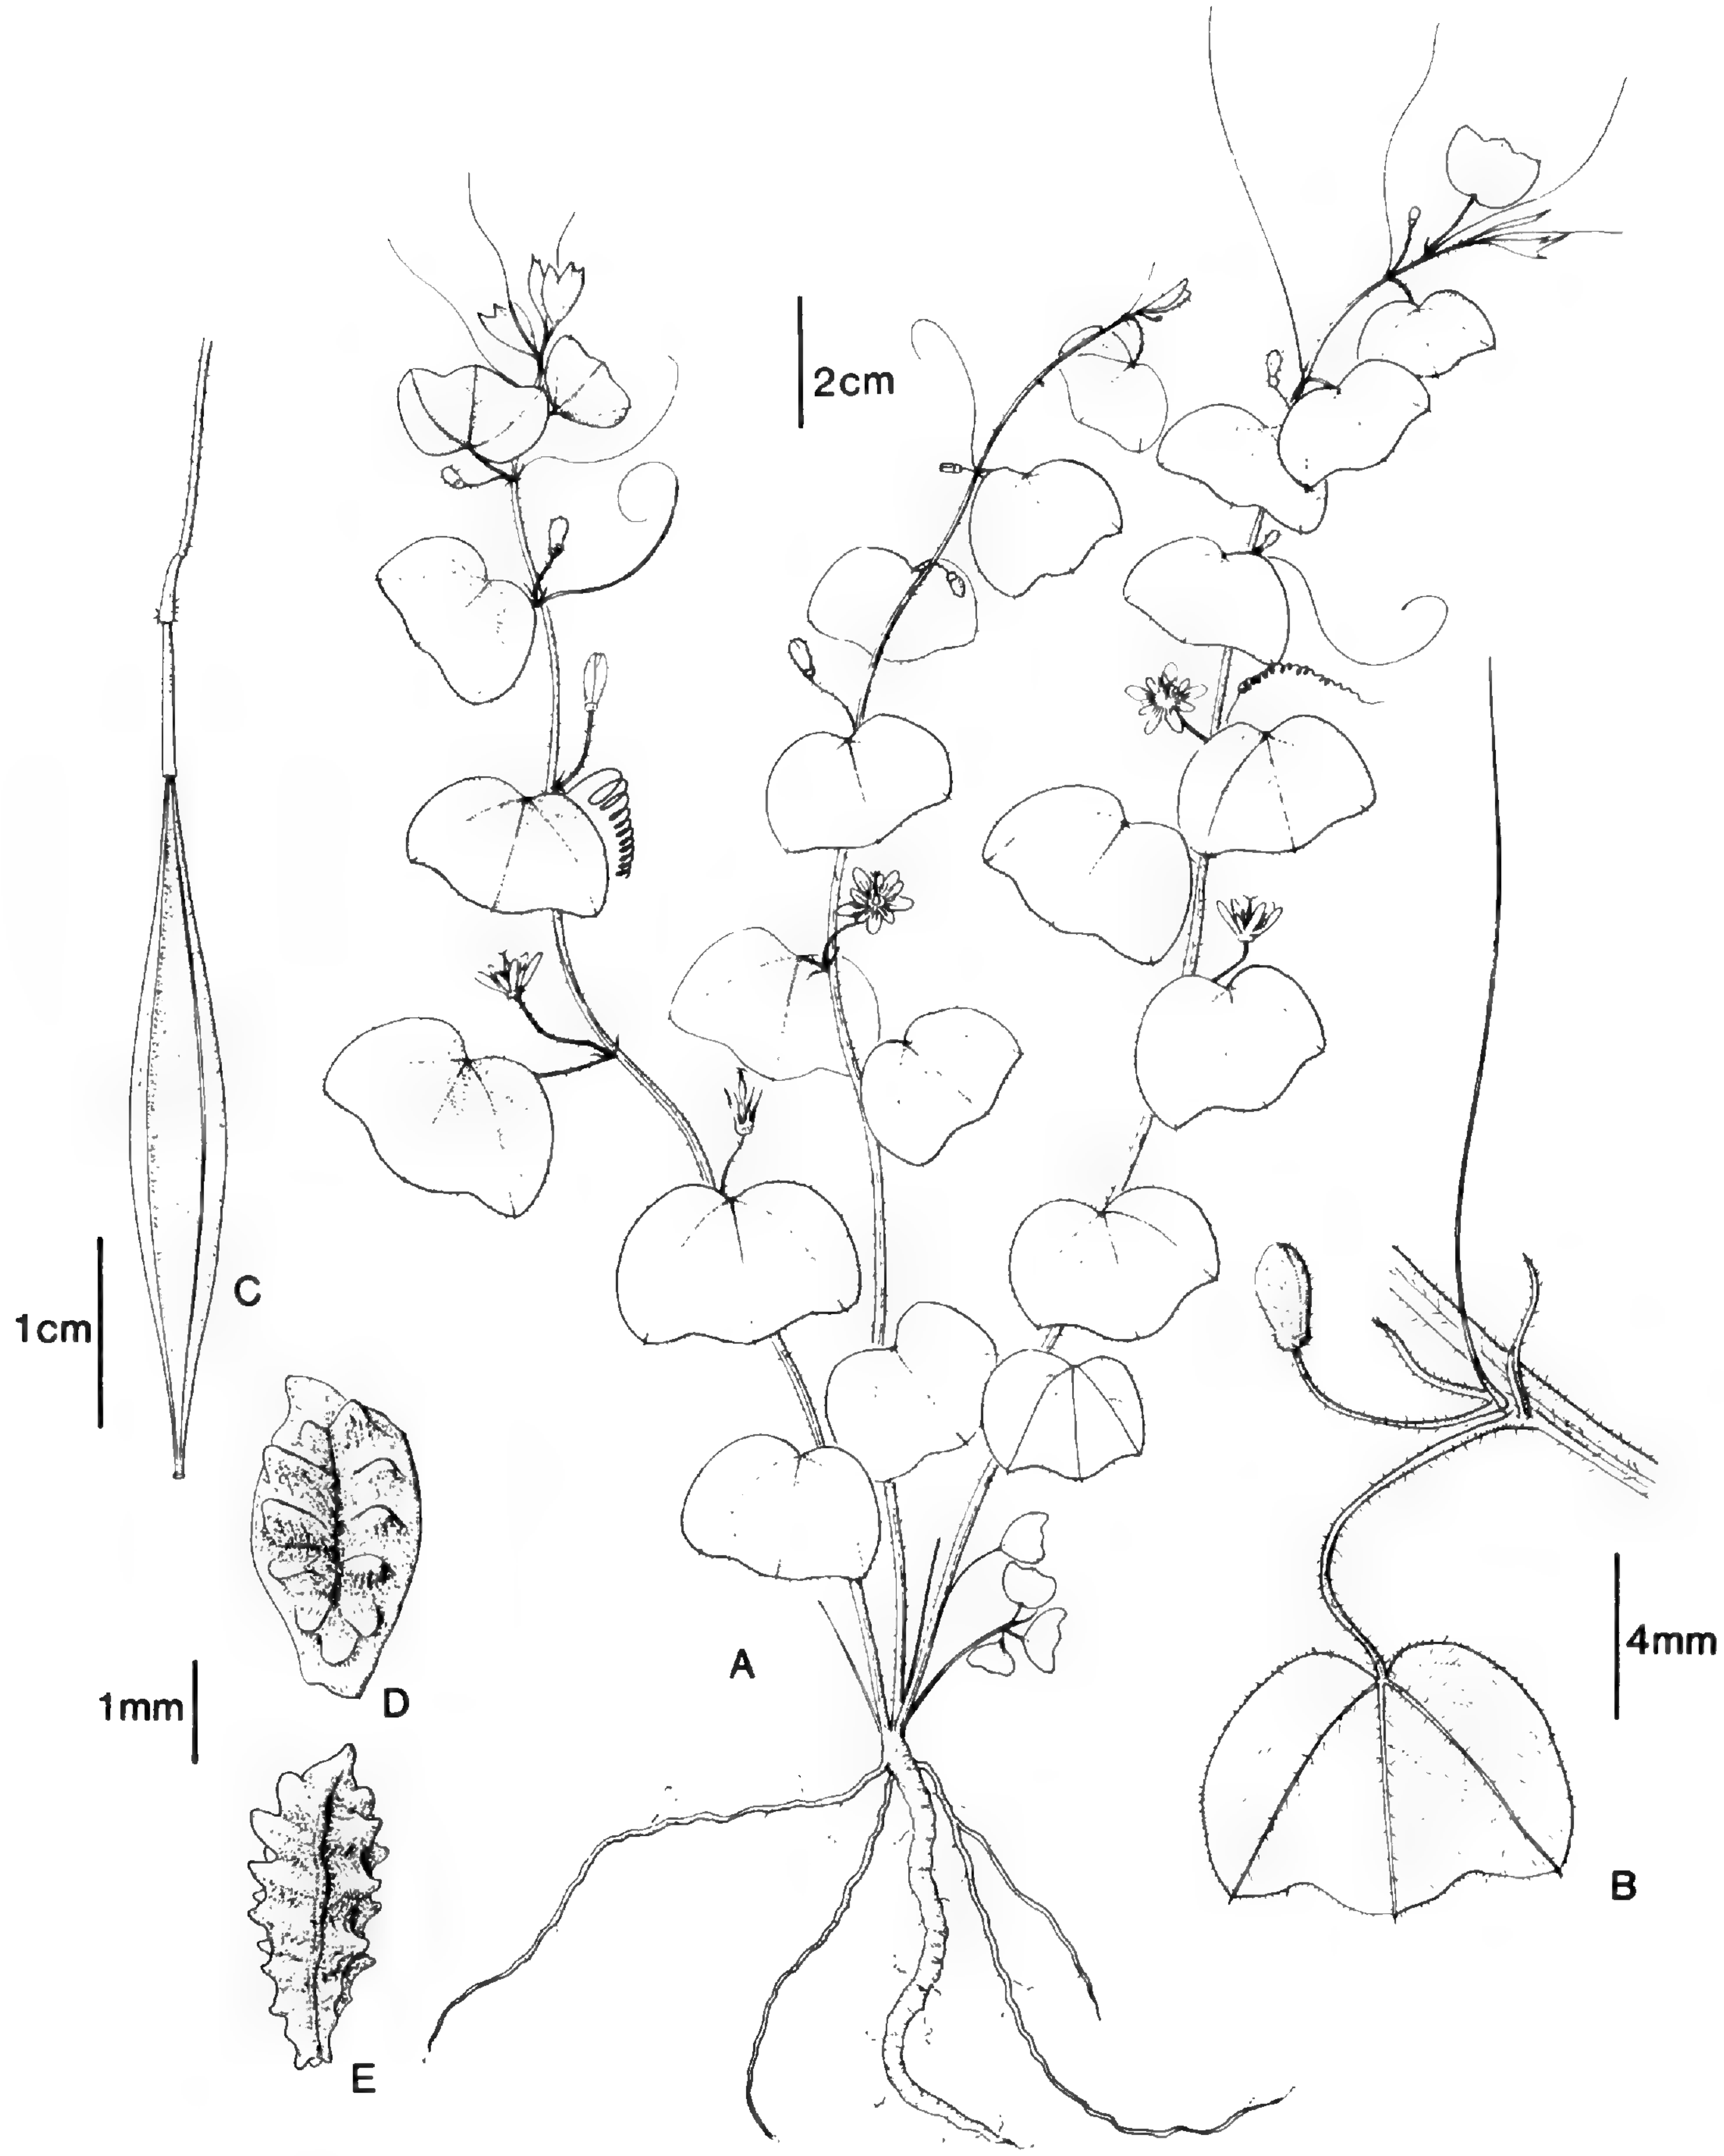

FIGURE 1. —Passiflora pusilla.—*A. Habit.—B. Detail of leaf, node, stipules, and peduncle.—C. Nearly mature fruit.—D, E. Seed.*

Decaloba (DC.) Mast., rather than in sect. *Xerogona*, based on the rugulose testal ridges and the presence of floral bracts. A close kinship between *P. pusilla* and *P. tenella*, phytogeographically plausible due to the close relationship of their respective habitats and vegetation types (Gentry, 1982), cannot be confirmed without further study of the poorly understood South American species.

Passiflora pusilla is also similar to both

P. conzattiana Killip and *P. goniosperma* Killip of Mexico. *Passiflora conzattiana* is a small, low-growing, often prostrate vine of wet montane or *Liquidambar* cloud forests in eastern Mexico. It has similar leaves, small flowers, and very similar fruits, but is a larger plant having apically truncate to lunately bilobed laminae with acute to acuminate lateral lobes, generally less pubescence, and seeds with five or six smooth transverse ridges. *Passiflora goniosperma* is likewise very similar and is from a more similar seasonally dry habitat in southern Mexico. This poorly known species is also a larger plant, having more deeply bilobed leaves, larger fruits, and unusually sculptured seeds that have a single toothed ridge down the length of the face of the testa. Both the more glabrous race of the Pacific tropical deciduous forests and the densely pubescent typical race from central Oaxaca share this form of seed (MacDougal, unpubl.). In contrast, the seed of *P. pusilla* has a furrow in the comparable position with two rows of teeth on either side. Both Mexican species possess only a single series of coronal filaments that are conspicuously and nearly uniformly reddish purple below their yellowish tips.

I thank Warren Douglas Stevens for habitat information and for reading and criticizing the manuscript. The illustration was prepared by John Myers with support from the Missouri Botanical Garden. This research was supported in part by a fellowship from the Noyes Foundation.

NOTES ON *RHODOGNAPHALOPSIS* AND *BOMBACOPSIS* (BOMBACACEAE) IN THE GUAYANAS

The genus *Rhodognaphalopsis* was established by A. Robyns in his revision of *Bombax* in the broad sense (1963). In his generic key, he separated *Rhodognaphalopsis* and *Rhodognaphalon* from *Bombacopsis*, *Eriotheca*, and *Pachira* using only pollen characters: "Pollina colpata vel colporata; sexinium reticulatum ad interdum fragmentimuratum" for characterizing the last three genera and "Pollina porata vel cop(or)ata [*sic*]; sexinium structura uniformi, tegellatum ad punctatitegillatum tegilloque processibus spinulatis vel baculatis praedito" for the first two. By comparing Robyns's generic descriptions, one can also find that *Rhodognaphalopsis* is often lepidote on several organs while *Bombacopsis* is not; apparently it was overlooked that at least *Bombacopsis quinata* (Jacq.) Dugand (= *Pochota quinata* (Jacq.) W. D. Stevens) has prominently lepidote flowers.

The palynological differences between *Rhodognaphalopsis* and *Bombacopsis* are not impressive (e.g., see fig. 25 in Robyns, 1967), but perhaps more importantly, *Bombacopsis* is palynologically diverse (see Nilsson & Robyns, 1986), enough so as to accommodate *Rhodognaphalopsis* easily. Since this questionable palynological difference is not correlated with any gross morphological characters, it appears more appropriate to merge the two genera. It should be noted, however, that while *Rhodognaphalopsis* is relatively homogeneous, *Bombacopsis* is not. It could well be that some species of *Bombacopsis*, as circumscribed by Robyns, will eventually be found to be better placed in *Pachira*. *Rhodognaphalopsis* most resembles the type element of *Bombacopsis* and there is little danger of *Rhodognaphalopsis* falling into the synonymy of *Pachira*. It can also be noted that Hutchinson (1967) judged the palynological difference to be of little importance and considered *Rhodognaphalopsis*, as well as the African genus *Rhodognaphalon*, to be indistinguishable from *Bombacopsis*.

Pittier erected the genus *Bombacopsis* for two Central American species that he considered intermediate between *Pachira* and *Bombax*. These, *Bombacopsis sessilis* (Benth.) Pittier and *B. fendleri* (Seem.) Pittier (= *Bombacopsis quinata* (Jacq.) Dugand), have the seeds embedded in wool, characteristic of the genus *Bombax*, as contrasted with *Pachira*, in which the seeds are embedded in the fleshy dissepiments of the capsule. They further share with *Bombax* the manner in which staminal fascicles divide at once into single filaments. Pittier distinguished *Bombacopsis* from *Bombax* by the fewer stamens and more slender flowers of the former. Later, Robyns (1963) also recognized the genus *Bombacopsis*. He distinguished it from *Bombax* by its persistent or even accrescent calyx, while from *Pachira* it was separated by having abundant, wooly, elongated investiture of the seed; by possession of smaller flowers; by differences in the pollen and cotyledons; and usually by smaller and more numerous seeds. Many of the species were transferred from *Bombax*, while some others had previously been recognized in *Pachira*.

Recently, it has been reiterated that *Pochota* Ramirez Goyena has nomenclatural priority over *Bombacopsis* (Stevens, 1987). Since then, *Bombacopsis* has been proposed for conservation (Nicolson & Robyns, 1987).

ANN. MISSOURI BOT. GARD. 75: 396–398. 1988.

Given that we cannot accept *Rhodognaphalopsis* and *Bombacopsis* as distinct genera and that several of these species will be treated in the upcoming *Flora of the Venezuelan Guayana*, we are left with the dilemma of how to treat them. One could make the new combinations of *Bombacopsis* in anticipation of conservation, but it must be taken into consideration that the two previous proposals to conserve *Bombacopsis* against *Pochota* have been rejected and that there is no assurance that the current proposal will be successful, a process which in any case will require years to complete. If, on the other hand, the more strictly correct approach of making the combinations in *Pochota* is followed, the distinct possibility of the names being overturned will remain. Although the latter choice will require the larger number of transfers, to account for *Bombacopsis* as well as for *Rhodognaphalopsis*, we have reluctantly concluded that it is preferable. Accordingly, the following new combinations are proposed:

Pochota amazonica (Robyns) Steyerm. & W. D. Stevens, comb. nov. *Bombacopsis amazonica* Robyns, Bull. Jard. Bot. État 33: 186. 1963.

Pochota coriacea (Martius & Zucc.) Steyerm. & W. D. Stevens, comb. nov. *Bombax coriaceum* Martius & Zucc. in Martius, Nov. Gen. Sp. Pl. 1: 93. 1826. *Rhodognaphalopsis coriacea* (Martius & Zucc.) Robyns, Bull. Jard. Bot. État 33: 289. 1963.

Pochota coriacea subsp. **orinocensis** (Robyns) Steyerm. & W. D. Stevens, comb. nov. *Rhodognaphalopsis coriacea* subsp. *orinocensis* Robyns, Mem. New York Bot. Gard. 17: 197. 1967.

Pochota cowanii (Robyns) Steyerm. & W. D. Stevens, comb. nov. *Bombacopsis cowanii* Robyns, Mem. New York Bot. Gard. 17: 190. 1967.

Chromosome numbers of plants have become increasingly important over the years in studies of systematics and evolution. Nearly all modern taxonomic monographs and revisions include chromosomal data and use this information in analyzing species or generic relationships or evolutionary patterns.

Chromosome counts accumulate at the rate of over 5.000 a year, scattered in the literature. They are reported in brief articles, as major compilations for families or genera, and in revisions and monographs in numerous botanical and other journals and in books.

The **Index to Plant Chromosome Numbers** is compiled by an international committee and collated and edited by Peter oldblatt. Missouri Botanical Garden It is indispensible to those engaged in a variety of botanical studies ranging from ystematics and evolution to plant breeding, forestry, and horticulture. Counts for all plant groups—algae, fungi, bryophytes, teridophytes, and spermatophytes—are included and arranged alphabetically by family, genus and species. Each count ncludes the name of the taxon as used in the original report, the number reported, and reference to the original report. eferences are contained in a bibliography which contains citations at the level of about 500 per year.

IPCN is published as separate volumes in the series MONOGRAPHS in Systematic Botany from the Missouri Botanical iarden.

The simplest way to order is to use the order form below or a photocopy of it. Please include information requested elow if you order on separate paper. Orders should be prepaid: a $1.00 fee will be added to orders requiring invoicing, nd no shipments are made until payment is received. Please add $1.50 for one book and $.50 for each additional book to over postage and handling.

POLLEN MORPHOLOGY OF *PILLANSIA* L. BOLUS (IRIDACEAE)[1]

Peter Goldblatt[2] *and Bruce A. Stein*[3]

ABSTRACT

The monotypic southwestern Cape genus Pillansia *is a taxonomically isolated member of Iridaceae subfamily Ixioideae. It shares some synapomorphies with Ixioideae, although it differs in its unspecialized leaf anatomy and inflorescence structure, a panicle rather than a spike. The pollen is typical of Ixioideae in having a micropunctate exine with minute supratectal papillae. Exine of most other genera and subfamilies of Iridaceae is reticulate. Membership of* Pillansia *in Ixioideae is thus supported by pollen morphology. Micropunctate exine must be regarded as the basic condition for the subfamily and an additional feature separating Ixioideae from other Iridaceae.*

Pillansia L. Bolus is a monotypic genus of Iridaceae–Ixioideae, the largest of the four subfamilies currently recognized. It is a relatively rare, narrow endemic of the southwestern Cape, South Africa (Goldblatt, 1977) and is restricted to rocky sandstone sites in the Caledon district. It has a basic chromosome number of $x = 20$ and thus appears to be paleopolyploid. Most other genera of Ixioideae have base numbers in the $x = 11–9$ range or are neopolyploid with $n = 16–13$. Although *Pillansia* diverges in some important respects from other members of the subfamily, it is widely accepted as belonging to Ixioideae. Nevertheless, it is taxonomically isolated and appears to have no identifiable close relatives. It accords with Ixioideae in several specialized features (synapomorphies) (Goldblatt, in prep.) that characterize the subfamily. These include a long-lasting perianth; sessile flowers subtended by a pair of opposed bracts; a well-developed, though short, perianth tube; and a basal rooting corm.

The pollen morphology of *Pillansia* has

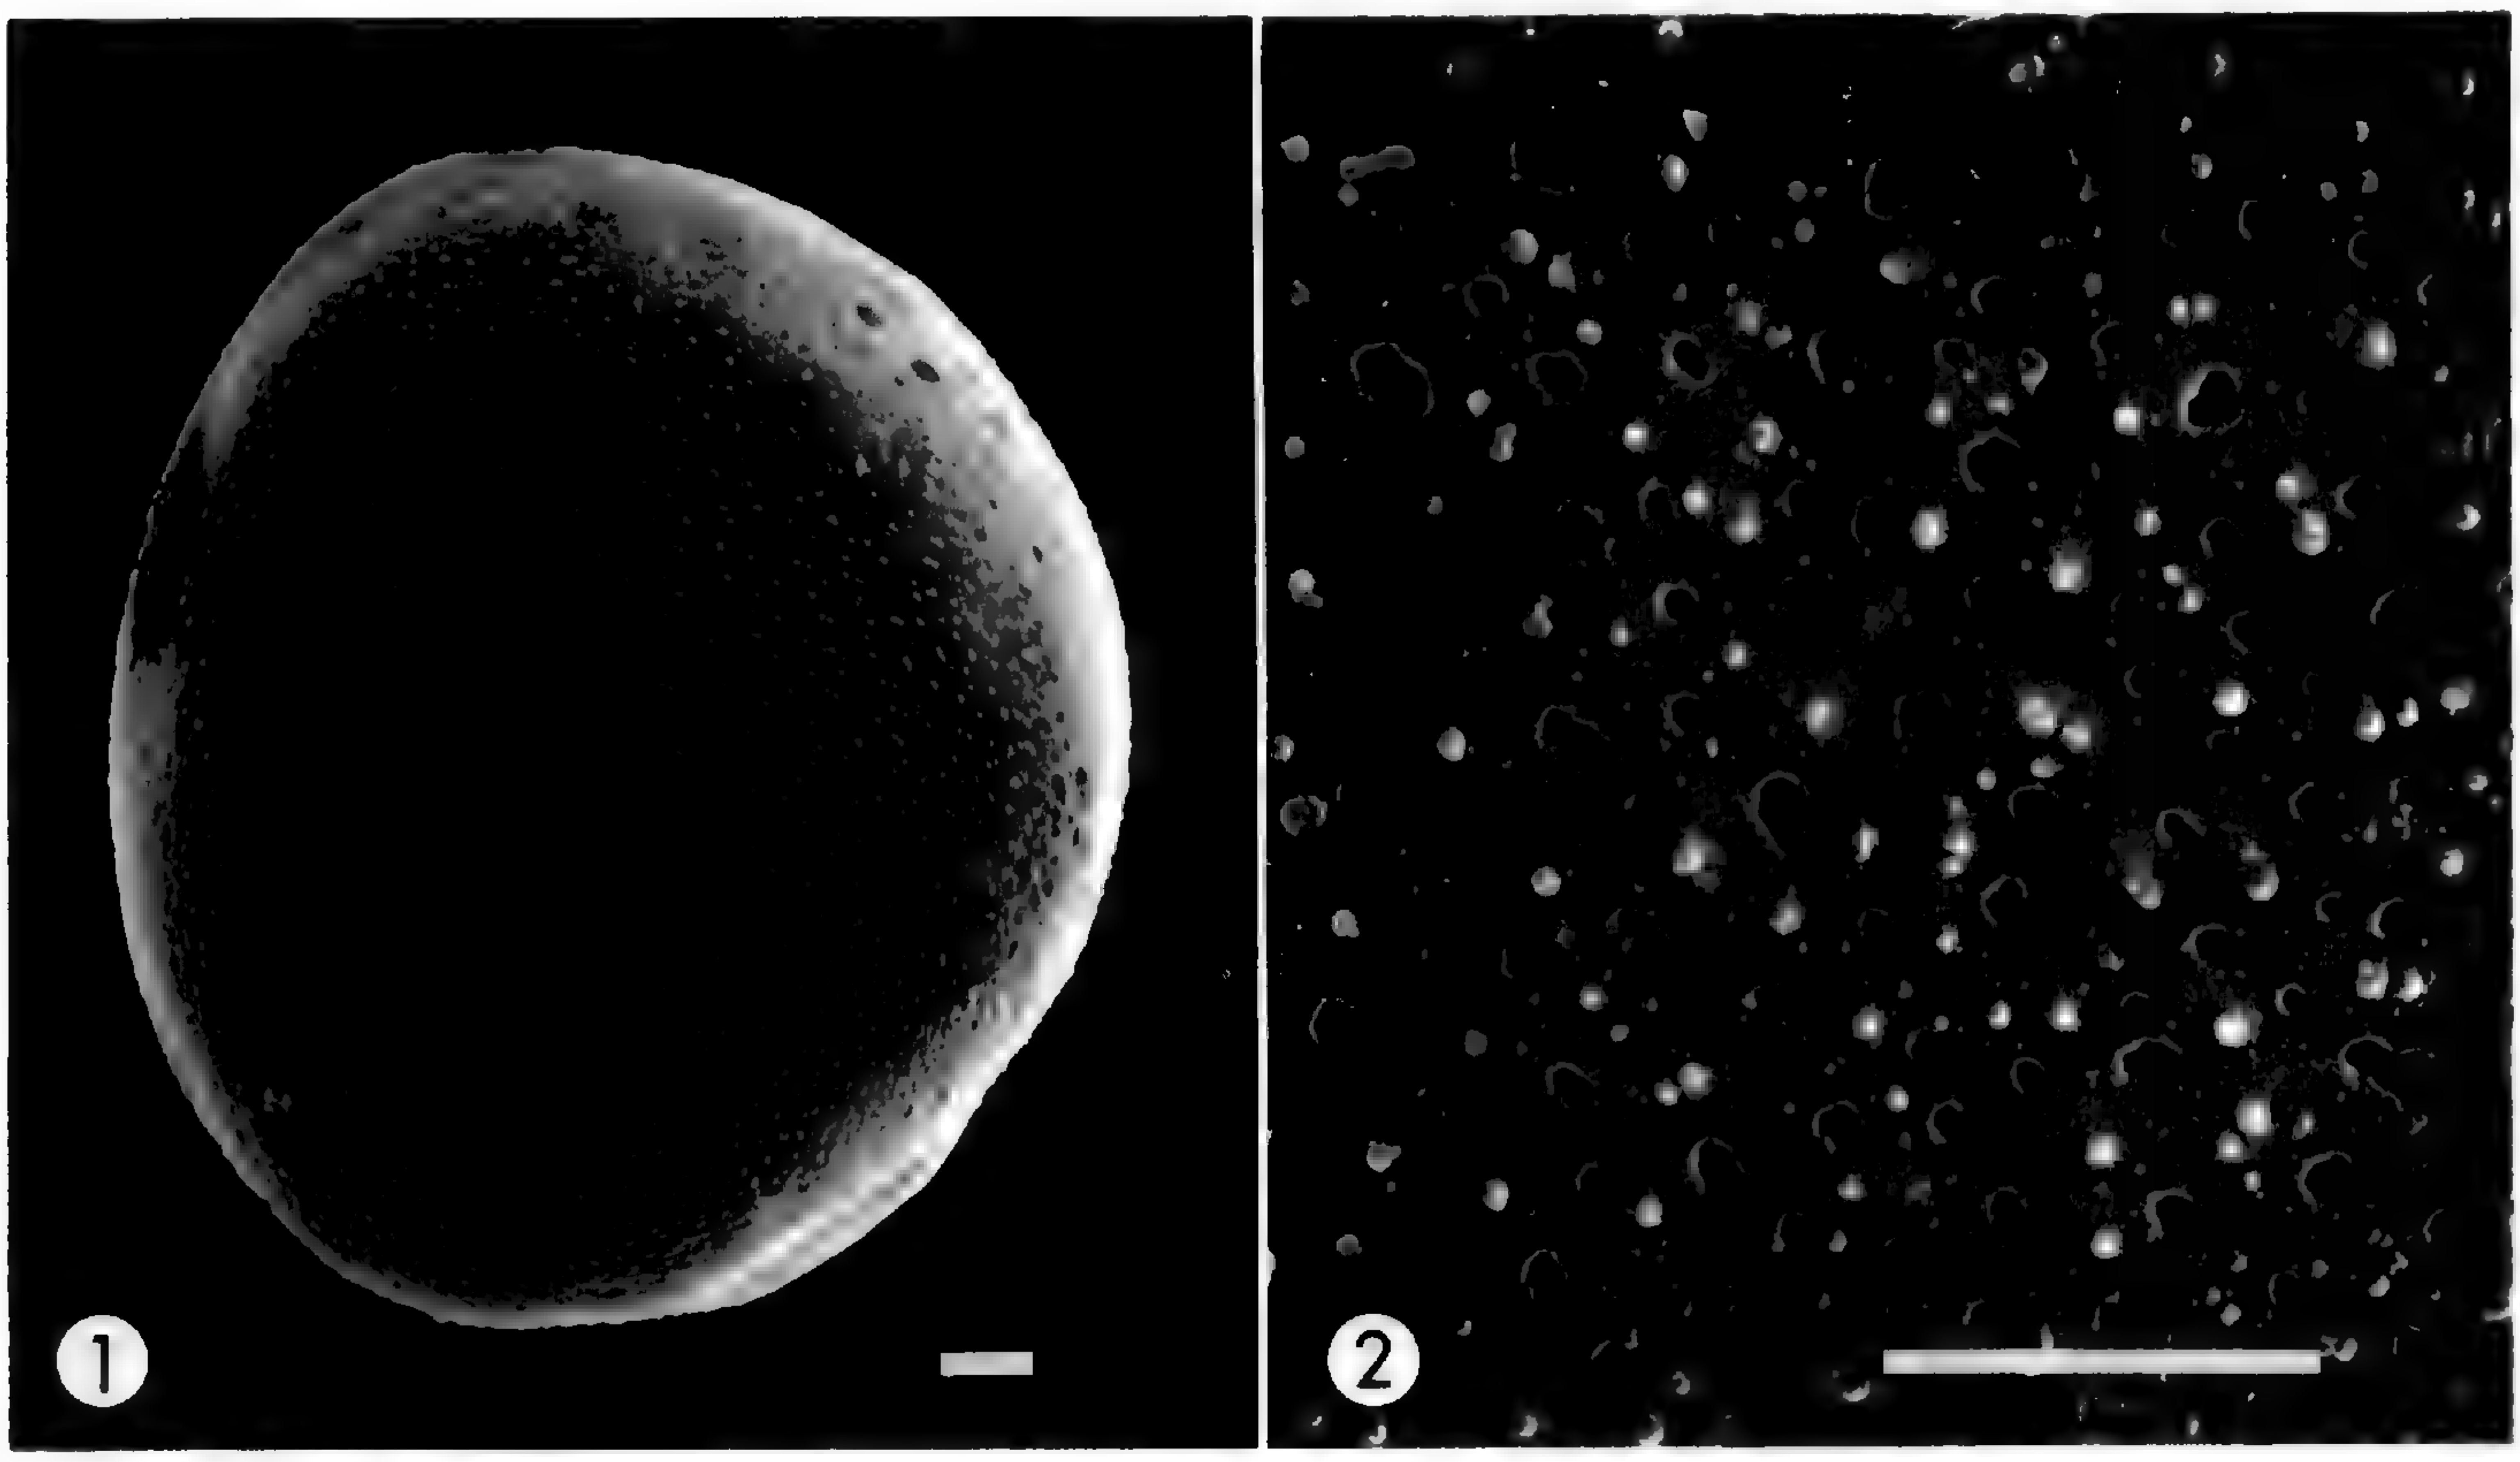

FIGURE 1, 2. *Scanning electron micrographs of* Pillansia templemanii.—*1. Whole grain in equatorial view ×1,200.—2. Detail of the exine surface ×6,000. Scale bars = 5 µm.*

until now been unknown, and it is important to establish whether it has the basic reticulate (to retipilate) exine of most Iridaceae (Schulze, 1971) or the specialized micropunctate and micropapillate exine characteristic of Ixioideae (Schulze, 1970, 1971).

METHODS

Pollen of *Pillansia templemanii* (Baker) L. Bolus was extracted from flowers from herbarium specimens (voucher: *Bolus s.n.*, MO 2080184) and subjected to standard acetolysis treatment (Erdtman, 1960). Acetolyzed pollen was mounted on aluminum stubs, gold coated, and viewed in a Hitachi S-450 scanning electron microscope.

OBSERVATIONS

Pollen of *Pillansia* is 65–75 µm long (polar axis as measured from scanning electron micrographs), ellipsoid to widely ellipsoid (Fig. 1), and monosulcate with the sulcus running the length of the grain. The exine is densely micropunctate (punctitegillate of some authors) and micropapillate (Fig. 2). The pores in the tectum are round to irregular in shape and 0.15–1 µm in diameter. There are ca. 50 pores/100 µm². The papillae are small, mostly rounded excrescences, and up to 0.4 µm in diameter and height. They are scattered fairly regularly with a density of ca. 52/100 µm² between the pores.

DISCUSSION

Pillansia differs from all other Ixioideae in its paniculate inflorescence and leaves lacking a distinct central vein or central cluster of veins, both unspecialized conditions. Other Ixioideae have a spicate inflorescence or one believed to be derived from a spike (flowers solitary on branches or flowers sessile in a corymbose panicle) and have distinct (or more or less distinct) central veins. *Pillansia* differs further from other Ixioideae in leaf anatomy (P. Rudall, pers. comm.) by having isodiametric to longitudinally elongated mesophyll cells and epidermal cells with nearly straight walls and one or no papillae. Other Ixioideae have transversely elongated mesophyll cells and epidermal cells with sinuous walls and two or more papillae.

The pollen of *Pillansia* clearly matches that of other Ixioideae, which lends further support for its retention in that subfamily. In a survey of pollen morphology in 21 of the 45 genera of Ixioideae, Schulze (1970, 1971) found that 20 have micropunctate exines. Only *Micranthus* is reported to deviate, having the retipilate exine characteristic of the other subfamilies. Schulze's observations have been confirmed by SEM studies by de Vos (1974a, b, 1982) for *Syringodea*, *Duthieastrum*, and *Tritonia*, and by Straka & Friedrich (1984) for a Malagasy species of *Gladiolus* (as *Geissorhiza*). Pollen morphology provides no additional evidence for the relationships of *Pillansia* within Ixioideae—it remains a puzzling isolated and apparently relictual genus. Its unusual combination of features suggests that it may represent a link between Ixioideae and the remaining Iridaceae and could, it fact, be very close to the ancestral type of Ixioideae.

It now seems all but certain that micropunctate exine is basic for Ixioideae, and the presence of retipilate exine in *Micranthus*, an apparently typical member of the subfamily, is surprising, particularly as the closely allied *Thereianthus* is reported to have micropunctate exine. This may represent an example of a reversal to an ancestral condition, but pollen of all three species of *Micranthus* should be critically reexamined.

EIGHT NEW SPECIES AND ONE NEW COMBINATION OF NEOTROPICAL LAURACEAE[1]

Henk van der Werff[2]

ABSTRACT

*Work in progress on the systematics of neotropical Lauraceae had yielded several undescribed species. In this contribution, eight species (*Aiouea obscura *van der Werff,* Aiouea vexatrix *van der Werff,* Caryodaphnopsis cogolloi *van der Werff,* Licaria velutina *van der Werff,* Nectandra mirafloris *van der Werff,* Persea pajonalis *van der Werff,* Phoebe elegans *van der Werff, and* Pleurothyrium hexaglandulosum *van der Werff) are described, illustrated, and discussed. A new combination,* Ocotea erectifolia *(Allen) van der Werff is made.*

Lauraceae are a large tropical family of trees and shrubs with the number of species in the New World estimated at 700–800. The taxonomy of the neotropical Lauraceae is poorly understood, and the entire family needs much work. The facts that many Lauraceae have small, inconspicuous flowers and are not frequently collected, that the genera are poorly defined, and that many species are known only from a few poor specimens have rendered the family almost inaccessible for the nonspecialist. Recent collections have shown that quite a few very distinct species await descriptions. In this contribution, eight species, mostly belonging to the smaller and relatively better-known genera, are described and discussed. A new combination is made and its synonymy given.

Aiouea obscura van der Werff, sp. nov. TYPE: Costa Rica. Puntarenas: along highway from Palmar Norte to Chacarita, ca. 2 km N of Chacarita. Tree, 10 m. Flowers pale green. *B. Hammel, M. Grayum & G. de Nevers 15197* (holotype, MO; isotypes, BM, CR, F, MEXU, NY, PMA, U). Figure 1.

Arbor, 10 m. Ramuli graciles, teretes, glabri. Gemma terminalis glabra. Folia alterna, anguste elliptica, basi apiceque acuta, 15–18 × 3–4 cm, membranacea, subtriplinervia, brochidodroma, in sicco olivacea; nervi laterales 2–3. Venatio super parve elevata, subtus magis elevata. Domatia plerumque in axillis nervorum lateralium basalium. Petioli teretes, glabri, 1–1.5 cm longi. Inflorescentiae axillis bractearum deciduarum super partem foliiferam, 15 cm longae, graciles. Pedicelli 8–10 mm longi. Tepala 6, aequalia, glabra, ca. 2 mm longa, late elliptica. Stamina 9, 2-locellata; 6 exteriora introrsa, ca. 1 mm longa, anthera parum latiore quam filamento, apice antherae locellos excedenti, filamento pubescenti; 3 interiora extrorsa, ca. 1.2 mm longa, apice locellos excedenti. Glandulae magnae, ca. 0.4 mm diametro, parum super basem affixae. Staminodia non visa. Ovarium glabrum, ovatum, ca. 1 mm longum, sensim in stylo brevi attenuatum. Fructus ignotus.

Tree, 10 m tall. Twigs slender, terete, glabrous. Terminal bud glabrous. Leaves alternate, narrowly elliptic, the base and tip acute, 15–18 × 3–4 cm, membranaceous, subtripliveined, the basal veins reaching ± ⅔ to the apex, the other 2–3 pairs of lateral veins in the upper half of the lamina, the lateral veins all curving toward the apex and loop-connected, drying olive green. Venation and reticulation slightly raised on upper surface, slightly more so on the lower surface. Domatia often present in the axils of the large lateral veins. Petioles terete, glabrous, 1–1.5 cm

---

[1] *I thank the various botanists working in Mexico, Panama, and Colombia for their often excellent collections, sent to me for identifications. Their work is essential for a better understanding of the Lauraceae. Dr. W. Burger commented on parts of the manuscript. Dr. J. Dwyer kindly checked the Latin descriptions. John Myers made the illustrations. Loans from BR, F, G, and NY are gratefully acknowledged.*

ANN. MISSOURI BOT. GARD. 75: 402–419. 1988.

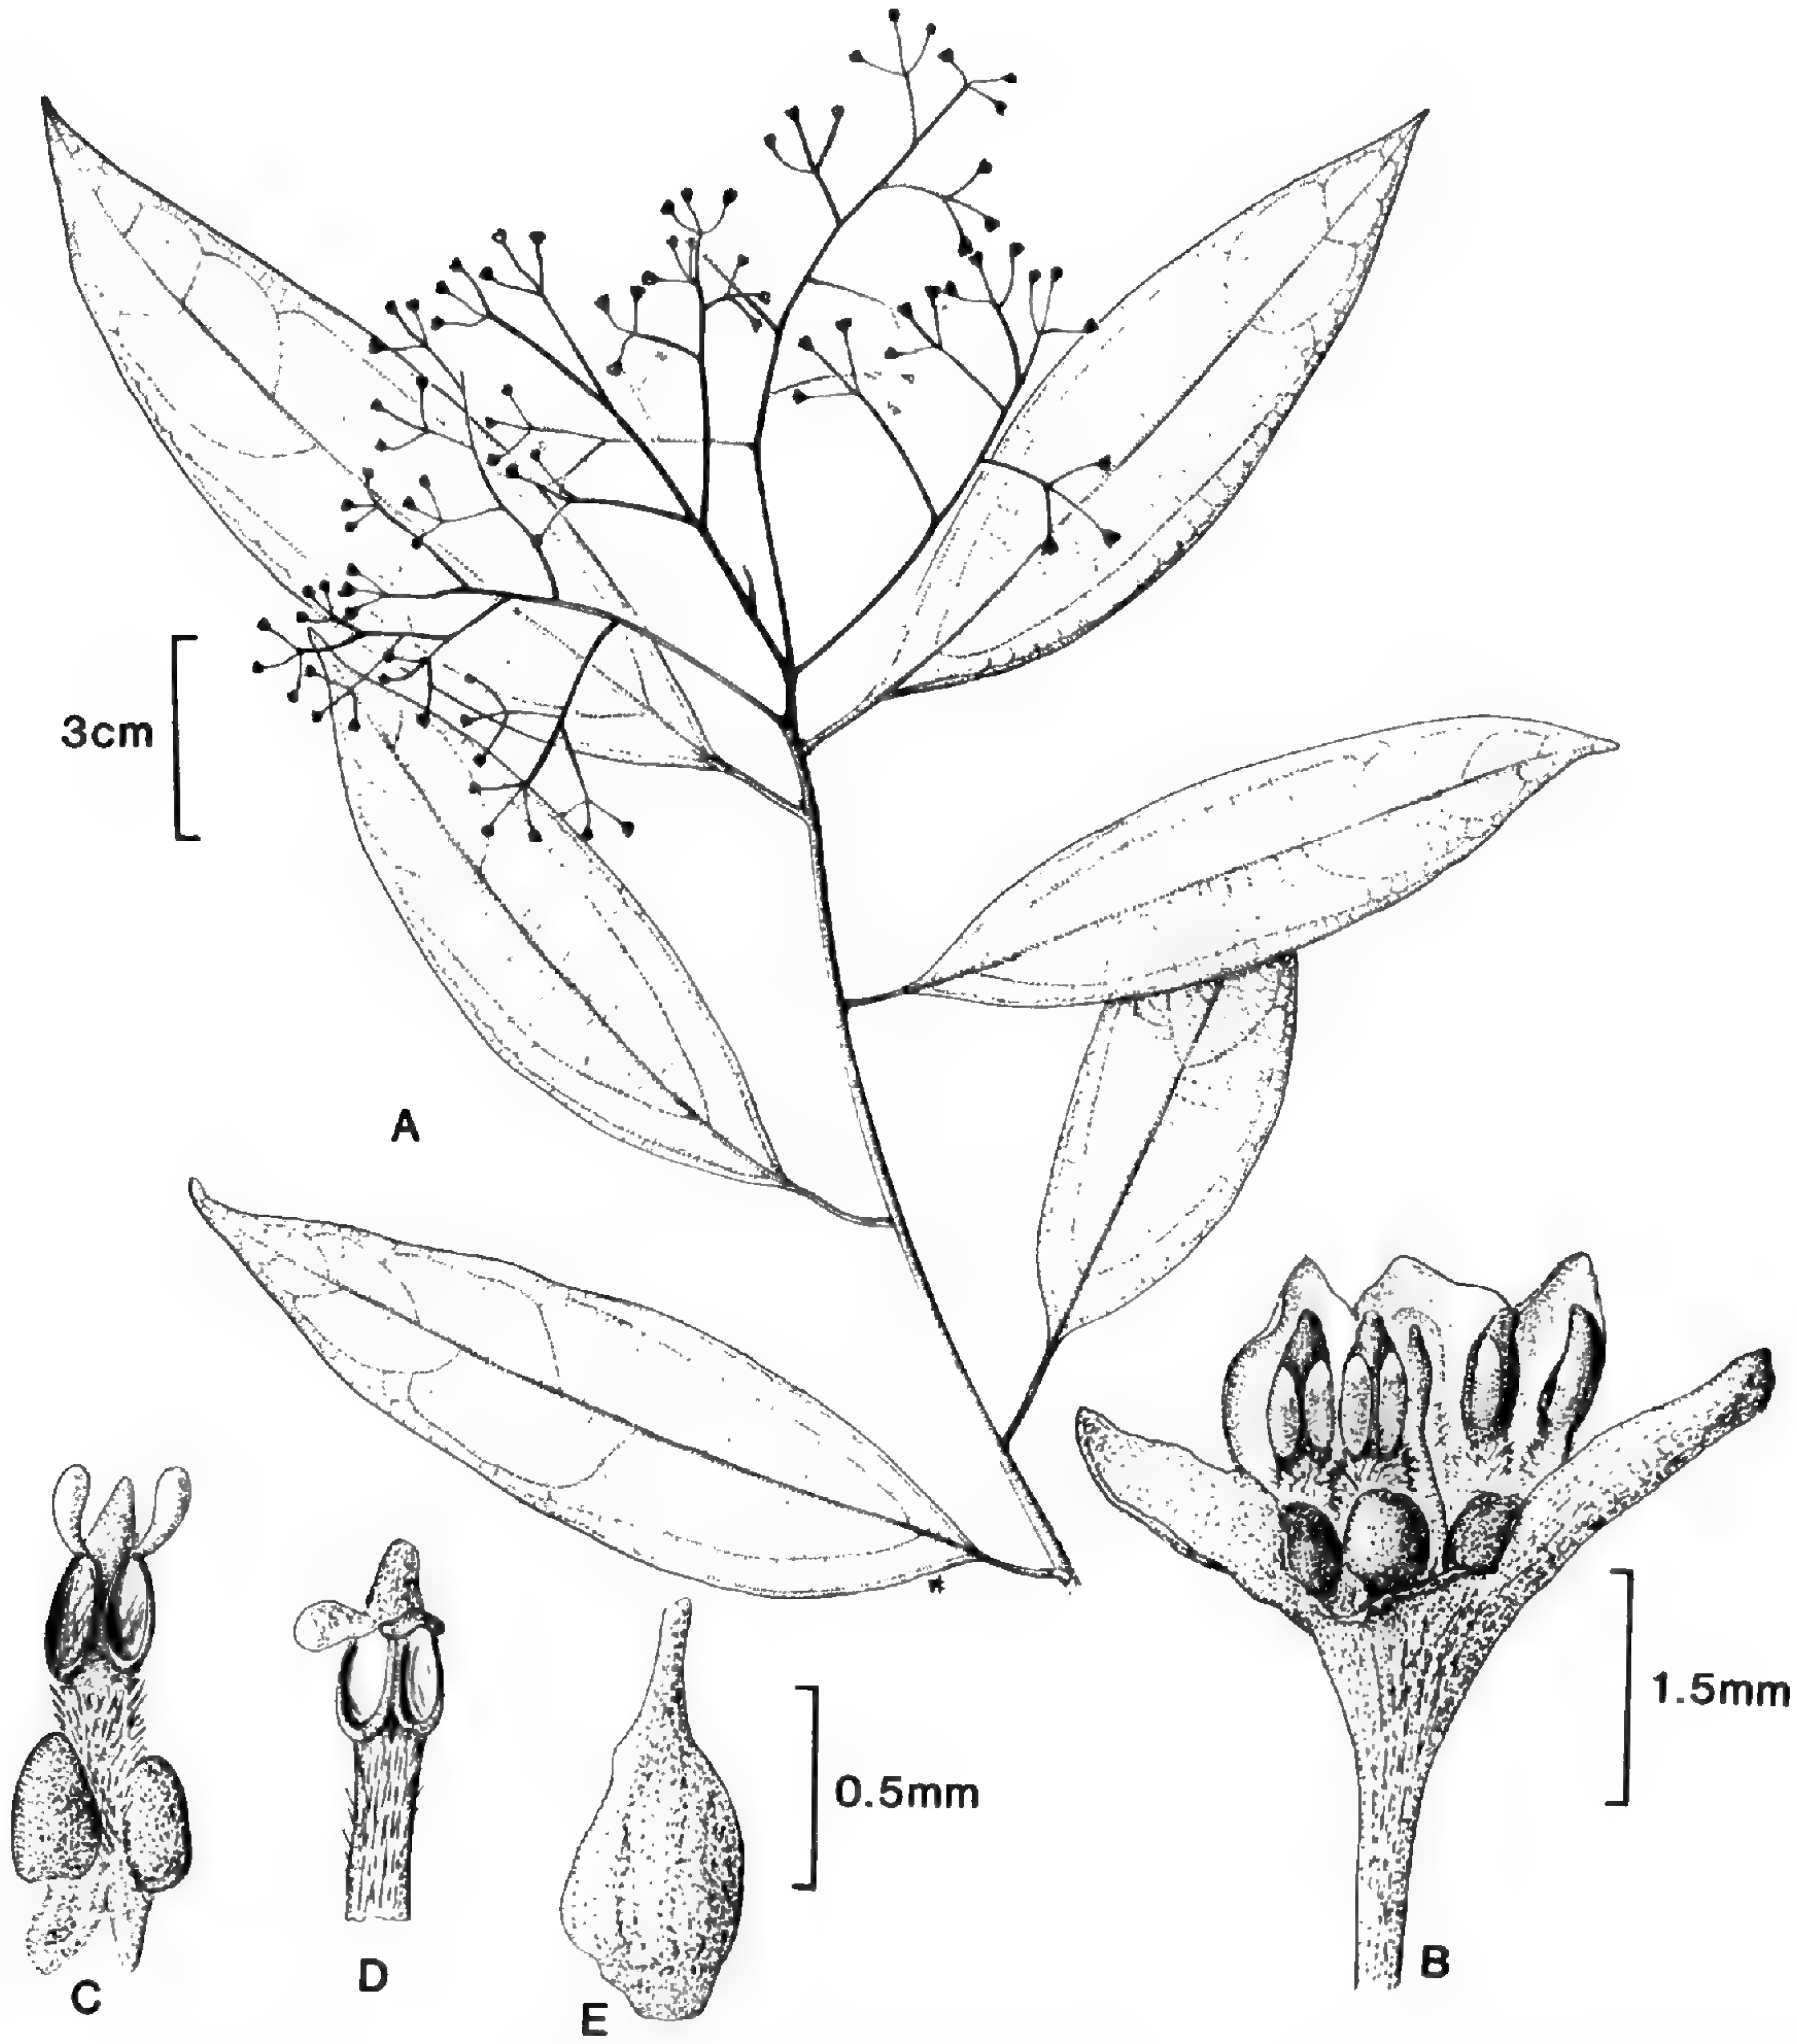

FIGURE 1. Aiouea obscura.—*A. Flowering branch.—B. Flower.—C. Inner stamen with basal glands.—D. Outer stamen.—E. Ovary.*

long. Inflorescences above the leaf-bearing part of the twigs, in the axils of deciduous bracts; terminal buds inconspicuous but always present above the lateral inflorescences. Inflorescences glabrous, to 15 cm long, slender, paniculate. Flowers pale green. Pedicels 8–10 mm long. Tepals 6, equal, glabrous, 2 mm long, broadly elliptic. Stamens 9, 2-celled; the outer 6 introrse, ca. 1 mm long, the anther slightly wider than the filament, the tip of the anther protruding beyond the anther cells, the filaments pubescent; inner 3 stamens extrorse, ca. 1.2 mm long, the glands large, ca. 0.4 mm diam., attached slightly above the base of the filaments, reaching the upper part of the filaments, leaving the anthers exposed but shielding the ovary; connective tissue also protruding beyond anther cells. Staminodia not seen. Ovary glabrous, ovate, ca. 1 mm long, gradually narrowed into the short style. Fruit unknown.

Aiouea obscura is only known from the type collection. Characteristics are laxly flowered inflorescences, relatively long pedicels, and dark-drying, subtriplivelned leaves with loop-connected lateral veins. It resembles closely several other dark-drying Lauraceae with membranaceous leaves and lax inflorescences, such as *Ocotea tenera* Mez & J. D. Smith (known from Costa Rica) and *Phoebe glabra* van der Werff (southern Mexico).

Aiouea obscura differs from both species in having two-celled anthers; from *O. tenera* it differs further in having subtripliveined leaves and from *P. glabra* in having narrower leaves with less prominently raised reticulation. None of the other Central American species are similar to *A. obscura*. These observations re-emphasize that our current generic concepts place seemingly closely related species in different genera and that these concepts urgently need re-examination.

Aiouea vexatrix van der Werff, sp. nov. TYPE: Panama. Panamá: Cerro Campana, above Capira, elev. ca. 900 m, 8°40'N, 79°50'W. Slender treelet, 3 m tall. Stem with small red ants in center. Perianth green. *McPherson 9226* (holotype, MO). Figure 2A–G.

Frutex vel arbor parva, ad 7 m. Ramuli juvenales angulati, minute fusco-puberuli, vetustiores teretes glabrique. Ramuli fistulosi frequenter formicis habitati. Petioli ad 1.5 cm longi, glabri vel minute puberuli. Folia alterna, in sicco atro-olivacea, glabra, chartacea, elliptica, basi apiceque acuta, 13–27 × 5–9 cm, super costa nervisque immersis, reticulatione parve elevata, subtus costa nervisque elevatis. Nervi laterales utroque costae latere 6–8. Inflorescentiae axillares, glabrae vel minute puberulae versus basim, ad 9 cm longae; ramuli inflorescentiarum complanati in sicco. Flores in vivo virides, ad 3 mm longi. Tepala 6, aequalia, glabra, erecta per anthesin, late ovata, 2 mm longa, 1.7 mm lata. Stamina 9, 2-locellata, glabra, inclusa, 6 exteriora introrsa, 3 interiora extrorsa filamentis quam antheris angustioribus. Staminodia nulla. Ovarium glabrum, ellipsoideum, sensim in stylo attenuatum. Infructescentiae ad 7 cm longae. Cupula ca. 8 mm diametro, tepalis in margine cupulae persistentibus, pedicello paulatim in cupula dilatato. Fructus ellipsoideus, ad 2 cm longus, fere omnino exsertus.

Shrub or small tree, 5(–7) m tall. Leafy twigs angular, minutely brownish puberulous, becoming round and glabrous on older parts; twigs consistently hollow and with pores giving access to the hollow center; often ants present in the hollow twigs (fide collectors). Terminal bud small, with very fine, copper-colored pubescence. Petioles to 1.5 cm long, minutely puberulous or glabrous, the lamina decurrent as narrow ridges. Leaves drying dark olive green, rarely gray-green, glabrous, chartaceous, elliptic, rarely slightly obovate, the base and apex both acute, 13–27 × 5–9 cm, the upper surface with immersed midrib and lateral veins, the final reticulation slightly raised; lower surface with midrib and lateral veins elevated, the final reticulation less elevated. Lateral veins 6–8 pairs. Inflorescences axillary, often seemingly terminal, glabrous or with some minute puberulence especially near the base, 6(–9) cm long, the branchlets not terete, these flattened after drying. Flower glabrous, ca. 3 mm long, on pedicels to 3 mm long; tepals 6, equal, glabrous, erect at anthesis, broadly ovate, ca. 2 mm long, 1.7 mm wide. Stamens 9, all 2-celled, the outer 6 introrse, the inner 3 extrorse. Outer stamens 1.5 mm long, the filament glabrous and ca. 0.6 mm long, the anther narrowly triangular, wider than the filament, ca. 0.9 mm long with a sterile apical section; anther cells large, ca. 0.3 mm long. Inner stamens 1.5 mm long, the anther 0.8 mm long, with sterile tip; filament slender with 2 large glands attached near the base. Glands collar-shaped, the basal part spreading horizontally, then abruptly curved inward and downward (toward the ovary), the tip of the gland flattened and resting on the upper part of the ovary. Staminodia lacking. Ovary glabrous, ellipsoid, ca. 0.8 mm long, largely sunken in the flower tube, at the tip gradually narrowed into the style, this 0.8 mm long. Infructescences to 7 cm long. Cupule ca. 8 mm diam., the tepals persistent on the rim, the pedicels gradually widened into the cupule. Fruit ellipsoid, ca. 2 cm long, almost completely exserted. Occasional stamens remaining attached to the cupule in late fruiting stage.

Aiouea vexatrix has a limited distribution

TABLE 1. *Diagnostic characters for* Aiouea vexatrix, Ocotea paulii, O. atirrensis, *and* O. nicaraguensis. *The numbers in parentheses given with the flowering and fruiting periods represent the number of collections examined.*

	Aiouea vexatrix	*Ocotea paulii*	*Ocotea atirrensis*	*Ocotea nicaraguensis*
Anthers	2-celled	4-celled	4-celled	4-celled
Cupule	tepals persistent	tepals deciduous	tepals deciduous	tepals persistent
Leaf color when dry	dark olive green	green	dark olive green	green
Leaf shape	elliptic	elliptic	obovate	obovate to oblanceolate
Leaf texture	thinly chartaceous	stiffly chartaceous	thinly chartaceous	thickly chartaceous
Length of inflorescence	½ leaf length or less	± equal to leaves	± equal to leaves	± equal to leaves
Flowering period	April–July (15)	October–January (11)	January–April (22)	
Fruiting period	July–November (20)	January–May (12)	April–September (13)	

in central Panama, where the abundance of collections indicates that it is common.

The placement of this new species in the genus *Aiouea* is provisional. The Central American species of *Aiouea* are quite different morphologically from the South American species, which include the type of the genus (van der Werff, 1984, 1987). *Aiouea vexatrix* is another example of such an aberrant *Aiouea* species. It has the following characters unusual for *Aiouea*: lack of staminodia, short inflorescences with flattened axes, dark olive green leaves, and persistent tepals on the cupule. It is included in *Aiouea* solely because of its hermaphrodite flowers with nine two-celled stamens and because it does not agree with the other, much better defined genera with nine two-celled stamens (*Aniba, Beilschmiedia, Cryptocarya, Kubitzkia, Phyllostemonodaphne, Urbanodendron*). As discussed below, *A. vexatrix* is probably related to *Ocotea*. The current circumscriptions of the neotropical genera of Lauraceae attach much importance to the number of cells of the anthers. This is an artificial character that obscures true relationships. However, discarding the present imperfect generic classification implies its replacement with a better classification, which I cannot offer at this moment. Therefore, I place this new species in *Aiouea*, a genus consisting of a group of closely related species in the lowlands of Venezuela, the Guianas, Brazil, and Paraguay, plus several unrelated species in the Andes and Central America. It is likely that the Andean and Central American species have been independently derived from *Ocotea* or *Nectandra* ancestors that lost two of their four anther cells.

Aiouea vexatrix is related to a group of *Ocotea* species that grow as shrubs or treelets, have angular (or almost winged), hollow twigs frequently inhabited by ants, flattened inflorescence branchlets, and glabrous flowers with erect tepals. The following names have been applied to these species: *Ocotea nicaraguensis* Mez, *O. paulii* Allen (Fig. 2H), *O. pedalifolia* Mez, *O. pentagona* Mez, *O. atirrensis* Mez & J. D. Smith and *O. wedeliana* Allen. Their distributions are in Panama, Costa Rica and Nicaragua. A survey of specimens at the Missouri Botanical Garden suggests that four species are involved, *A. vexatrix, O. paulii* (isotype, MO!), *O. atirrensis* (isotype, US!), and *O. nicaraguensis* (type W, probably destroyed; type photo, MO!). The main differences between these species are presented in Table 1. *Ocotea wedeliana* is known to me only from three isotypes (MAD, US, GH), all rather poor specimens from which one cannot draw firm conclusions. The flowers have four-celled anthers; the leaves are chartaceous and dry dark. A fruiting collection identified by Allen as *O. wedeliana* has the cupule of *O. paulii*, but thinner leaves.

The distributions of the four recognized species follow: *Aiouea vexatrix* is only known from areas rather close to Panama City (Pa-

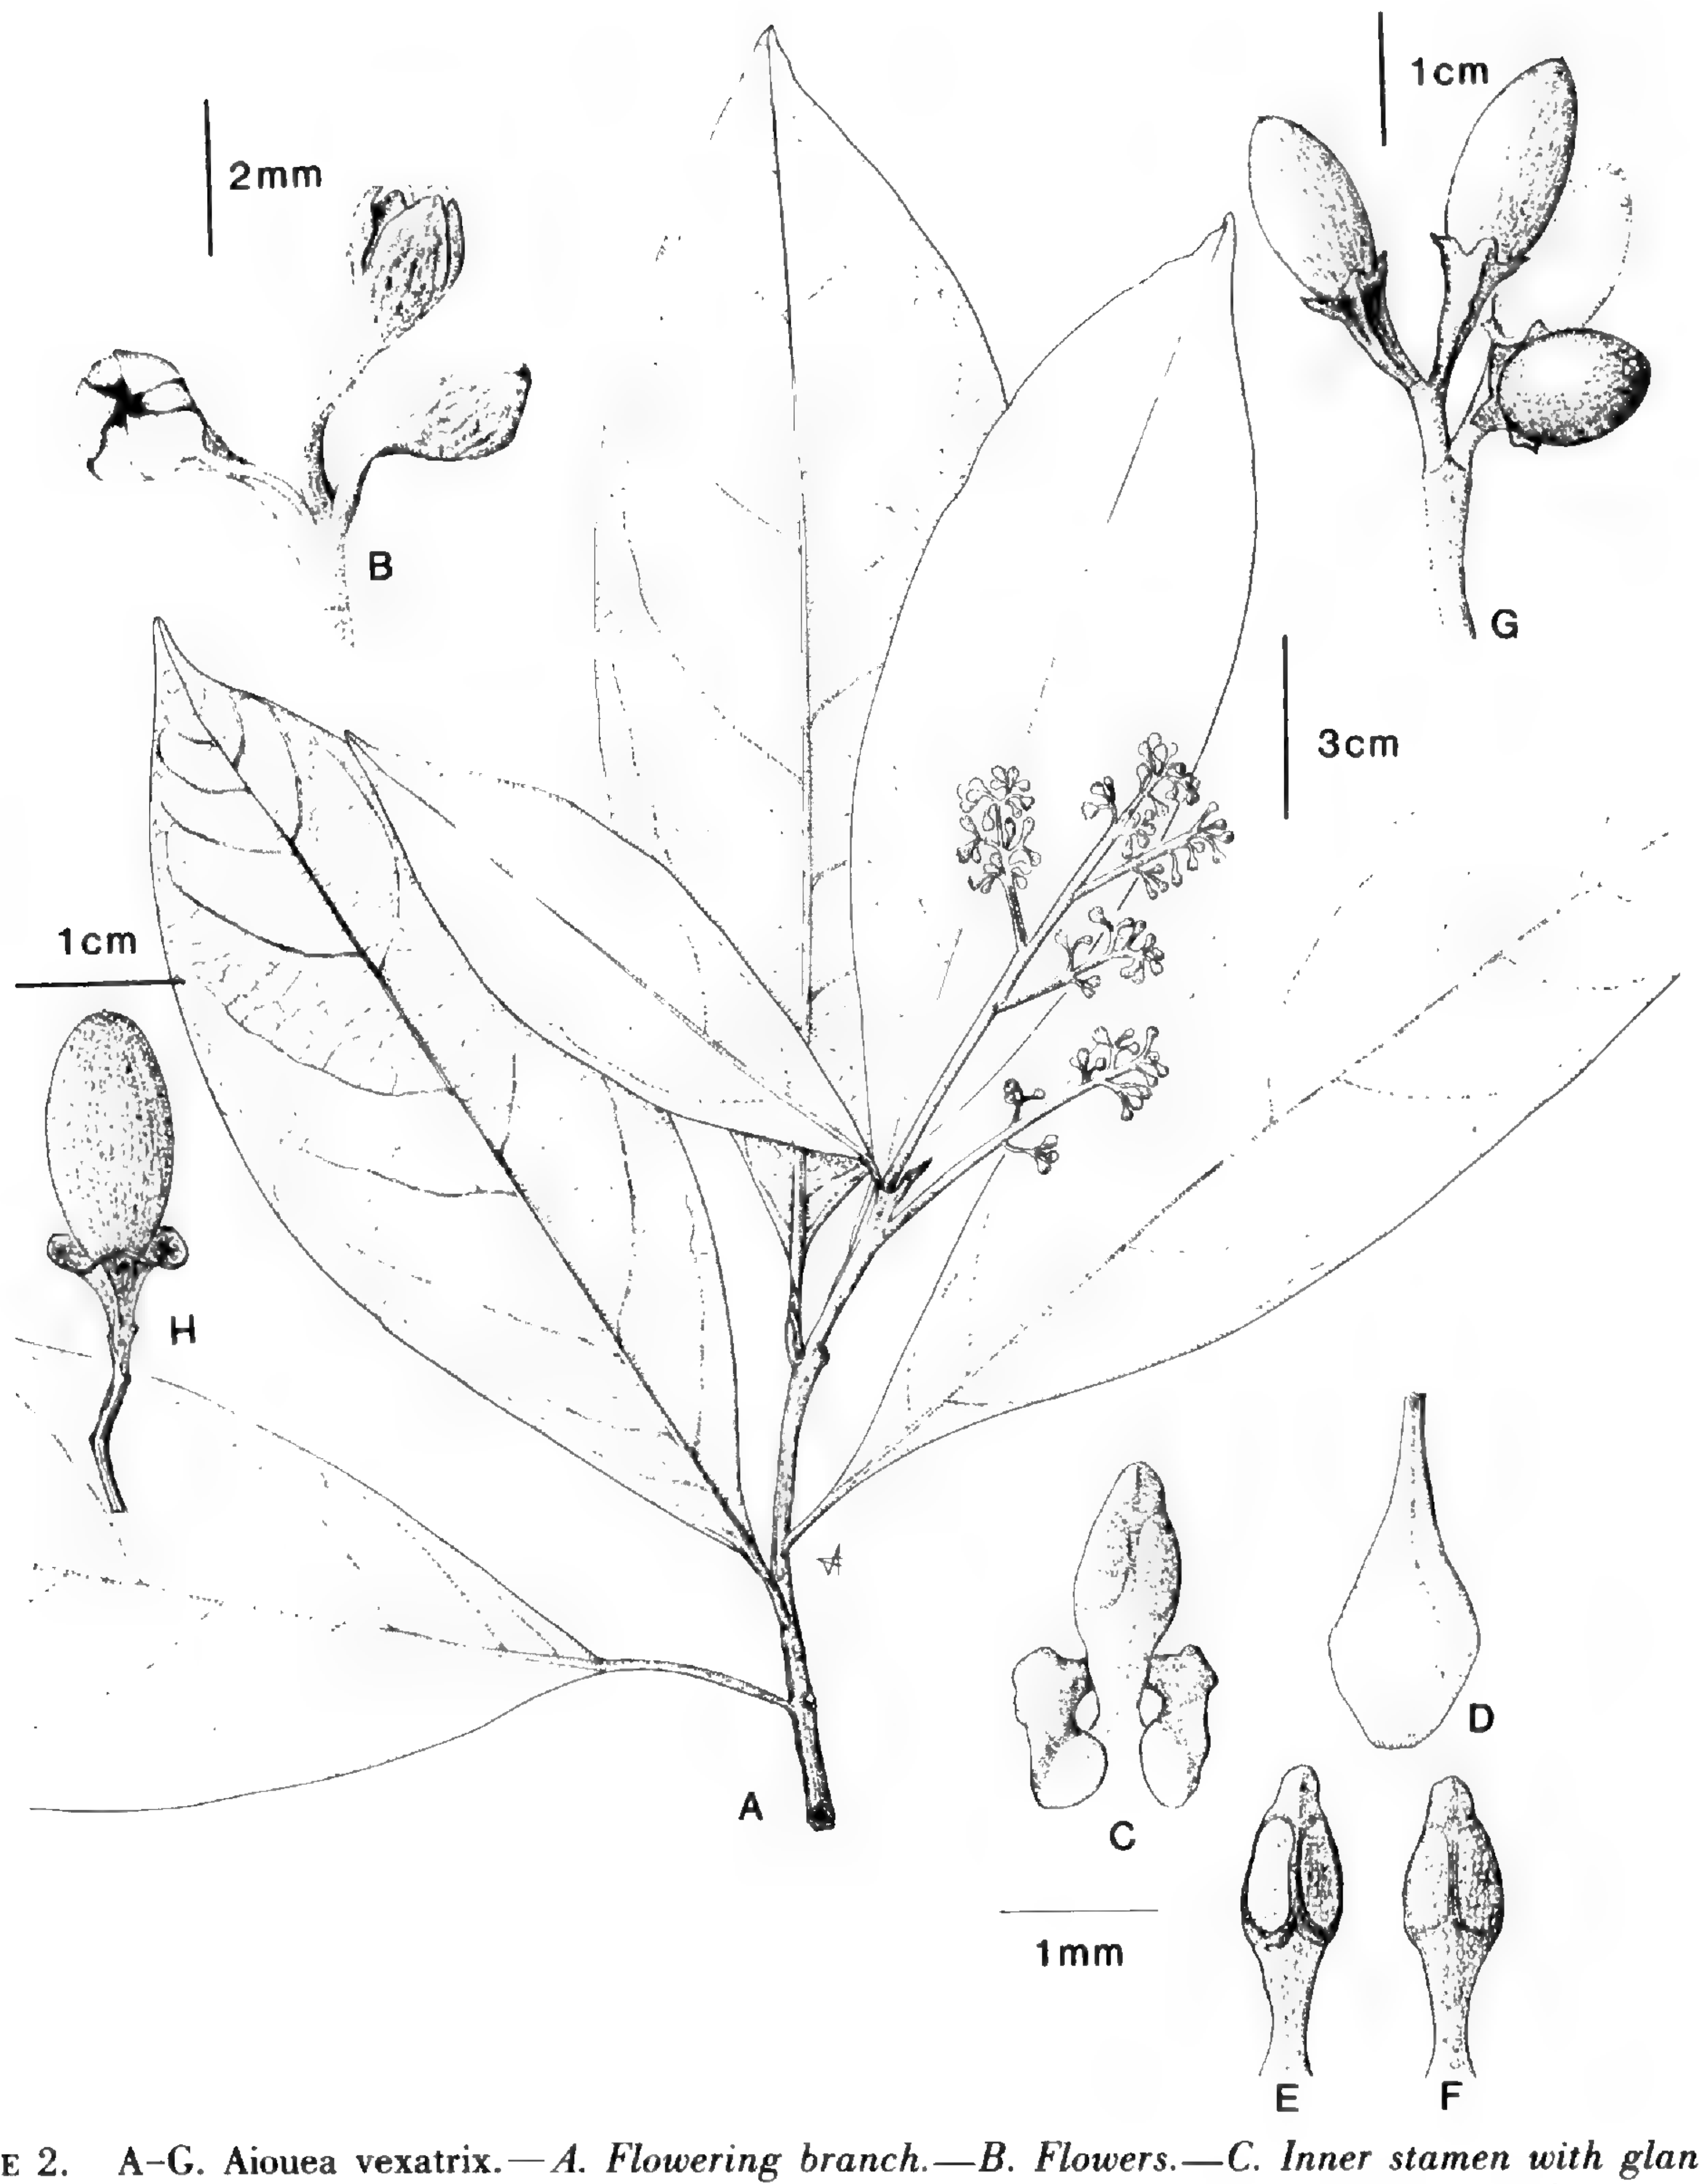

FIGURE 2. A–G. Aiouea vexatrix.—*A. Flowering branch.—B. Flowers.—C. Inner stamen with glands.—D. Ovary.—E, F. Outer stamens seen ventrally and dorsally.—G. Fruits.—H. Fruit of* Ocotea paulii.

namá, Colón, Comarca de San Blas). *Ocotea paulii* has a wider distribution in Panama (from Darién to Veraguas) and is uncommon in Costa Rica. It occurs with *A. vexatrix* on Cerro Campana, but no intermediates have been found there. Three collections, intermediate between *A. vexatrix* and *O. paulii*, are known from the western edge of the distribution of *A. vexatrix*. Both *Hammel 3557* (MO) and *Sytsma 4407* (MO) have leaf texture and color of *A. vexatrix*, flowers with four-celled anthers, and inflorescences longer than typical for *A. vexatrix*, but shorter than for *O. paulii*. *Allen 3439* (AA), identified as *O. wedeliana* Allen by Allen, has the thin leaves of *A. vexatrix* and cupule shape of *O. paulii*. These specimens, as well as the type of *O. wedeliana* Allen (US!, GH!, MAD!) are probably hybrids between *A. vexatrix* and *O. paulii*.

Ocotea atirrensis has been collected frequently in Costa Rica, but I have seen only two collections from Panama, both from Bocas del Toro. No intermediates between *O. atirrensis* and *O. paulii* are known to me. *Ocotea atirrensis* is characterized by large, obovate, chartaceous leaves that dry dark green and have acuminate tips; its tepals are not persistent on the cupule.

Ocotea nicaraguensis includes *O. pentagona* (syntypes: *Biolley 7106, Tonduz 7613, 8362,* all BR!) and a syntype of *O. pedalifolia* (*Pittier 9172,* BR!). The other syntype of *O. pedalifolia* (*Pittier 9179,* BR!) is *O. atirrensis.* Not as well represented as the other species, *O. nicaraguensis* awaits more specimens for a better understanding. Diagnostic characters are the strongly angled stems and stiffly chartaceous, green-drying leaves with acute tips; the cupule is crowned with persistent tepals. The few collections do not indicate a well-defined flowering period. Its obovate to oblanceolate leaves are distinct from the other species. *Ocotea nicaraguensis* is known from Costa Rica and Nicaragua.

Old collections of *A. vexatrix* have been distributed as *O. subsericea* Standley and as *O. atirrensis* and may be present in other herbaria under these names.

Caryodaphnopsis cogolloi van der Werff, sp. nov. TYPE: Colombia. Antioquia: Municipio de San Luis, left bank of Río Claro, 325–500 m, 5°53′N, 74°39′W. Tree, 15–18 m, flowers yellow. *A. Cogollo & R. Borjo 2019* (holotype, JAUM, n.v.; isotype, MO). Figure 3.

Arbor, 30 m. Ramuli teretes, juniores minute ferrugineo-pubescentes, vetustiores glabrescentes. Folia opposita, decussata, venatione pinnata, nervis utroque costae latere 8–12. Laminae ellipticae, 15–20 × 5–8 cm, basi acuta, apice acuminata; super glabrae, venatione immersa; subtus glaucae, costa nervisque elevatis et minute ferrugineo-pubescentibus, nervis minoribus paucis pilis ferrugineis praeditis. Petioli teretes, 1.5–2 cm longi, minute ferrugineo-pubescentes. Inflorescenciae axillares, ramulis oppositis, pyramidato-paniculatae, foliis perbreviores, minute et dense ferrugineo-pubescentes. Flores flavi. Tepala 6, inaequalia; 3 exteriora anguste triangularia, ca. 1.5 mm longa, apicibus saepe recurvatis, minute pubescentia; 3 interiora anguste ovata, apicibus acutis recurvatisque, ca. 4 mm longa, minute pubescentia; stamina 9, 4-locellata; 6 exteriora ca. 2 mm longa, glabra, filamentis ca. 0.6 mm longis, antheris ca. 1.3 mm longis, locellis introrsis; 3 interiora ca. 2 mm longa, glabra, filamentis ca. 1.2 mm longis, basibus 2 glandulis globosis auctis, antheris ca. 0.6 mm longis, locellis extrorsis. Staminodia 3, glabra, apicibus dilatata. Ovarium globosum, ca. 0.5 mm diametro. Stylum gracile, ca. 1.2 mm longum. Fructus pyriformis, in sicco ca. 4 cm longus.

Tree, to 30 m tall. Twigs terete, the younger ones with minute, ferruginous pubescence, becoming glabrous with age. Leaves opposite, decussate, pinnately veined, lateral veins 8–12 pairs. Laminae elliptic, 15–20 × 5–8 cm, the base acute, the apex acuminate, the upper surface glabrous with immersed veins, the lower surface gray-glaucous, waxy, the midrib and lateral veins elevated and with minute, ferruginous pubescence, the smaller veins with few ferruginous hairs. Petioles 1.5–2 cm long, with minute ferruginous pubescence, terete. Inflorescences axillary, to 8 cm long, much shorter than the leaves, branched from the base, pyramidal-paniculate, minutely and densely ferruginous pubescent. Flowers yellow; pedicels 2–3 mm long. Tepals 6, unequal; the outer 3 narrowly triangular, ca. 1.5 mm long, the tip often recurved, minutely brown pubescent; inner three ca. 4 mm long, narrowly ovate, the tip acute and recurved, minutely brown pubescent. Stamens 9, all 4-celled, the outer 6 ca. 2 mm long, glabrous, filaments ca. 0.6 mm long; anthers ca. 1.3 mm long, the cells introrse; the inner 3 slender, glabrous, ca. 2 mm long, filaments ca. 1.2 mm long, with anthers ca. 0.6 mm long, the cells extrorse; the filaments with 2 rather small, globose, basal glands. Staminodia 3, glabrous, ca. 1 mm long, the tip widened. Ovary globose, ca. 0.5 mm diam., the upper part with brown hairs; style slender, ca. 1.2 mm long. Fruit avocado-shaped, ca. 4 cm long when dry.

Paratype. COLOMBIA. ANTIOQUIA: Municipio de San Luis, Río Claro, 350 m (fr), *A. Cogollo et al. 2195* (JAUM, MO).

Caryodaphnopsis cogolloi is known only from a small (± 2 km^2) forest remnant in the Magdalena Valley in Colombia. This forest patch is home to, based on collections by Cogollo, two other undescribed species of *Caryodaphnopsis* (known from fruiting material)

FIGURE 3. Caryodaphnopsis cogolloi.—*A. Flowering branch.—B. Detail of lower leaf surface.—C. Flowers.—D. Flower with several tepals removed, showing outer and inner stamens, staminodia, and ovary with slender style.—E. Outer stamen.—F. Inner stamen with basal glands.—G. Ovary.—H. Fruit.*

and two undescribed species of *Licaria*. This shows how poorly collected neotropical Lauraceae are.

Caryodaphnopsis cogolloi is closely related to *C. inaequalis* (A. C. Smith) van der Werff & Richter, a species known from the Peruvian–Brazilian border area. Both species have pinnately veined leaves, a rare character in *Caryodaphnopsis* (van der Werff & Richter, 1985). The two species differ as follows: *C. cogolloi* has four-celled anthers, outer tepals 1.5 mm long having acute, recurved tips, denser tomentum on the flowers, and a glaucous undersurface of the leaves. *Caryodaphnopsis inaequalis* has two-celled anthers, outer tepals ca. 0.5 mm long with blunt tips and not recurved, rather scarce tomentum on the flowers, and leaves green below.

Recent collections of *Caryodaphnopsis* show that the neotropical species fall into two groups. One group includes the species with pinnately veined (or subtripliveined) leaves and an avocado-shaped fruit (*C. cogolloi*, *C. inaequalis*, *C. theobromifolia*); the other group includes the species with strongly three-veined leaves (the basal lateral veins reach the leaf apex) and small, round fruits (*C. fosteri* and three or four undescribed species).

The new species is named after its collector, Alvaro Cogollo, who collected several undescribed species of Lauraceae in the Magdalena Valley in Colombia.

Licaria velutina van der Werff, sp. nov. TYPE: Mexico. Veracruz: Mpio. San Andres Tuxtlas, Cerro Vigía near Estación de Biología Tropical Las Tuxtlas, 300 m, tree 18 m with yellowish flowers, *G. Ibarra M. & S. Sinaca C. 100* (holotype, MEXU; isotypes, CHAPA, HBG, MO). Figure 4.

Arbor, 8–20 metralis. Ramuli obtuse angulati, lenticellati, juveniles albido-vel bubalino-velutini, veteres fusco-pubescentes. Folia alterna, anguste elliptica vel anguste ovata, apice basique acuta, 12–30 × 2.5—6.5 cm; glabrescentia, nervis lateralibus 10–14, venatione super immersa vel perobscure elevata, subtus costa manifeste elevata, nervis et venatione elevata. Petioli 1–2 cm longi. Inflorescentiae foliis perbreviores, paniculatae, in axillis bractearum deciduarum, ad 13 cm longae, immaturae velutinae, veteres pubescentes sparsiore. Flores pedicellis 2–4 mm longis, glabri, globosi vel late elliptici, ca. 2 mm longi, 1.5 mm lati; tepala 6, exteriora parum majoria interioribus, incurvata, ca. 0.3 mm longa, ca. 0.5 mm lata; stamina 3, 2-locellata, connata, ca. 1 mm longa, inclusa; locelli extrorsi, aperientes ad apicem antherarum. Glandulae staminum praesentes. Ovarium glabrum, ellipsoideum, sensim in stylum attenuatum, ca. 1.3 mm longum. Infructescentia ad 7 cm longa, plerumque solo fructu. Cupula cylindrica, ad 2 cm longa, 2.5 cm lata, 1.5 cm profunda margine simplici; fructus (in sicco) cupula ca. 1 cm longior.

Tree, 8–20 m tall. Twigs obtusely angled, with gray lenticels, the inflorescence-bearing part covered with white or yellowish velutinous pubescence, this changing to very short, brown pubescence on fruiting twigs. Leaves alternate, narrowly elliptic or narrowly ovate, the tip gradually acute or narrowly rounded, the base acute, 12–30 × 2.5–6.5 cm, when young with appressed pubescence, but soon glabrescent, with 10–14 pairs of lateral veins, the venation immersed or faintly elevated above, the midrib prominently raised below, the lateral veins and tertiary venation raised below. Petioles 1–2 cm long. Inflorescences much shorter than leaves, paniculate, in the axils of deciduous bracts, to 13 cm long; immature inflorescences velutinous; older inflorescences with sparser pubescence; bracts of the inflorescence with white pubescence on the outside, glabrous inside, ovate, ca. 2.5 mm long, deciduous at anthesis. Flowers on glabrous pedicels, these 2–4 mm long; flowers glabrous, globose or broadly elliptic, ca. 2 mm long and 1.5 mm wide; tepals 6, incurved, the outer 3 broader than the inner 3, ca. 0.3 mm long, 0.5 mm wide; fertile stamens 3, their tips just exposed; anther cells almost apical, small, opening toward the tip and extrorse. Stamens fully connate, forming a dome ca. 1 mm high and ca. 1.3 mm wide at the base; ovary globose, ellipsoid, gradually narrowed into style, ca. 1.3 mm long. Staminal glands 6, reduced to small flaps, ca. 0.3 mm tall, visible at the base of the anthers. Infructescences to 7 cm long, usually with only one fruit. Cupule deeply cup-shaped, 2 cm long, 2.5 cm wide, the cup ca. 1.5 cm deep with gray lenticels, rather thin, ca. 1 mm thick at the margin, not double-rimmed, often with dried stamens attached to the margin. Fruit to 1 cm longer than the cupule when dry, ovoid, ca. 2.5 cm long.

Common names. Laurel baboso, Laurel pimienta.

Paratypes. MEXICO. CHIAPAS: Mpio. Tecpatán, Colonia El Diamante, cerce del punto Trine de Chiapas–Tabasco–Vera Cruz, Aug. 1984 (fr), *Serrano B. & Rojas s.n.* (CHAPA, HBG, MEXU, MO). VERACRUZ: Mpio. San Andres Tuxtlas, Estación de Biología Tropical Las Tuxtlas (fr), *Calzada 178* (F, MO); same locality (fr), *Calzada 695* (F, MO); same locality, May 1981 (fr), *Gentry & Lott 32260* (MO); same locality, June 1981 (st), *Gentry & Lott 32521* (MO); same locality, April 1984 (fr), *Ibarra M. 1462* (CHAPA, HBG, MEXU, MO); same locality, lote 67, July 1984 (fr), *Ibarra M. & Sinaca C. 1916* (CHAPA, HBG, MEXU, MO); Laguna Escondida, 3 km NW of Estación Las Tuxtlas, 200 m, June 1985 (fl), *Sinaca C. 107, 110, 111* (CHAPA, HBG, MEXU, MO); Camino a Cárdenas, 4.5 km de la Estación Las Tuxtlas, June 1985 (fl), *Sinaca C. 114* (MO); lote 71, Estación Las Tuxtlas, 350 m, Aug. 1985 (fr), *Sinaca C. 207* (CHAPA, HBG, MEXU, MO); Estación Las Tuxtlas, June 1981 (fr), *Wendt et al. 3418* (CHAPA, CAS, LL, MEXU, MO).

Licaria velutina is closely related to *L. excelsa,* known from southern Mexico and Panama. *Licaria velutina* differs by having narrow leaves 4–6 times longer than wide, densely pubescent young twigs, less pubescent inflorescences, the pubescence contrasting with the glabrous flowers, and large cupules with simple margins (our fruiting material of *L. excelsa* shows always double-rimmed cupules). All collections of *L. excelsa* are from above 1,000 m elevation, whereas *L. velutina* is only known from elevations of 200–300 m.

Measurements and illustrations of stamens, staminal glands, and ovary are based on boiled parts, which shrink and change shape while drying.

Nectandra mirafloris van der Werff, sp. nov. TYPE: Nicaragua. Jinotega: Laguna de Miraflores, small tree at edge of swamp, 12 May 1976, 1,200 m, *Neill 329* (distributed by Seymour as no. *7204*), (holotype, MO). Figure 5.

Arbor parva, 2–8(–15) m. Ramuli modice appresse strigosi, glabrescentes, vetustiores lenticellati. Folia alterna, elliptica, firme chartacea, 15–20 × 7–10 cm, apice obtuse acuta, basi acuta vel obtusa; petioli 1–1.5 cm longi; laminae super nitidae, reticulatione elevata sed costa nervisque immersis, glabra; subtus opacae, leviter adpresse pubescentes, praesertim prope basim, domitiis axillaribus, costa manifeste elevata, nervis reticulationeque elevatis; nervi 6–9 jugi. Inflorescentiae in axillis foliorum vel bractearum deciduarum, foliis perbreviores; axes centrales adpresse pubescentes, ramuli pubescentia densiore, saepe albo-pubescentes. Flores pedicellati, extus dense albo-pubescentes; tepala 6, aequalia, basi connata, intus dense papillosa, ca. 3 mm longa; stamina 9, 4-loculata, 6 exteriora ca. 0.9 mm longa filamentis brevissimis, antheris quadrangularibus, locellis introrsis; 3 interiora ca. 1.2 mm longa, filamentis ca. 0.3 mm longis, 2 glandulis magnis munitis, locellis lateralibus; staminodia 3, ca. 0.8 mm longa, claviformia. Ovarium globosum, glabrum; stylus ovario perbrevior. Fructus late ellipticus, 2 × 1.5 cm, cupula parva, discoidea; pedicellus frugifer inflatus.

Small tree, 2–8(–15) m tall. Twigs gray, with small, appressed hairs, becoming glabrous, often developing lenticels after the first year. Leaves alternate, elliptic, firmly chartaceous, 15–20 × 7–10 cm, the tip bluntly acute, the base acute to obtuse, petioles 1–1.5 cm long, laminae shiny above, glabrous with raised reticulation, but with immersed midvein and lateral veins, these in 6–9 pairs, opaque below, these with some appressed short hairs (especially near the base) and frequently tufts of axillary hairs, the midvein prominently raised, the lateral veins and final reticulation raised. Inflorescences in the axils of persistent leaves or deciduous bracts, 6–12 cm long, paniculate, the main axis with some appressed pubescence, the branchlets with much denser pubescence, sometimes appearing white pubescent. Flowers pedicellate, the pedicels ca. 2 mm long, densely white-pubescent; tepals 6, all equal, united at their bases, densely white pubescent outside, densely papillose inside, ca. 3 mm long; stamens, 9, 4-celled, the outer 6 with a very short filament, appearing sessile, quadrangular, ca. 0.9 mm long, the anther cells introrse, occupying almost the entire anther and arranged ± in an arc, papillose; the inner 3 anthers ca. 1.2 mm long, with lateral anther cells, the filament ca. 0.3 mm long, each with 2 large glands near the base; staminodia present, club-shaped, ca. 0.8 mm long. Ovary globose, glabrous; style much shorter than ovary, glabrous. Fruit broadly ellipsoid, 2 × 1.5 cm, seated on a small, platelike cupule; pedicel swollen in fruit.

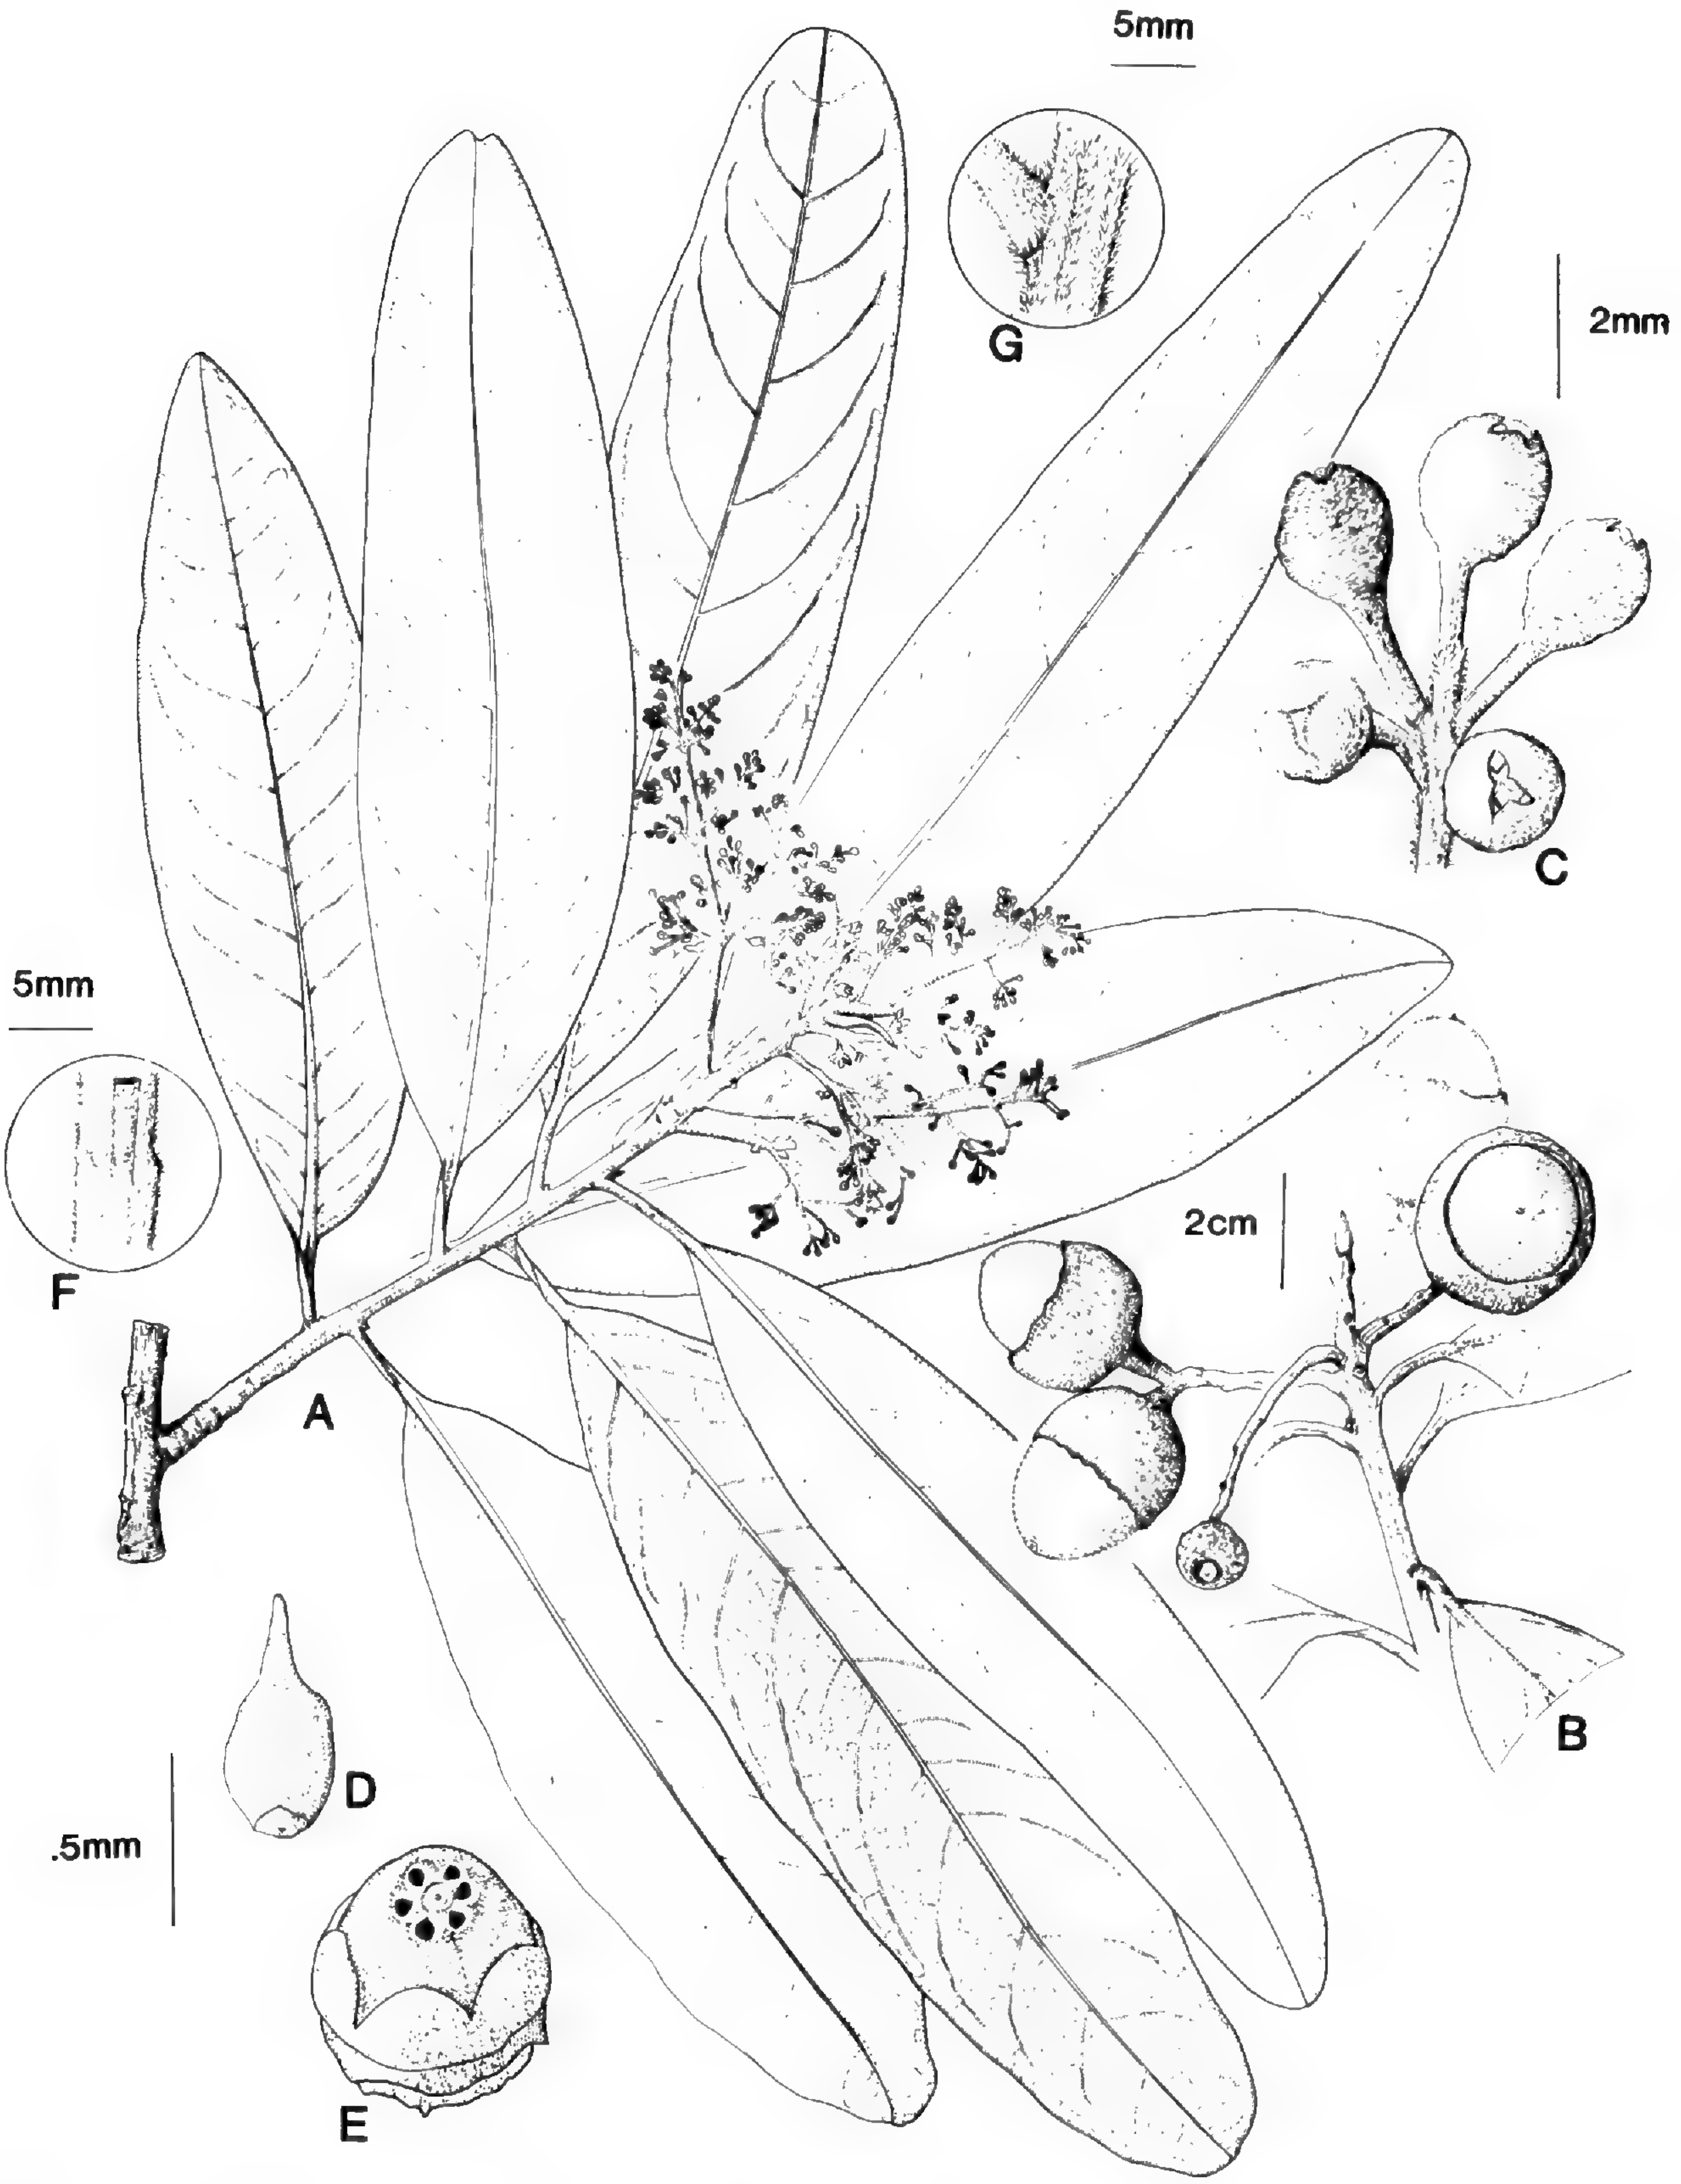

FIGURE 4. Licaria velutina.—*A. Flowering branch.—B. Fruits.—C. Flowers.—D. Ovary.—E. Flower with tepals removed, showing three two-celled stamens with fused filaments and lobe-shaped basal glands.—F. Detail of twig, showing pubescence.—G. Detail of inflorescence branch, showing pubescence.*

Paratypes. NICARAGUA. ESTELI: Laguna Miraflor, *Laguna 336* (MO); same location, *Moreno 19434, 21118, 8227* (MO); Cerro Quiabú, *Stevens 16918, 16247* (MO); same locality, *Grijalva & Araquistain 641* (MO); same locality, *Moreno 1309, 19266, 21185A* (MO); Mesas Plan Helado, 2 km from Laguna Miraflor, *Moreno 15846* (MO); El Chaparral, 1 km W of Laguna Miraflor, *Moreno 22382* (MO); Mesas Plan Helado, 21.5 km E of Esteli, *Moreno 15410* (MO). JINOTEGA: km 150 de la carretera Matagalpa–Jinotega, *Moreno 472* (MO); Laguna de Miraflores, *Neill 339* (MO) (distributed by Seymour as *Neill 7198*).

Nectandra mirafloris is only known from an area with cloud forest on the border of the

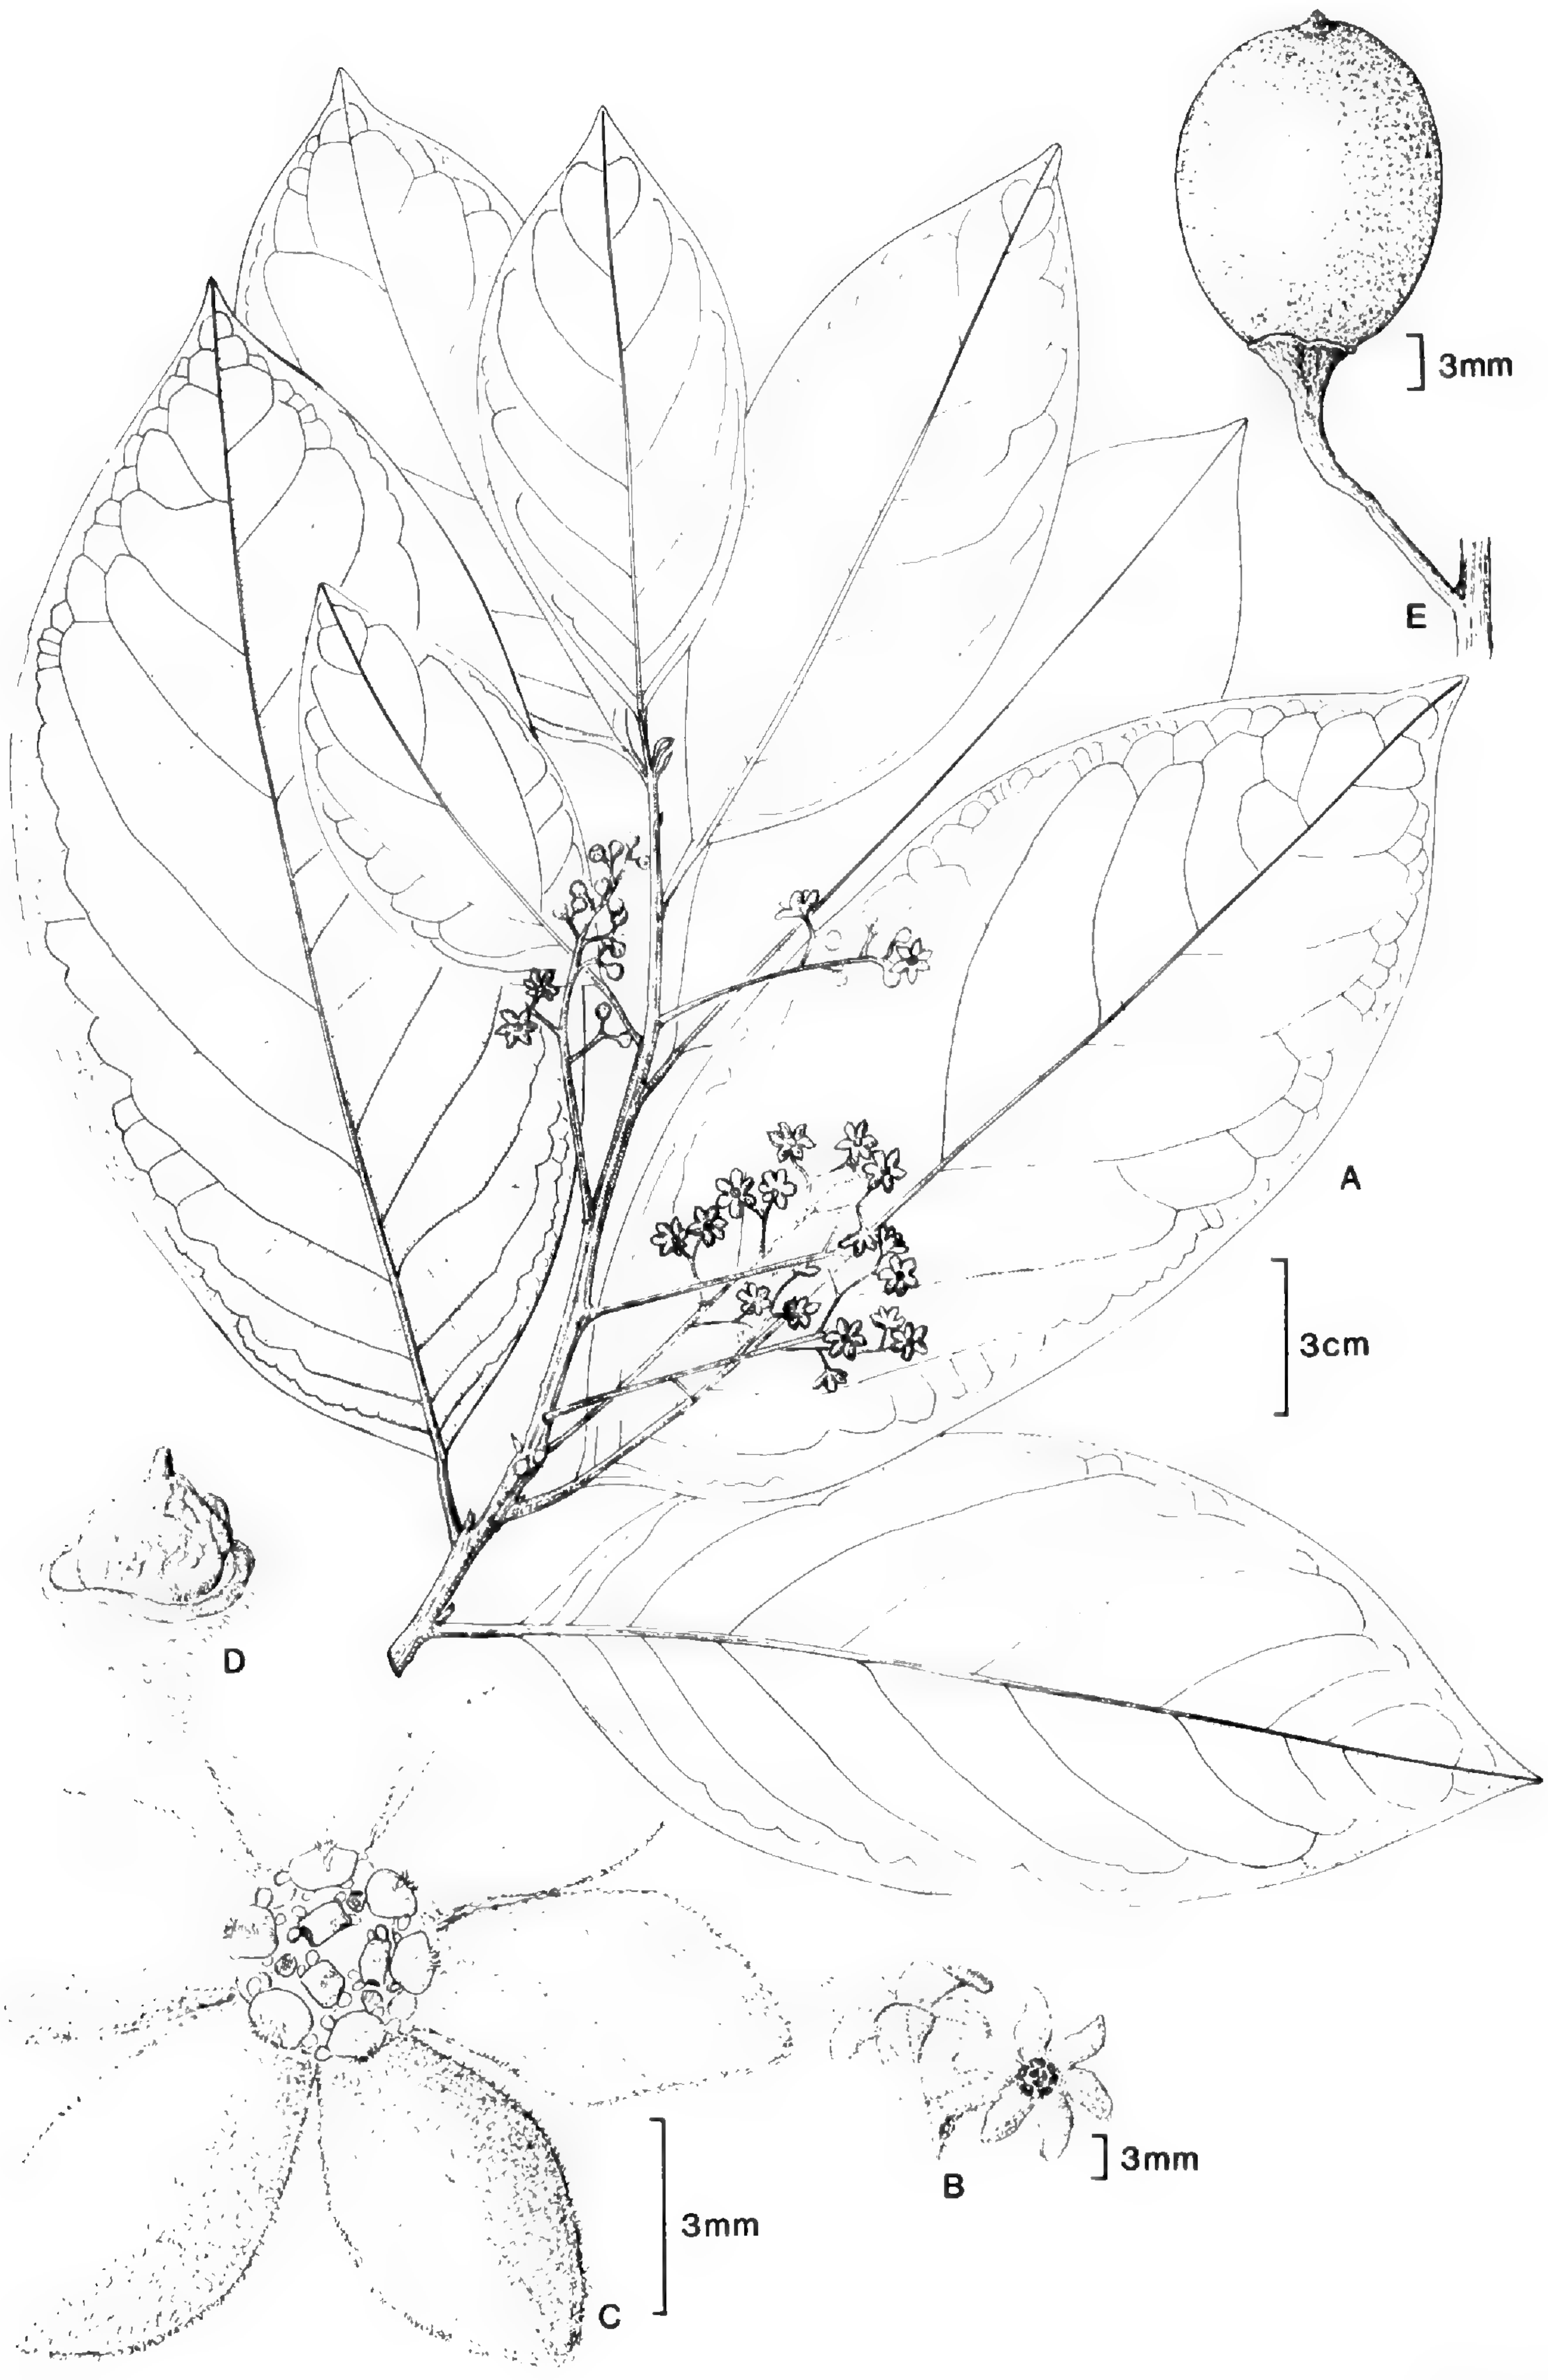

FIGURE 5. Nectandra miraﬂoris.—*A. Flowering branch.—B. Flowers.—C. Dehisced tepals with attached stamens.—D. Young fruit, showing abscission line of tepals.—E. Fruit.*

departamentos of Esteli and Jinotega. This is one of the best-developed montane areas in Nicaragua and is inhabited by several species otherwise unknown in Nicaragua, such as *Osmunda regalis* (W. D. Stevens, pers. comm.). Specimens with buds or flowers have been collected from late December to May; the fruiting collection (*Stevens 16347*) was made in November.

Nectandra and *Ocotea* are the two largest genera of neotropical Lauraceae. The differences between the two genera are not always easy to see and some authors have proposed to merge them under *Ocotea* (Kostermans, 1957; Howard, 1981; Liogier, 1982; the last-mentioned two transferred several West Indian *Nectandra* species to *Ocotea*). The character most frequently mentioned in the literature as separating the two genera is the position of the anther cells; they are arranged in an arc in *Nectandra* and in two rows in *Ocotea*. This character separates most species quite readily but is intermediate in some. Two additional characters help separate *Nectandra* from *Ocotea*. In *Nectandra* the inner faces of the tepals and the anthers have papillose pubescence; in *Ocotea* these surfaces are either glabrous or strigose. Also, in *Nectandra* the tepals are usually basally connivent, and in older flowers an abscission line forms underneath the tepals, which fall off as a unit together with all anthers. In *Ocotea* the tepals are free and fall off individually, often leaving stamens attached to the floral tube. Thus, on the young cupules of *Nectandra* species, one never finds stamens, but in *Ocotea* very frequently a few stamens can be found on young cupules.

In *Nectandra mirafloris* the position of the anther cells is intermediate between *Nectandra* and *Ocotea*, but the papillose indumentum on the tepals and anthers and the dehiscence of the tepals as a unit lead me to place this species in *Nectandra*. I regard a montane species from Panama and Costa Rica, *Nectandra cufodontisii* (O. Schmidt) Allen (basionym: *Ocotea cufodontisii* O. Schmidt; heterotypic synonym: *Ocotea seibertii* Allen according to W. Burger in litt.), as its closest relative. This species is very similar in leaf shape, venation type, and fruit shape but differs by lacking white pubescence on flowers and buds; its flowers are slightly larger, as are the leaves; and the outer stamens have anthers on filaments ca. 0.3 mm long, contrasted with nearly sessile anthers in *N. mirafloris*. Several collections of *N. mirafloris* were annotated as *Persea*, one as *Nectandra sanguinea* and one (the type) as *Anacardium occidentale*.

The epithet *mirafloris* refers to the type locality and is a reminder to collectors to look out for flowering Lauraceae.

Persea pajonalis van der Werff, sp. nov. TYPE: Peru. Boundary of provinces Oxapampa and Pasco: San Gotardo; 3 m shrub in pajonal, 2,500–3,000 m, 29 Dec. 1983, *Foster, Chanco & Alban 7647* (holotype, MO). Figure 6A–E.

Frutex vel arbor parva. Ramuli crassi, 5–8 mm in diametro, angulares, hornotini sparsim adpresse cinereopubescentes, vetustiores glabri; cicatricibus conspicuis aggregatis. Folia alterna, coriacea, obovata, apice rotundata vel subacuta, basi obtusa vel subcordata, 10–17 × 4–8 cm; super glabra costa nervisque (10–12 jugis) immersis; subtus sparsim adpresse pubescentia, praecipue secus costam nervosque; costa, nervis venationeque elevata. Petioli crassi, 5–8 mm longi. Inflorescentiae axillares, 5–18 cm longae, paniculatae; flores pedicellique aeneo-puberuli, pubescentia evanescente versus basim inflorescentiae. Tepala 6, inaequalia, 3 exteriora ovata, 3 × 3 mm, 3 interiora ellipsoidea, 4.5 × 2.5 mm, aeneo-puberula. Stamina 9, 4-locellata, 6 exteriora introrsa, 3 mm longa; 3 interiora extrorsa, 3.5 mm longa, basi filamentorum 2 glandulis sessilibus praedita. Staminodia 3, 1.5 mm longa, pubescentia. Ovarium glabrum subobovatum, 2 mm longum. Fructus immaturus viridis, magnopere tepalis persistentibus obtectus.

Shrub or small tree, 2–6 m tall. Twigs thick, 5–8 mm diam. during first year, angled, hollow, when young with gray appressed pubescence, glabrescent, 2-year-old twigs glabrous. Terminal buds with appressed gray pubescence, usually hidden by the leaves. Twigs with conspicuous clusters of scars from bracts of old terminal buds. Leaves alternate, evenly distributed along twigs, coriaceous, obovate, the tip rounded or slightly acute, the base obtuse or subcordate, 10–17 × 4–8 cm; laminae glabrous above, sparsely ap-

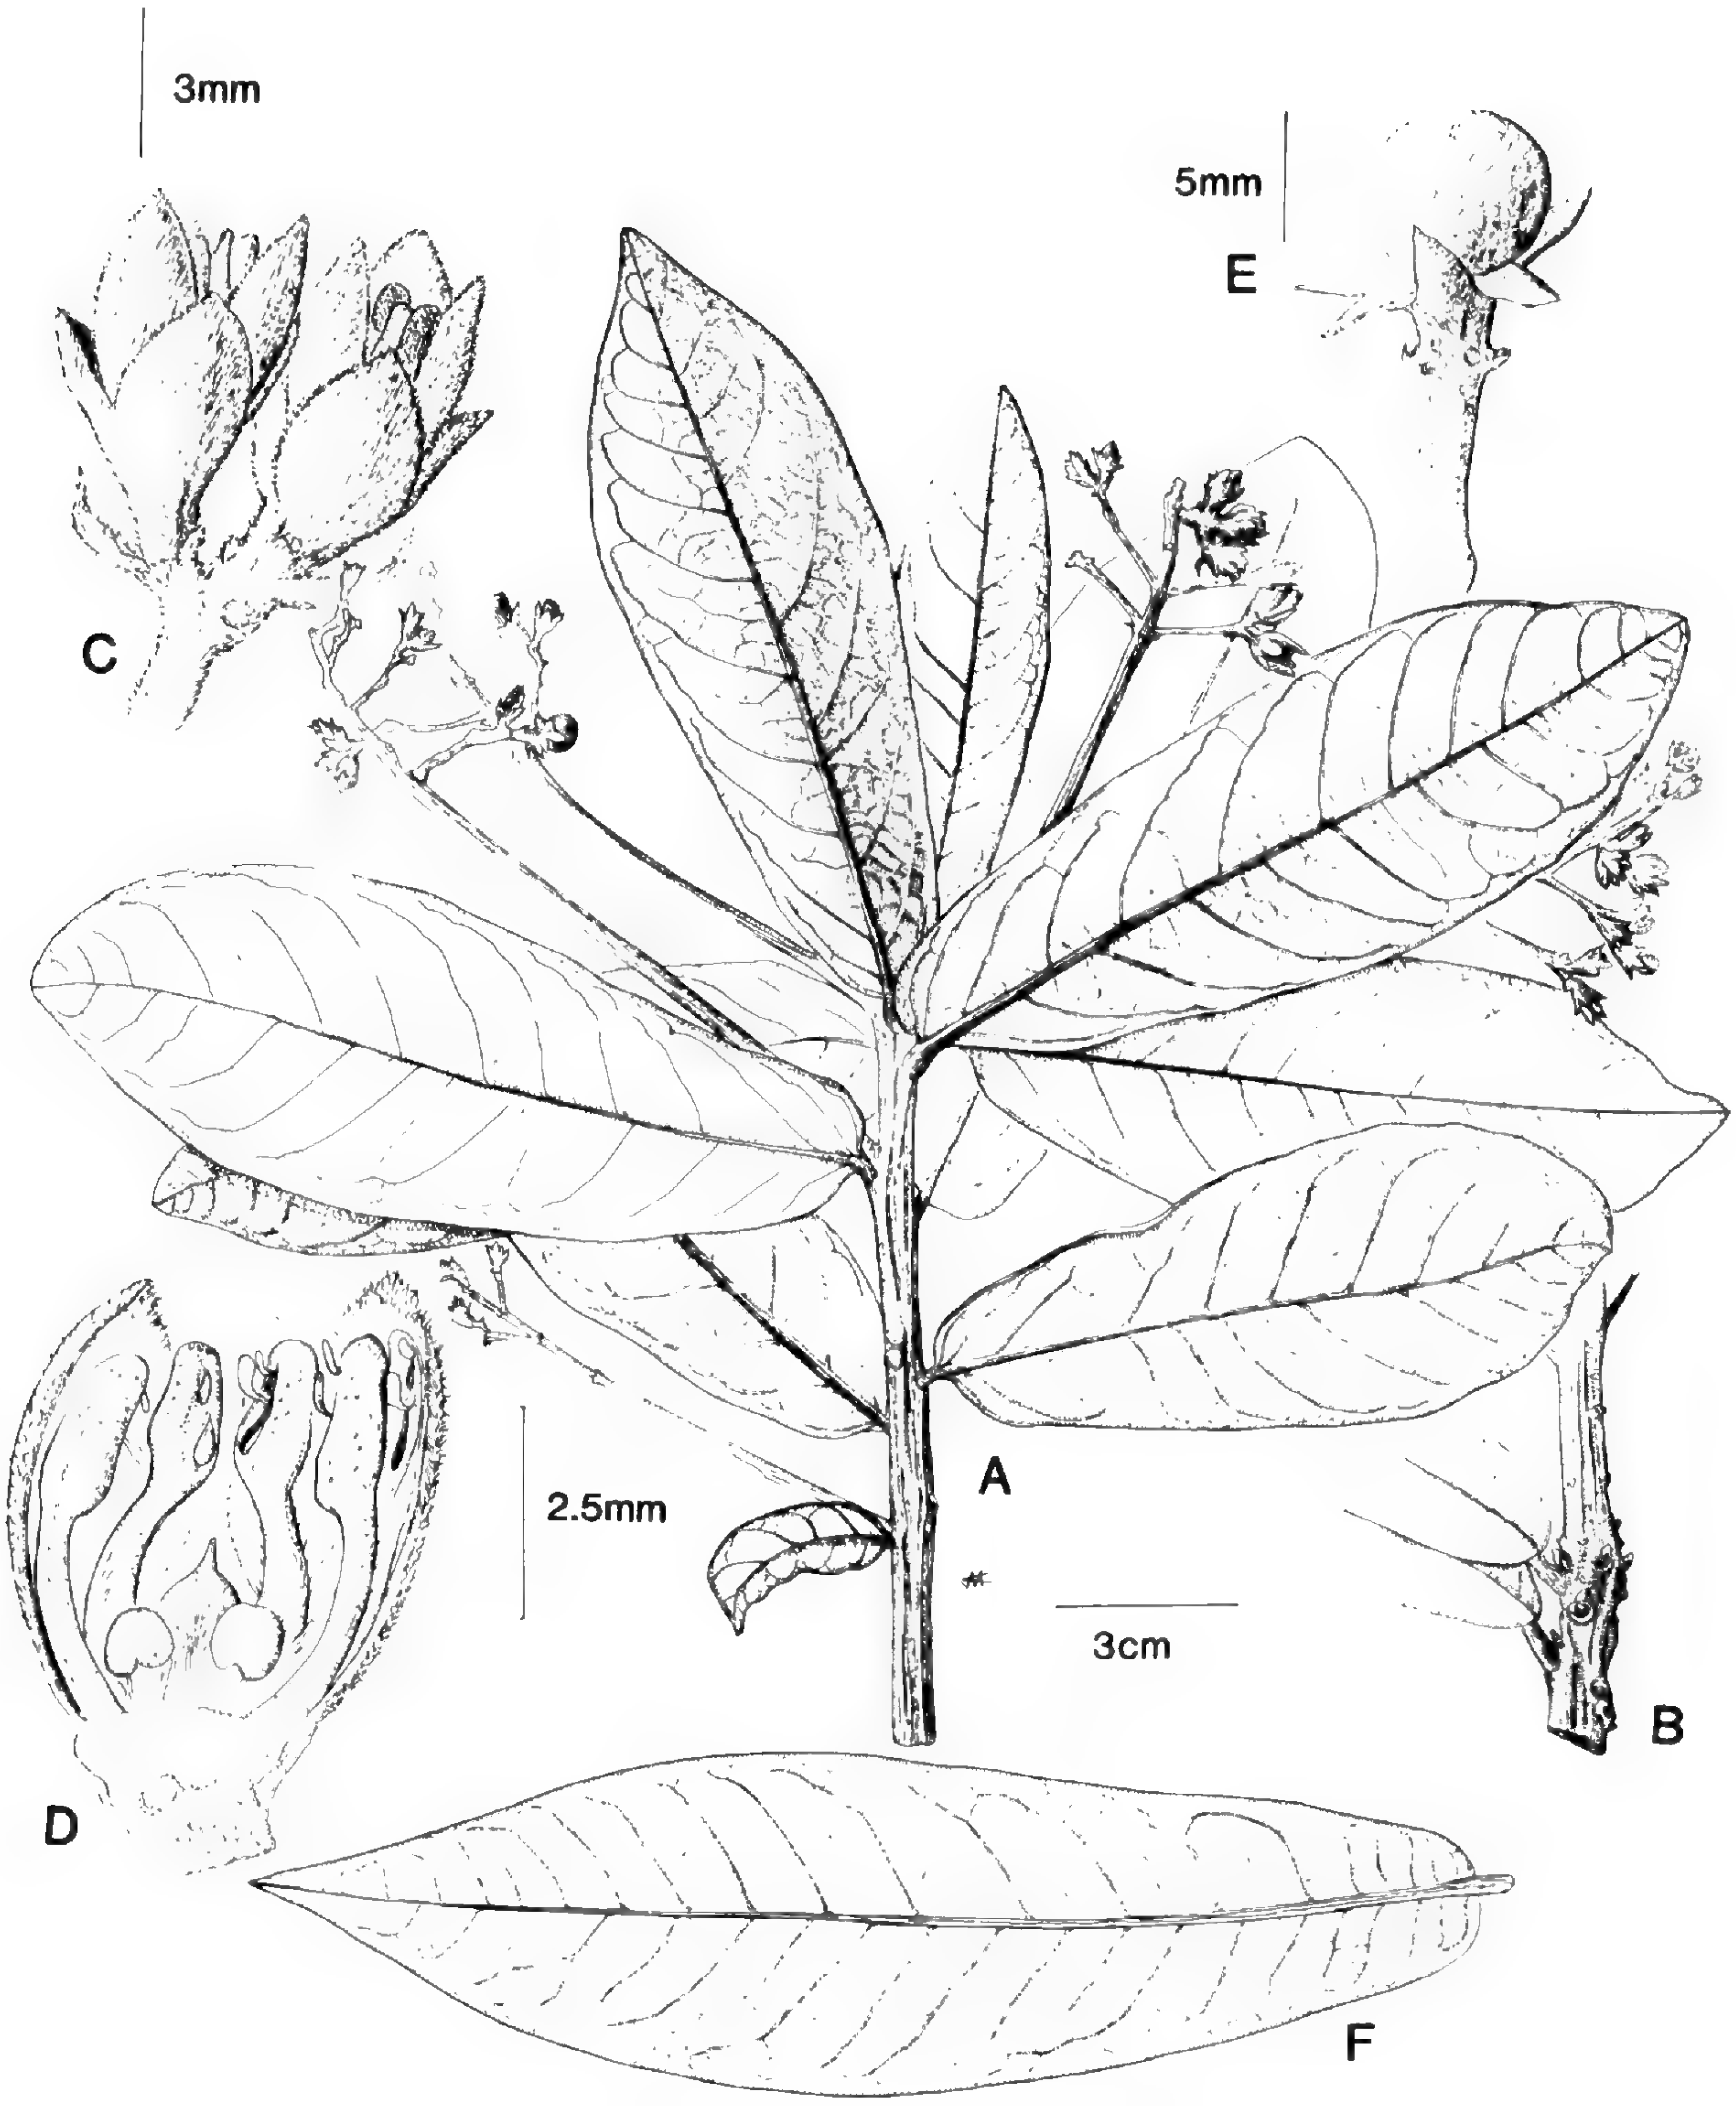

FIGURE 6. A–E. Persea pajonalis.—*A. Flowering branch.—B. Detail of twig with scars from bracts.—C. Flowers.—D. Flower with tepals removed, showing stamens, two basal glands, and staminode.—E. Fruit.—F. Leaf of* Persea sessilis.

pressed pubescent below, especially along major veins; midrib and lateral veins (10–12 pairs) immersed above, prominently raised on lower surface, tertiary venation also raised on lower surface. Petioles thick, 5–8 mm long. Inflorescences in axils of persistent leaves, 5–18 cm long, shorter than or about as long as the subtending leaves; paniculately branched, the peduncle to 12 cm long; flowers and pedicels with dense, bronze-colored puberulence, this becoming much sparser toward the base of the inflorescence. Tepals 6, unequal, the outer 3 ovate, ca. 3 × 3 mm, the inner 3 ellipsoid, ca. 4.5 × 2.5 mm, bronze-puberulent outside. Stamens 9, all 4-celled, the outer 6 introrse, ca. 3 mm long, the filaments ca. 1.5 mm long, narrower than the anther; the anther cells arranged in 2 rows; inner 3 stamens extrorse, ca. 3.5 mm long, with 2 globose glands attached near the base of the filaments. Staminodia 3, ca. 1.5 mm long, pubescent, with a broad triangular head. Ovary glabrous, round or slightly obovate, ca. 2 mm long; style distinct, ca. 1.5 mm long. Immature fruits green, largely hidden by persistent tepals.

Paratypes. PERU. BOUNDARY OF OXAPAMPA AND PASCO: San Gotardo, in dwarf forest, 2,650–2,800 m, *Gentry et al. 39998* (MO); same locality, *van der Werff et al. 8578* (MO).

Persea pajonalis is only known from a few collections from the San Gotardo area west of Oxapampa at rather high elevations. It is restricted to a vegetation type called *pajonal*, a name used for open, nonforest vegetation. Some of the pajonales seem to have an edaphic origin (only found on nutrient-poor sandstone), but in the San Gotardo area the pajonal represents a subparamo scrub rich in Ericaceae and Myrsinaceae; other taxa frequently found in high-elevation vegetation (Araliaceae, *Jamesonia*, *Weinmannia*) were present as well. However, groups indicative of nutrient-poor soil, such as Eriocaulaceae, terrestrial *Utricularia*, and *Pinguicula*, were found in the area too.

Persea pajonalis belongs to subg. *Eriodaphne* sect. *Eriodaphne*, using Kopp's (1966) classification. Among the South American species of this subgenus, *Persea pajonalis* can be immediately recognized by its nearly sessile leaves with rounded or subcordate base. *Persea sessilis* Standley & Steyerm., a Guatemalan species only known from the fruiting type collection, has similar leaves (Fig. 6F) The holotype (F!) consists of good vegetative material and remnants of infructescences. The following differences are evident between *P. pajonalis* and *P. sessilis*: in *P. pajonalis* the leaves have scarce scattered hairs on the lower surface, 10–12 pairs of lateral veins, and rounded or slightly acute tips, and the twigs are hollow; in *P. sessilis* the leaves have glabrous lower surfaces, acute to acuminate tips, and 15 or more pairs of lateral veins, and the twigs are solid. I expect that when flowers of *P. sessilis* become available, additional differences will be found and that the striking leaf shape is more a habitat adaptation (both are shrubs occurring on high-elevation mountain ridges) than an indication of close relationship.

Phoebe elegans van der Werff, sp. nov. TYPE: Mexico. Oaxaca: Mpio. San Miguel Chimalapa, Cima del Cerro Salomón, 16°46′15″N, 94°11′45″W, 1,770 m, 3 m tree, flowers green with red margin, pedicels reddish. Abundant. 11 Apr. 1986 (fl, fr) *M. Ishiki 1501* (holotype, MO; isotypes, CHAPA, HBG, LL, MEXU, n.v.). Figure 7.

Arbor parva, ad 6 m. Ramuli tenues, teretes, glabri; gemma terminalis glabra vel aliquot pilis adpressis aucta. Petioli glabri, 1–2 cm longi, leviter canaliculati. Folia alterna, glabra, ovata, 5–9 × 2–3 cm, basi obtusa vel rotundata, apice valde acuminata; acumine ad 2 cm longo; laminae trinerves, ceteris nervis lateralibus (3–4 jugis) debilibus; super venatione immersa subtus venatione leviter elevata; minute sub lente punctatae. Inflorescentiae axillares, glabrae, 2.5–4 cm longae, pauciflorae. Flores glabrae. Tepala 6, aequalia, per anthesin erecta, ca. 1.5 mm longa, ca. 2 mm lata, apice rotundata. Stamina 9, quadrilocellata, 6 exteriora introrsa, ca. 1.2 mm longa; 3 interiora extrorsa, ca. 1.5 mm longa, omnia basi filamentorum pilis translucentibus aucta; glandula staminum interiorum parva; staminodia 3 ca. 1 mm longa, apice triangulari. Ovarium globosum, glabrum, stylo ca. 0.8 mm longo. Fructus ellipsoideus, ca. 1 cm longus, 0.7 cm latus; cupula parva, non profunda, sensim in pedicello attenuata tepalis persistentibus.

Small tree, 3–6 m tall, the main stem thin, ca. 1 cm diam., branches smooth, delicate, horizontal. Twigs slender, terete, glabrous, the terminal bud with few appressed hairs or glabrous. Petioles glabrous, 1–2 cm long, the margins of the laminae decurrent as narrow ridges and the petioles thus slightly canaliculate. Leaves alternate, glabrous, ovate, mostly 5–9 × 2–3 cm, the base obtuse or rounded, the apex strongly acuminate, the acumen to 2 cm long, often falcate; laminae tripliveined, the basal laterals leaving the midvein at or very near the base of the laminae; other laterals (3–4 pairs) weakly developed; upper leaf surface with immersed venation, the lower surface with slightly raised venation; numerous small oil cells present on lower surface; margins of laminae smooth and slightly thickened. Inflorescences in the axils of normal leaves, glabrous, 2.5–4 cm long, shorter than the leaves, once or twice cymosely branched,

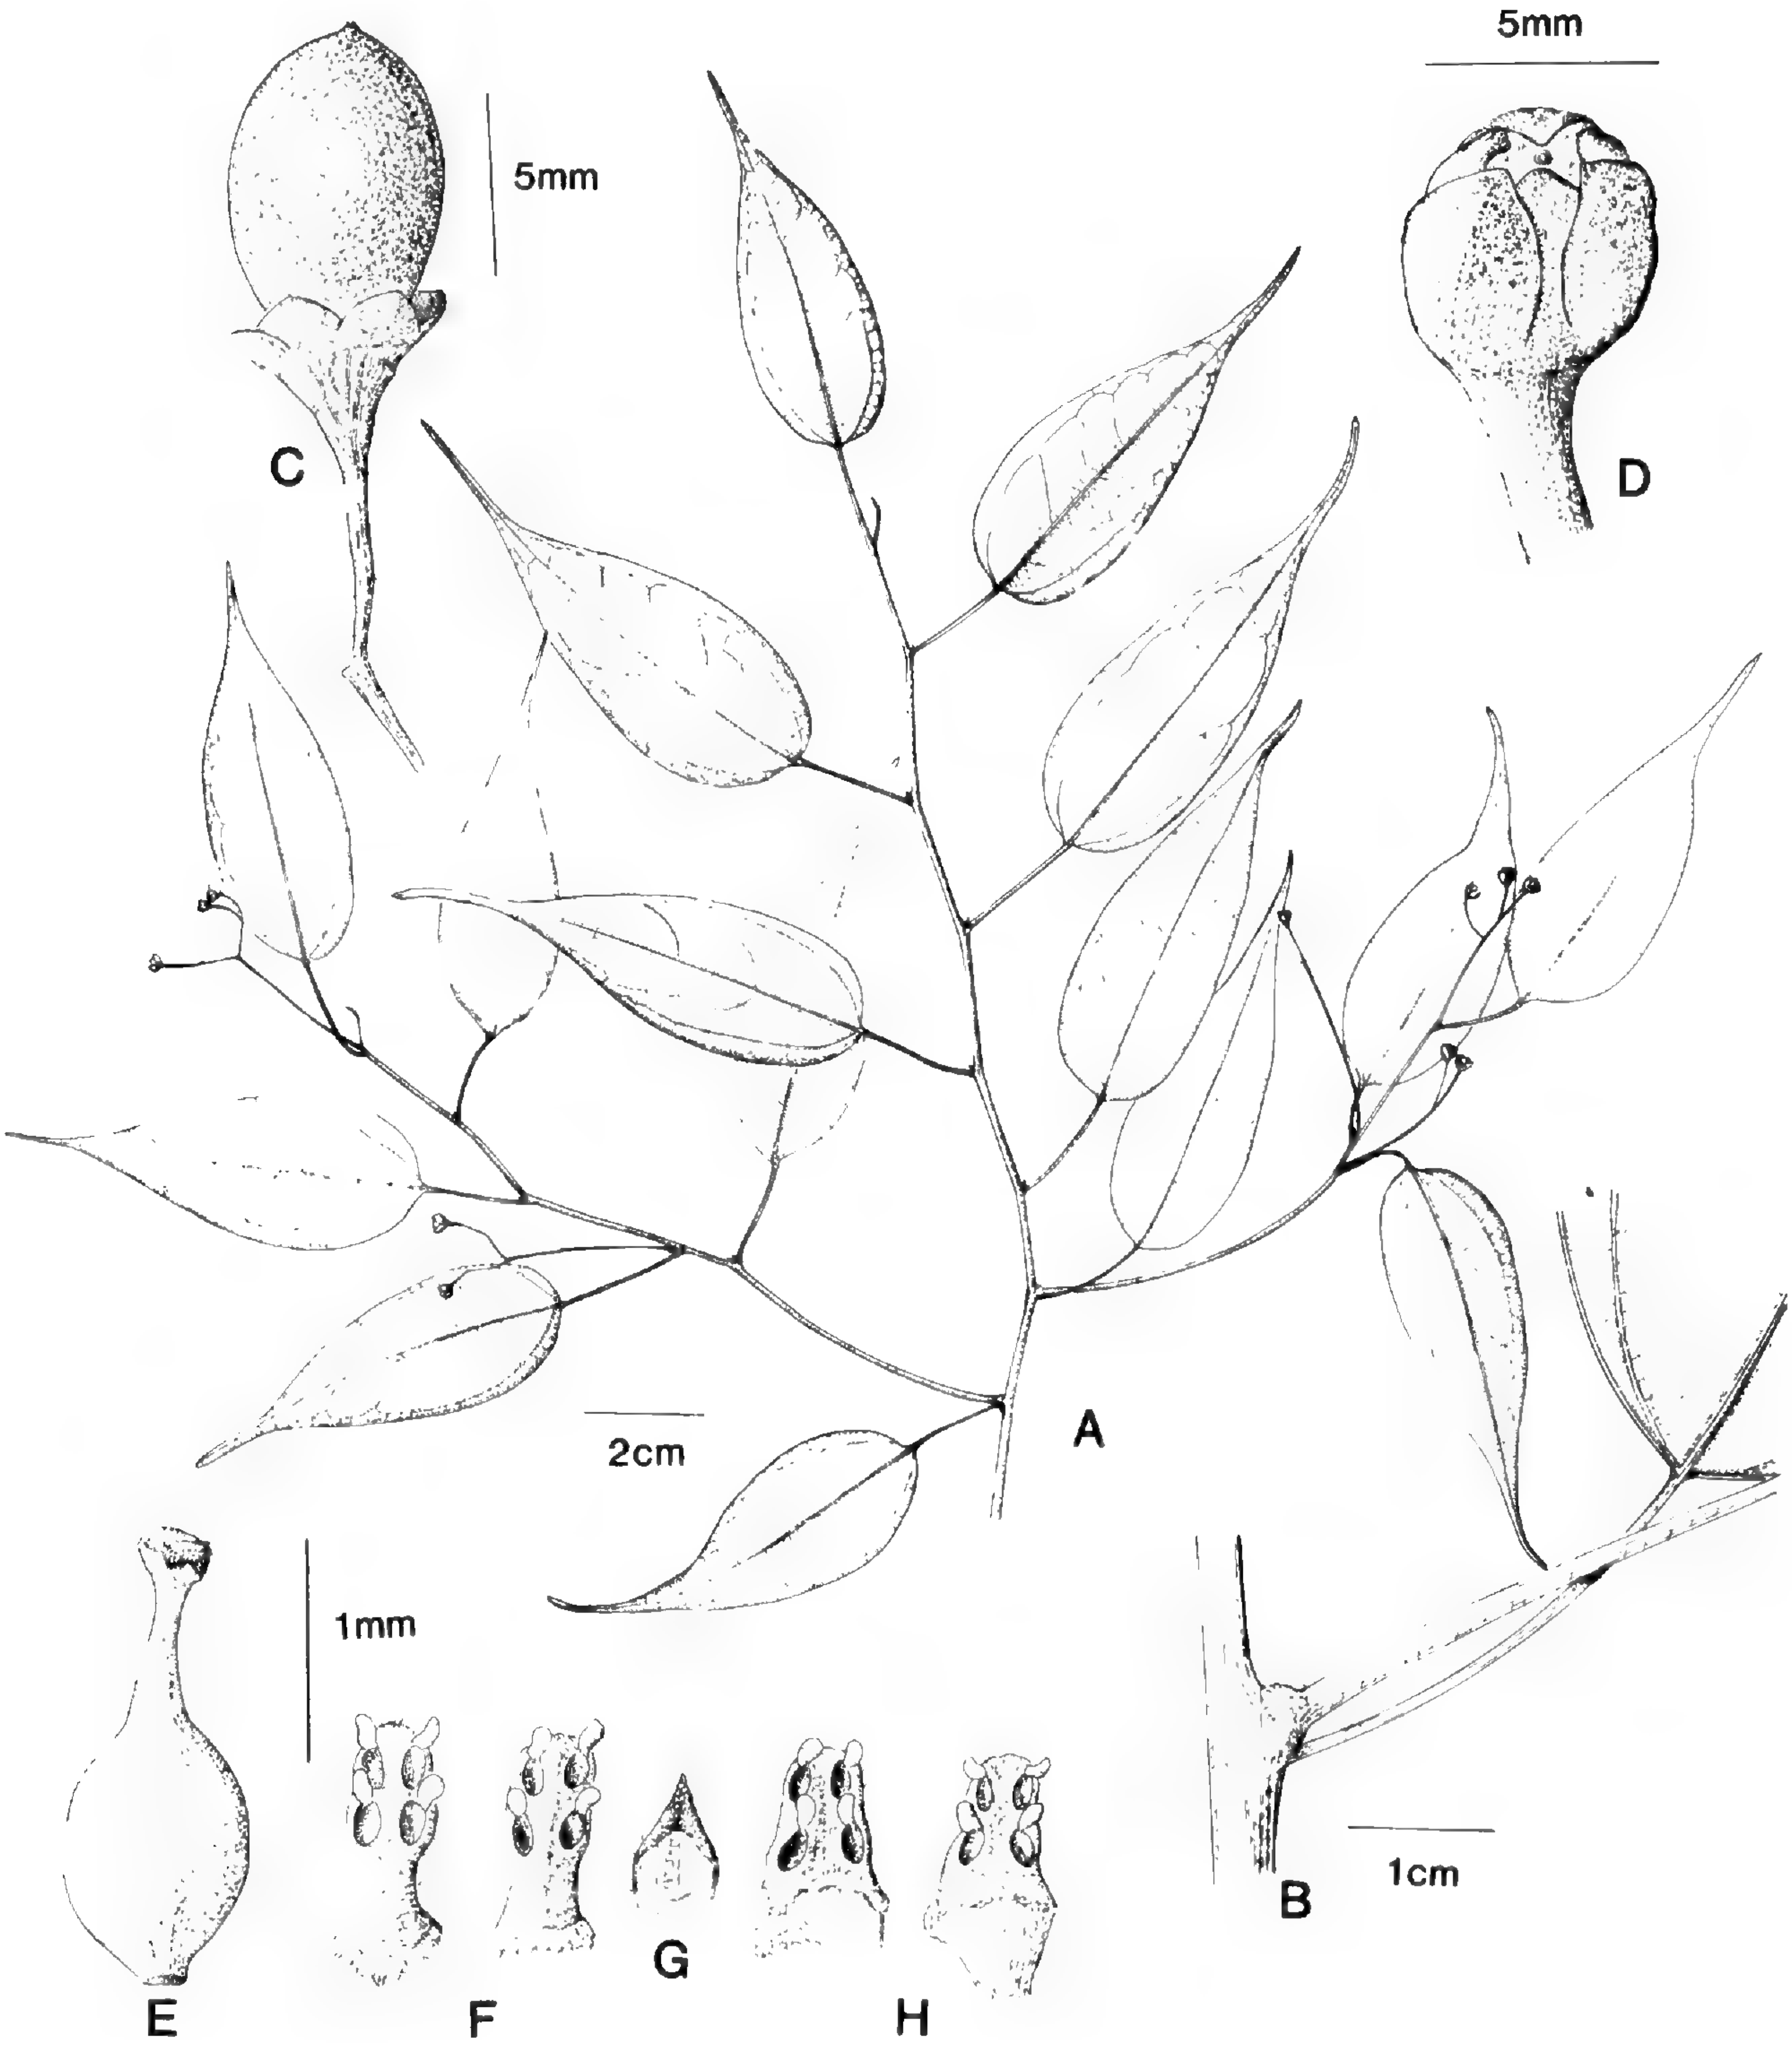

FIGURE 7. Phoebe elegans.—*A. Flowering branch.—B. Detail of twig showing petiole and base of inflorescence.—C. Fruit.—D. Flower.—E. Ovary.—F. Outer stamens.—G. Staminode.—H. Inner stamens with small basal glands.*

but on each inflorescence usually 2 or 3 flowers; bracts present in young inflorescences, linear, ca. 1.5 mm long, deciduous with age; pedicels slender, to 1 cm long. Flowers glabrous, ca. 2 mm long, 3.5 mm wide. Tepals 6, equal, erect at anthesis, rounded at tip, ca. 1.5 mm long and 2 mm wide. Fertile stamens 9, all 4-celled, glabrous, the outer 6 ca. 1.2 mm long, the filament slightly wider than the anther, the locelli arranged in 2 rows, introrse; the inner 3 stamens with extrorse cells, the filaments wider than the anthers, ca. 1.5 mm long; staminal glands small and visible as two small bulges at the base of the inner anthers. Staminodia 3, ca. 1 mm long, with a triangular head. Ovary globose, glabrous, ca. 1 mm diam. Style distinct, ca. 0.8 mm long with a large stigma. Base of the floral tube and base of the stamens covered with stiff, translucent hairs. Fruit an ellipsoid berry, ca. 1 cm long, 0.7 cm wide; cupule small plate, gradually narrowed into the pedicel and crowned with persistent tepals.

Paratypes. MEXICO. OAXACA: Mpio. San Miguel Chimalapa, Cima del Cerro Salomón, (buds) *Ishiki 1454,* (fr) *1529* (MO, CHAPA), (fl) *Ishiki 1616* (CHAPA, MEXU, MO).

Phoebe elegans is a very delicate and attractive species, so far only known from one mountain in Oaxaca, Mexico, near the border with Chiapas; it is said to be abundant in elfin forest and transition into cloud forest. The relatively long, spreading petioles, and the ovate, long-acuminate, triveined leaves separate it at once from the other neotropical *Phoebe* species, although it possesses all diagnostic characters for the group: tepals erect at anthesis, tepals persistent in fruit, flowers with long pedicels, staminodia present, and tripliveined leaves.

Phoebe, as accepted here, is a large (at least 180 binomials) genus occurring in the Asian and American tropics. Agreement on the generic boundaries of *Phoebe* has not yet been reached, and it is not clear how and if *Phoebe* can be separated from *Cinnamomum* and *Ocotea* (Kostermans, 1961; van der Werff, 1987). Until a careful study of these three groups has been made, I will continue the traditional usage of *Phoebe* for a heterogenous group of species in the Neotropics. I realize that the discordant species have to be transferred to other genera, and earlier (van der Werff, 1987) I discussed the characters I consider diagnostic for neotropical *Phoebe.* Altogether, the neotropical *Phoebe* species form a large group to which more than 70 species have been attributed.

Pleurothyrium hexaglandulosum van der Werff, sp. nov. TYPE: Panama. Colón: Río Guanche, ca. 5 km upstream from Portobelo, 50 m, tree, 5 m, inflorescence pendent, flowers green, becoming yellow. *Hammel & Trainer 14781* (holotype, MO; isotype, BR, others to be distributed). Figure 8.

Arbor parva, 5 m. Folia alterna, chartacea; petioli dense tomentelli; laminae anguste obovatae, 30–45 × 10–15 cm, versus basim sensim attenuatae, basi abrupte rotundatae vel subcordatae, apice acuminatae; super venatione immersa, subtus elevata; nervi secundarii sursum curvati et in nervo submarginili uniti. Inflorescentiae axillares, puberulae, paniculatae, 40–65 cm longae. Pedicelli cinereo-pubescentes, 1.5–2 cm longi. Flores virides, 8–9 mm diametro. Tepala 6, aequalia, extus cinereo-pubescentia, intus glabra ubicumque in alabastro antheras glandulasque staminum contingentia, demum pubescentia. Stamina 4-locellata, 6 exteriora locellis lateralibus, 3 interiora locellis extrorso-lateralibus. Filamenta staminum interiorum 2 glandulis magnis, stamina exteriora cingentibus aucta. Ovarium late globosum, pubescens. Fructus ignotus.

Small tree, 5 m tall. Twigs terete, densely brown tomentellous, 5 cm below the tip 4–5 m diam. Leaves alternate, chartaceous; the petioles ca. 5 mm long, densely tomentellous; laminae narrowly obovate, 30–45 × 10–15 cm, gradually narrowed toward the base, there abruptly rounded to subcordate, the tip acuminate; glabrous above, with appressed hairs on main veins below, especially near the base, otherwise glabrous; venation immersed above, midvein prominently raised below, secondary veins (14–18 pairs) raised and the final reticulation slightly less raised; secondary veins arching upward near the margin and prominently loop-connected in the upper ⅔ of the lamina. Inflorescences axillary, 40–65 cm long, brown puberulous, paniculate, laxly branched, the basal lateral branches 20–25 cm long, the upper ones gradually shorter. Pedicels 1.5–2 cm long, densely gray-pubescent. Flowers ca. 8–9 mm diam., greenish becoming yellow (fide collector). Tepals 6, equal, 4 mm long, glabrous inside except where in bud the glands and stamens not pressed against tepals, thus showing a narrow line of hairs central in the lower part of the tepal (the 6 glands not completely fused in this species), this line expanded in a diamond-shaped outline marking the space between anther and glands and with lines to the margin and tip of the tepal. Glands of the inner 3 stamens prominent, surrounding the outer stamens, but not becoming fused. Stamens 9, raised above the glands, the filament with some hairs on the back, 0.8–1 mm long; anthers 4-celled, the outer 6 anthers curved

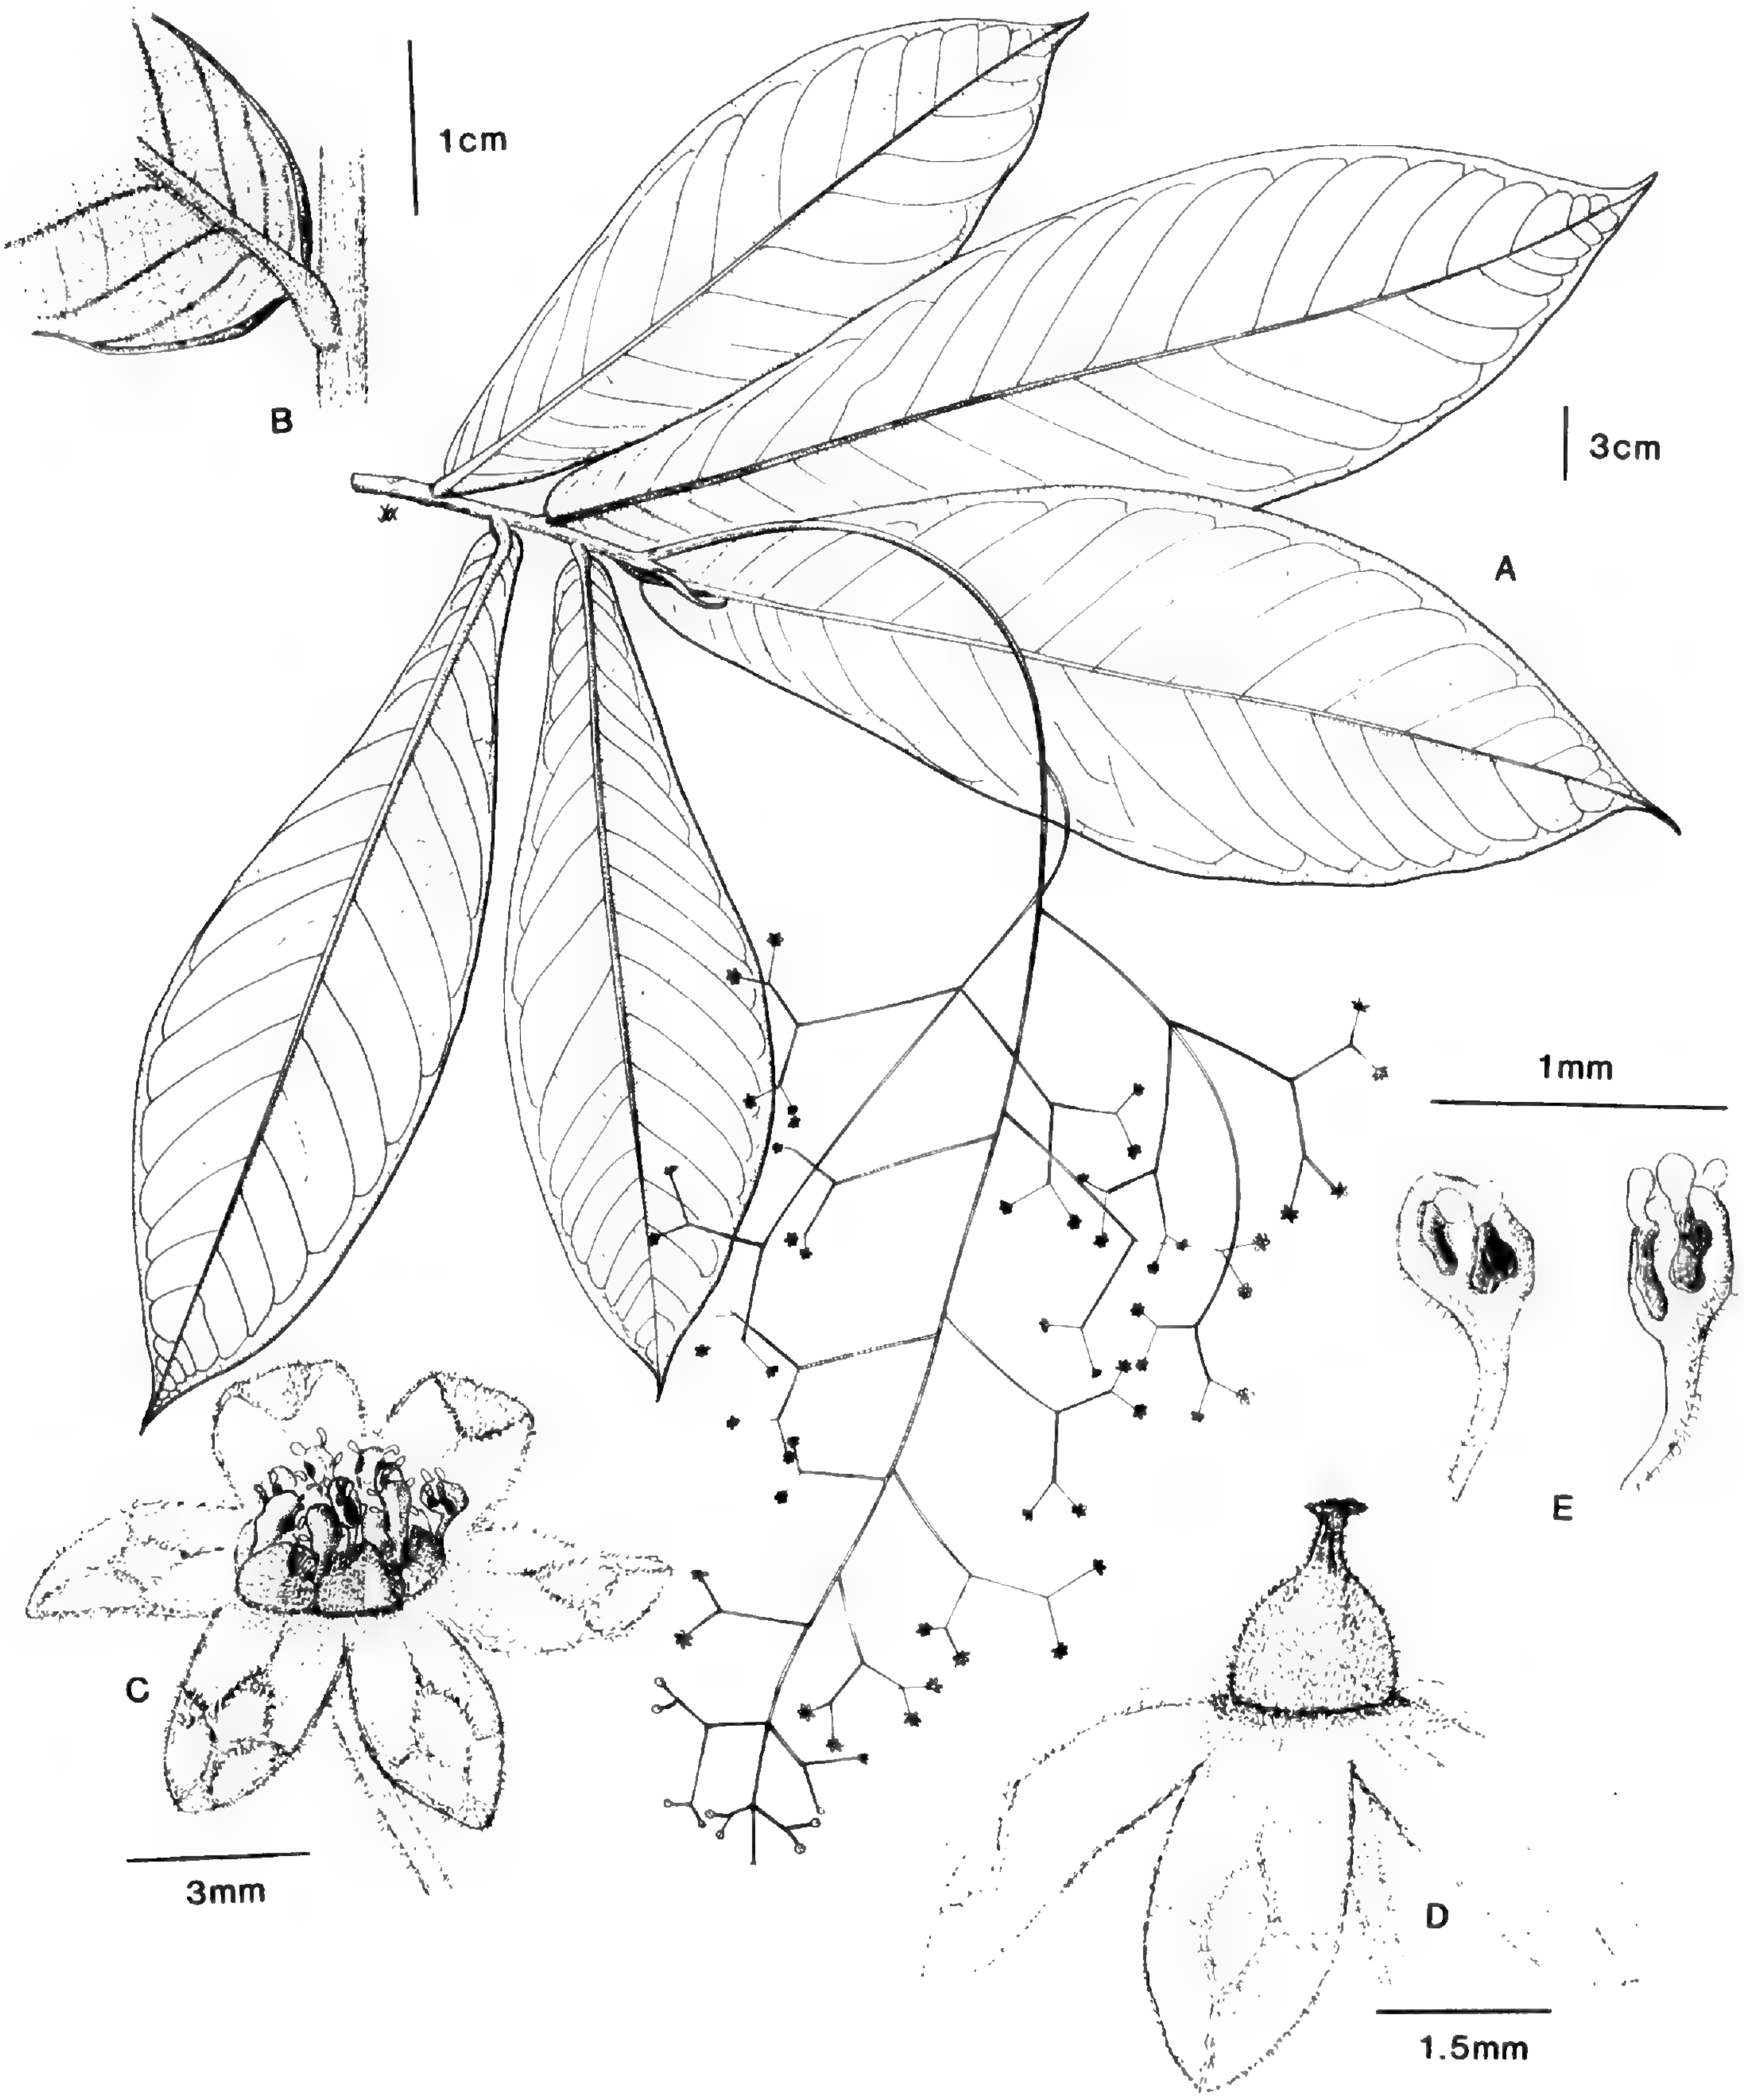

FIGURE 8. Pleurothyrium hexaglandulosum.—*A. Flowering branch.—B. Detail of leaf base and petiole.—C. Flower, showing pubescence pattern on tepals, large staminal glands, and stamens.—D. Old flower, glands and stamens fallen off.—E. Outer (left) and inner (right) stamen.*

inward, the anther cells lateral; inner anthers shorter, the anther cells lateral. No staminodia seen. Ovary broadly ovate, 1 mm long, 1.5 mm wide, with short, gray pubescence. Style short, 0.2–0.3 mm long, gray pubescent. Stigma platelike. Glands and stamens deciduous in older flowers and the tepals becoming reflexed, thus fully exposing the ovary. Fruit unknown.

Pleurothyrium hexaglandulosum is only known from two collections. It is closely related to *P. maximum* O. Schmidt from Amazonian Peru. Shared characters are large inflorescences, oblanceolate-obovate leaves with thick, short petioles, and loop-connected secondary veins, forming a submarginal vein. It differs in having gray or brown pubescence (rufous in *P. maximum*), much smaller flowers with dense gray pubescence (rufous in *P. maximum*), and more widely branched inflorescence (lateral branches ca. 2 cm long in *P. maximum*, to 20 cm long in *P. hexaglandulosum*). Schmidt (1933) noted a relationship between *P. maximum* and *P. williamsii* O. Schmidt. I have not seen material of the latter species; it differs from *P. hexaglandulosum*, according to its description, in the shorter inflorescences (to 12 cm long), shorter pedicels (4–6 mm long), and brown-tomentose flowers.

Pleurothyrium hexaglandulosum is the first record of *Pleurothyrium* in Panama. Its specific epithet refers to the six glands of the inner three stamens. In nearly all *Pleurothyrium* species these are fused and cannot be recognized individually, and for a long time it was assumed that in *Pleurothyrium* all nine stamens had two glands. In *Pleurothyrium hexaglandulosum* (and to a lesser degree in *P. maximum*), the glands remain separated and show clearly that in *Pleurothyrium* only the inner stamens have glands, as Rohwer & Kubitzki (1985) stated.

Croat & Grayum 59792 (F, MO), collected in Costa Rica, Puntarenas, along road between Rincón de Osa and Rancho Quemado, is provisionally placed here. It differs from the type collection in being less pubescent.

Ocotea erectifolia (Allen) van der Werff, comb. nov. BASIONYM: *Phoebe erectifolia* Allen, Mem. New York Bot. Garden 23: 860. 1972. TYPE: Venezuela. Bolívar: Meseta del Jaua, *Steyermark 97926* (holotype, NY!).

Ocotea budowskiana Bernardi, Candollea 30: 256. 1975. TYPE: Venezuela. Bolívar: Meseta de Jaua, *Steyermark 109330* (holotype, G!; isotype, F!).

Ocotea erectifolia is very distinct with coriaceous, few-veined, ascending leaves. It was first published as a *Phoebe* species. When Bernardi later recognized it as an undescribed *Ocotea* species, he overlooked the earlier description of *Phoebe erectifolia*. However, there is no doubt that the two species are the same, and hence the new combination in *Ocotea* is made.

A REVISION OF *PANICUM* SUBGENUS *PHANOPYRUM* SECTION *STOLONIFERA* (POACEAE: PANICEAE)[1]

Fernando O. Zuloaga[2] *and*
Tatiana Sendulsky[3]

ABSTRACT

A revision of Panicum *subgenus* Phanopyrum *section* Stolonifera *is presented.* Panicum soderstromii *is described as new, and* P. andreanum, P. biglandulare, P. crateriferum, P. irregulare, P. chapadense, P. rude, P. piauiense, P. stoloniferum, P. latissimum, P. pulchellum, *and the controversial* P. venezuelae *are included in this section, which can be characterized by the inflorescences with unilateral racemose branches, the upper anthecium short stipitate at its base and glabrous and smooth, and the presence of non-Kranz leaf anatomy. The presence of one or two (rarely three) pairs of crateriform, ocellate glands is a singular feature of this section; these glands may be constantly present, present or absent in some specimens, or completely absent in others. Keys to all 13 species and SEM micrographs of the upper anthecium and glands on the lower lemma are provided. Each species is illustrated.*

Section *Stolonifera* is one of the most attractive and interesting sections of the genus *Panicum*. The name was given as an informal group by Hitchcock & Chase (1910), who included in it *P. stoloniferum* Poiret, *P. frondescens* G. Meyer, *P. pulchellum* Raddi, and *P. biglandulare* Scribner & Smith. These species were mainly distinguished in the view of Hitchcock & Chase as summarized in the following diagnosis:

> Decumbent or creeping perennials, rooting at the lower nodes, with branching culms; ligule short, membranous; leaf blades lanceolate or ovate-lanceolate; panicles of racemose, secund, spikelike, ascending branches, ± divergent from the axis, with spikelets in pairs along one side of the branches; upper glume and lower lemma exceeding the anthecium in length.

In 1940, Pilger gave the rank of section to species of the Stolonifera group. Hsu (1965), in his worldwide treatment of *Panicum*, characterized this section basically as having a papery ligule, panicles with spikelike racemes, upper glume and lower lemma longer than the upper anthecium, the latter smooth, lodicules very thin and weakly three-nerved. Hsu placed this section in his subgenus *Sarmentosum*, along with, among others, sections *Sarmentosa* Pilger, *Parviglumia* (A. Hitchc. & Chase) Pilger, and *Parvifolia* (A. Hitchc. & Chase) Pilger.

In the present work, *Stolonifera* is treated, according to the infrageneric classification of

Zuloaga (1987) within subg. *Phanopyrum* (Raf.) Pilger, being most closely related to sect. *Phanopyrum* and *Laxa*. Section *Phanopyrum* Raf. was raised to generic rank by Nash (1903), taking into consideration as diagnostic characters spikelet compression, habitat, length of the upper anthecium, and presence of a stipe in the base of the upper anthecium. This idea was accepted in recent years by various authors (Brown, 1977; Gould & Shaw, 1983; Lazarides & Webster, 1984). However, we believe that none of these characters are strong enough to maintain *Phanopyrum* apart from *Panicum*. As Hitchcock & Chase (1910) stated: "this species [*P. gymnocarpon*] departs somewhat from the usual characters of the genus *Panicum*, but the divergence does not seem sufficient to justify segregating the single species as the type of a separate genus."

Subgenus *Phanopyrum* includes non-Kranz species, these being anatomically distinguished by having two bundle sheaths around the vascular bundles, the inner mestome sheath with thick-walled cells surrounded by a parenchymatous sheath with thick-walled and completely empty cells (with these parenchymatous sheath cells bigger than the mesophyll cells). The number of mesophyll cells between the vascular bundles ranges from 5 to 12, with a distance of (150)230–270 (–380) μm. Exomorphologically, the spikelet is characterized by having a lower glume 1–3 (occasionally –5)-nerved and upper glume and lower lemma 5(occasionally –7)-nerved. The species are usually found in shady and humid places, with some exceptions in species of sect. *Lorea*, *Parvifolia*, and *Stolonifera*, some of which grow in open and more or less drier habitats.

Within this subgenus, sect. *Stolonifera* is defined by the following diagnostic features:

Inflorescence type. All species are characterized by having the spikelets congested on short, unequal pedicels along racemose, unilateral branches (occasionally with short tertiary branchlets in *P. latissimum* Mikan ex Trin., *P. rude* Nees, and *P. venezuelae* Hackel), with the branches usually alternate, remote, and diverging from the axis. This character is also present in sect. *Phanopyrum* and sect. *Laxa* (A. Hitchc. & Chase) Pilger. In the former, the spikelets are usually borne on tertiary branchlets appressed unilaterally along secondary branches. Within sect. *Laxa* there is a variation from short-pedicelled spikelets in unilateral racemose branches (as for example in *P. pilosum* Sw. and *P. leptachne* Doell) to spikelets disposed along either side of short tertiary branchlets (e.g., *P. boliviense* Hackel, *P. bresolinii* L. B. Smith & Wassh.). Sections *Parvifolia*, *Monticola* Stapf, and *Verrucosa* (A. Hitchc. & Chase) C. C. Hsu, included in subg. *Phanopyrum*, are characterized by open and lax panicles with long-pedicelled spikelets; in sect. *Lorea* Zuloaga some species have open and lax panicles, whereas others have spikelike inflorescences. In sect. *Megista* Pilger, all the branches of the panicle are whorled, with the spikelets short-pedicelled along the branches. In sect. *Parviglumia*, there is a gradation from species with spikelets arranged in open and diffuse panicles to others with short-pedicelled spikelets along racemose, not unilateral branches.

Surface and ornamentation of the upper anthecium. The epidermis of the upper anthecium is completely glabrous, indurate, smooth, and shiny, with scattered stomata toward the upper margins of the palea (Fig. 2c, d). A similar pattern is present within the subgenus in sect. *Phanopyrum* and sect. *Lorea* (in the latter it is possible to find occasional prickle hairs, stomata, and bicellular microhairs toward the apex of lemma and palea). On the other hand, sect. *Laxa* differs by having conspicuous prickle hairs toward the apex as well as simple papillae regularly distributed in longitudinal rows. Membranous anthecia are present in some species of this section.

Stipe presence, type of spikelet, and relative length of the upper anthecium. In all of the species of the section, the spikelets are biconvex with the upper anthecium shortly stipitate at the base; additionally, the anthecium is reduced in relation to the length of the upper glume and lower lemma (usually ½–¾ the length of the upper glume and lower lemma).

Sections of subg. *Phanopyrum* can be separated by the following key:

KEY TO THE SECTIONS OF SUBG. *PHANOPYRUM*

1a. Upper glume and lower lemma 7–9-nerved; panicles with all the branches whorled .... sect. *Megista*
1b. Upper glume and lower lemma 3–5(occasionally –7)-nerved; with the branches alternate to opposite, not whorled.
2a. Leaf branches stiff, pungent .... sect. *Lorea*
2b. Leaf blades not pungent, not stiff.
3a. Upper anthecium covered with long, cylindric hairs (occasionally glabrous, when glabrous lower palea absent, lower glume ⅕ the length of the spikelet) .... sect. *Parviglumia*
3b. Upper anthecium without long, cylindric hairs all over its surface (if glabrous lower palea present, and lower glume more than ⅕ the length of the spikelet).
4a. Panicles with racemose, unilateral branches, the spikelets disposed in pairs on short pedicels along one side of the branches, sometimes with the spikelets short-pedicelled in short tertiary branchlets on both sides of the branches; upper anthecium smooth, glabrous or with short prickle hairs at the summit.
5a. Upper anthecium glabrous, smooth and shiny, indurate, shortly stipitate, and shorter than the upper glume and lower lemma.
6a. Grasses aquatic, culms succulent; lower glume ⅘ the length of the spikelet; upper anthecium ⅓ the length of the spikelet. Southeastern United States .... sect. *Phanopyrum*
6b. Grasses inhabiting forests or edges of forests or in open habitats, culms not succulent; lower glume ⅓–¾ the length of the spikelet; upper anthecium ½–¾ the length of the spikelet. Mesoamerica to South America .... sect. *Stolonifera*
5b. Upper anthecium papillose, with simple papillae regularly distributed in longitudinal rows and prickle hairs toward the apex of lemma and palea, indurate to membranous, almost reaching the same length of the upper glume and lower lemma, not stipitate .... sect. *Laxa*
4b. Panicles lax and diffuse, the spikelets long- to short-pedicelled, not in unilateral, racemose branches; upper anthecium pilose, with bottlelike bicellular microhairs all over the surface, rugose to smooth.
7a. Upper anthecium smooth and shining .... sect. *Parvifolia*
7b. Upper anthecium rugose, with transverse or longitudinal and transverse wrinkles.
8a. Upper anthecium with transverse wrinkles. Lower glume ⅕ the length of the spikelet; upper glume and lower lemma verrucose. Eastern United States .... sect. *Verrucosa*
8b. Upper anthecium with longitudinal and transverse wrinkles. Lower glume ⅓–½ the length of the spikelet; upper glume and lower lemma not verrucose. Mesoamerica to Argentina .... sect. *Monticola*

A singular and isolated, although not constant, feature of species of sect. *Stolonifera* is the presence of one or two (rarely three) pairs of crateriform and ocellate glands on either side of the midnerve on the outer surface of the upper lemma. These glands are always present in *P. pulchellum*, *P. biglandulare* (Fig. 1a, b), *P. soderstromii* Zuloaga & Sendulsky (Fig. 1c–f), and *P. crateriferum* Sohns, while in *P. rude*, *P. piauiense* Swallen, *P. chapadense* Swallen, and *P. venezuelae* they are sporadic; they are completely absent in *P. stoloniferum*, *P. andreanum* Mez, *P. brachystachyum* Trin., *P. latissimum*, and *P. irregulare* Swallen. Occasionally, one pair of glands is present on the upper glume of spikelets of *P. venezuelae*; in this species the glands differ from those of the other species by being slightly depressed rather than crateriform (Fig. 2a, b). *Panicum venezuelae* has cleistogamous flowers in most of its spikelets, this character showing up elsewhere in *Panicum* only in subg. *Dichanthelium*. *Panicum irregulare* is the only species within the genus with the lower flower hermaphrodite.

The pubescence of the spikelet may vary from pilose to hispid (as in *P. chapadense*, *P. andreanum*), papillose-pilose (in *P. brachystachyum*), or entirely glabrous (in *P. irregulare* and *P. stoloniferum*).

Swallen (1966) included eight species in the group Latissima of *Panicum,* but he did not delimit it or indicate its links with other species of *Panicum.* The species accepted as valid from the Latissima group (*P. rude, P. latissimum,* and *P. piauiense,* together with *P. chapadense* and *P. soderstromii*) are treated in the present work in sect. *Stolonifera,* since we regard the habit and size of the plants as insufficiently strong characters to keep them in a different section. It should be pointed out that further anatomical studies would be useful to establish the relationship between species of the Latissima group and the rest of species of sect. *Stolonifera.*

Species of sect. *Stolonifera* occur from Mexico to Argentina. Some are widely distributed while others are found only in restricted areas. To the former group belong *P. stoloniferum* and *P. pulchellum,* the first ranging from Mexico, the Lesser Antilles, and South America to Argentina; *P. pulchellum* ranges from Mexico to Brazil and Bolivia. Two species are confined to Mesoamerica; *P. biglandulare* in Mexico and Guatemala and *P. crateriferum* in Mexico. *Panicum irregulare* grows from Costa Rica to Colombia and *P. andreanum* in Colombia and Venezuela, while *P. venezuelae* is found from Mexico to Brazil. The other species are all endemic to Brazil: *P. brachystachyum* from Minas Gerais, *P. rude* from Espírito Santo to Rio Grande do Sul, *P. latissimum* from Espírito Santo and Rio de Janeiro, *P. chapadense* from Goiás,

Magnifications: a, ×35; b, ×100; c, ×100; d, ×100.*

P. piauiense from Piauí and Bahia, and *P. soderstromii* from Bahia.

Classical taxonomic methods have been applied utilizing a Wild M5 dissecting microscope. Observations at higher magnification were made using the scanning electron microscope. Anthecia were removed from dried herbarium specimens, secured on stubs, carbon coated in a vacuum evaporator, coated with a gold-palladium alloy, and examined in a Cambridge S4-10 or Cambridge Stereoscan 250 Mk2 scanning electron microscope operating at 10–20 kV.

TAXONOMIC TREATMENT

Panicum section **Stolonifera** A. Hitchc. & Chase ex Pilger, in Engler, Nat. Pflanzenfam. ed. 2, 14e: 16. 1940. TYPE: *P. stoloniferum* Poiret.

Group Stolonifera A. Hitchc. & Chase, Contr. U.S. Natl. Herb. 15: 120. 1910 (nom. inval.); Contr. U.S. Natl. Herb. 17: 461, 500. 1915.

Perennial, plants small to robust, stoloniferous or decumbent, rooting and branching at the lower nodes to erect, leaning in the vegetation or not leaning; *culms* hollow, rarely solid, simple or branching. *Ligule* membranous-ciliate to membranous. *Leaf blades* ovate-lanceolate to long-lanceolate, flat, densely pilose to glabrous, shortly pseudopetiolate. *Panicles* pyramidal, sometimes oblong, composed of few to numerous, unilateral, racemose branches arranged along either side of the axis and bearing secund, paired, short-pedicellate spikelets. *Spikelets* ellipsoid to lanceolate, pilose to glabrous. *Lower glume* 3(rarely –5)-nerved, ¼–¾ the length of the spikelet, pilose toward the apex or glabrous. *Upper glume* and *lower lemma* subequal (or upper glume shorter than the lemma), acute to acuminate, 5(occasionally –7)-nerved; lower lemma with or without 1 or 2 (occasionally 3) pairs of crateriform, ocellate glands on the middle portion. *Lower palea* hyaline, glabrous; male flower present or absent (hermaphrodite flower present in *P. irregulare*). *Upper anthecium* ellipsoid to lanceolate, glabrous, smooth and shiny, indurate, shortly stipitate at the base; upper lemma with the margins inrolled over the palea. Lodicules 3-nerved. *Caryopsis* with punctiform or ovate hilum, the embryo less than half the length of the caryopsis.

An American section, including 13 species distributed from Mexico to Argentina, commonly found in forests or at the margins of forests, occasionally on "campos rupestres" (*P. brachystachyum*) and on "cerrados" (*P. chapadense, P. soderstromii, P. piauiense*). Collections come from 0–2,800 m elevation.

KEY TO THE SPECIES OF SECTION *STOLONIFERA*

1a. Lower flower hermaphrodite; caryopsis free from the lemma and palea, similar to the caryopsis in the upper anthecium .... 6. *P. irregulare*
1b. Lower flower male or neuter, not hermaphrodite.
2a. Spikelets 4.9–5.2 mm long .... 3. *P. brachystachyum*
2b. Spikelets 1.8–3.8(–4) mm long.
3a. Leaf blades amplexicaul, 7–12 cm wide .... 7. *P. latissimum*
3b. Leaf blades not amplexicaul, 0.3–5 cm wide.
4a. Spikelets mostly with cleistogamous flowers; anthers of these flowers 0.2–0.3 mm long; lower lemma gibbous with the upper margins inrolled; upper glume with or without glands .... 13. *P. venezuelae*
4b. Spikelets with chasmogamous flowers only; anthers 1–2 mm long; lower lemma not gibbous, the upper margins not inrolled; upper glume always without glands.
5a. Spikelets glabrous; lower lemma without glands .... 12. *P. stoloniferum*
5b. Spikelets pilose; lower lemma with or without glands.
6a. Lower glume ½–¾ the length of the spikelet; culms robust and erect; leaf blades lanceolate, 10–45 cm long; Brazil, from Bahia to Rio Grande do Sul.
7a. Lower glume with long, papillose-pilose hairs toward the apex; pedicels and branches with long hairs exceeding the length of the spikelet .... 11. *P. soderstromii*
7b. Lower glume shortly pilose to nearly glabrous, without long, papillose-pilose hairs toward the apex; pedicels and branches short-pilose to scabrous.
8a. Plants with long, creeping rootstocks, each erect culm with the lowest internodes orange and cormlike .... 4. *P. chapadense*
8b. Plants short-rhizomatous, without the lowest internodes orange and cormlike.
9a. Plants with thickened, fusiform roots; culms branched; panicles 7–22 cm long; Brazil, Bahia, Piauí .... 8. *P. piauiense*

9b. Plants with thin roots; culms simple or rarely branched; panicles 20–60 cm long; Brazil, Espírito Santo to Rio Grande do Sul .... 10. *P. rude*

6b. Lower glume ⅓–½ the length of the spikelet; culms extensively creeping and rooting at the lower nodes; leaf blades ovate-lanceolate to lanceolate, 2.5–10 cm long; Mesoamerica to Colombia and Venezuela (*P. pulchellum* in Brazil, species with leaves 2.5–5.5 cm long, spikelets 1.8–2.3 mm long).

  10a. Lower lemma without glands; spikelets length : width ratio 5–6 : 1. Leaf blades lanceolate .... 1. *P. andreanum*

  10b. Lower lemma with glands; spikelets length : width ratio 3–4 : 1. Leaf blades ovate-lanceolate to lanceolate.

    11a. Spikelets (3–)3.2–3.7(–4) mm long; nodes glabrous .... 2. *P. biglandulare*

    11b. Spikelets 1.8–3.1 mm long; nodes densely pubescent.

      12a. Spikelets 1.8–2.3 mm long; lower glume separated from the upper glume by a conspicuous internode; leaf blades length : width ratio 2.5 : 1 .... 9. *P. pulchellum*

      12b. Spikelets 2.5–3.1 mm long; internode inconspicuous between the lower and upper glume; leaf blades length : width ratio 6 : 1 .... 5. *P. crateriferum*

1. **Panicum andreanum** Mez, Bot. Jahrb. Syst. 56, Beibl. 125: 5. 1921. TYPE: Venezuela. Trujillo: Escuque, *Moritz 1538* (lectotype, B, fragments at US (80458, 1108611)). Figure 3.

Slender, creeping perennials with the *culms* decumbent and rooting at the lower nodes, then becoming erect and climbing up to 2.5 m into the shrubs, freely and densely branching at the lower and upper nodes; internodes cylindric, hollow, glabrous to sparsely pilose, 1.5–8 cm long; nodes brown, glabrous to sparsely pilose. *Leaf sheaths* 2–7 cm long, commonly longer than the internodes at basal nodes or shorter at the upper ones, glabrous, striate and auriculate, the auricles small, densely pilose, one of the margins densely ciliate, the other glabrous. *Ligule* membranous-ciliate, 0.3–0.5 mm long; external ligule conspicuous, formed by a row of dense whitish hairs. *Leaf blades* lanceolate, 3–9 cm long, 0.3–0.6(–1.1) cm wide, flat, tapering into a finely attenuate apex, slightly narrowed to subcordate basally, hirsute, with long, thick papillose hairs to glabrous on both surfaces, the margins scabrous and cartilaginous, ciliate or glabrous basally; *pseudopetiole* glabrous, ca. 2 mm long. *Panicles* terminal, oblong, 6–16 cm long, 1–3 cm wide, with racemose primary branches alternate and divergent from the axis, the spikelets borne in pairs on short, unequal scabrous or pilose pedicels (the lower subsessile), these arranged along lower sides of branches; axis longitudinally ridged, smooth, scabrous, the axis of the branches triquetrous, scabrous, the axils of the branches pilose with dark hairs. *Spikelets* lanceolate, somewhat compressed laterally, 2.5–2.8 mm long, 0.4–0.6 mm wide, acuminate, greenish to stramineous, pilose, with the upper glume and lower lemma subequal (or the upper glume a little shorter than the lemma). *Lower glume* ovate, acute, 1.1–1.4 mm long, ⅓(–½) the length of the spikelet, 3-nerved, the midnerve scabrous toward the apex, shortly pilose on the inner surface, sparsely pilose on the outer surface, bearing a few long hairs at the base. *Upper glume* 2.2–2.4 mm long, 5(–7)-nerved, the midnerve scabrous toward the apex, with long hairs in the hyaline margins. *Lower lemma* glumiform, 2.4–2.6 mm long, 5-nerved, hispid toward the margins. *Lower palea* lanceolate, 1.8–2.1 mm long, 0.3–0.4 mm wide, hyaline, short-pubescent at the apex, otherwise glabrous, the margins scabrous; male flower present. *Upper anthecium* lanceolate, 1.7–1.8 mm long, 0.4 mm wide, stramineous. *Caryopsis* ovoid, 1.2 mm long, 0.3 mm wide; hilum oblong. In flower November to May.

Distribution. Venezuela and Colombia. In wet forests on sandy soils at 400–1,800 m elevation.

Additional specimens examined. COLOMBIA. CUNDINAMARCA: near Quetame, Río Negro valley, between Quetame and Piperal, *Killip 34220* (COL, US); entre Quetame y Sasumuco, *Triana 263* (US); Quetame, *Triana*

US). Without department and locality, *Karsten s.n.* (paratype, US). VENEZUELA. MÉRIDA: between Mucuchachi and Canagua, *Steyermark 56345* (US). TÁCHIRA: Cordero, *Muller s.n.*, 14 Nov. 1939 (US-1762338); Cerro Las Minas, 18 km SE of Santa Ana, *Steyermark et al. 120043* (US); Cerro La Camirí, just south of the town of Río Negro, *Davidse & González 21555* (US); 2 km E of El Variante, *Davidse & González 21523* (US).

When describing this species, Mez cited three syntypes for it, of which the specimen

Moritz 1538 is selected here as lectotype of *P. andreanum*, taking into consideration its protologue.

2. **Panicum biglandulare** Scribner & Smith, U.S.D.A. Bull. (1895–1901) 4: 13, pl. 4. 1897. TYPE: Mexico. Chiapas: near Pinabete, 8 Feb. 1896, at an altitude of 6,500 to 8,000 feet, *Nelson 3781* (holotype, US; isotype, GH). Figure 4.

Perennials 40–80(–100) cm tall. *Culms* decumbent and rooting at the lower nodes or ascending, branching, with many nodes; internodes cylindric, hollow, sparsely pilose to glabrous, with thin, whitish hairs; nodes greenish to purplish, constricted, glabrous. *Leaf sheaths* 2–4 cm long, usually shorter than the internodes, striate, densely ciliate at the margins, otherwise glabrous. *Ligule* membranous, shortly ciliate or glabrous at the apex, 0.3–0.5 mm long, external ligule a conspicuous ring of white hairs or absent; collar shortly pilose. *Leaf blades* ovate-lanceolate to lanceolate, 3–10.5 cm long, 1.1–1.9 cm wide, acuminate, with strigose to papillose hairs on both surfaces to glabrous, asymmetrical and subcordate basally, the margins ciliate to scabrous, the lateral nerves anastomosing; *pseudopetiole* short, glabrous to short-pilose. *Panicles* exserted, oblong, 8–18 cm long, 1–4 cm wide, with 5–10 short, sparse, alternate, and racemose branches, these slightly divergent from the axis, the spikelets borne in pairs (the lower one occasionally abortive) on the branches, the axis of the branches triquetrous (rather flat), hirsute, more so toward the base; the axils of the branches densely pilose; pedicels short, hispid. *Spikelets* lanceolate, acuminate, hispid, (3–)3.2–3.7(–4) mm long, 1–1.1 mm wide, greenish to purplish. *Lower glume* ovate, acute, 1.3–1.8 mm long, ⅓ the length of the spikelet, hirsute on the outer surface, sparsely and shortly pilose basally, with long, papillose-pilose hairs toward the apex, 3-nerved, the midnerve finely scabrous at the upper part. *Upper glume* shorter than the lower lemma, sometimes leaving the summit of the anthecium exposed, acute, 5(–7)-nerved, glabrous on the inner surface, with stiff, papillose hairs on the outer surface, these becoming more abundant toward the hyaline margins. *Lower lemma* acute, 5(–7)-nerved, scabrous, with long, papillose hairs toward the hyaline margins; 2 conspicuous crateriform glands present between the midnerve and the 2 immediate lateral nerves. *Lower palea* lanceolate, acute, 3–3.2 mm long, 0.8 mm wide, membranous, scabrous at the margins, otherwise glabrous; male flower present, anthers ca. 1.3 mm long. *Upper anthecium* lanceolate, acute, 2–2.5 mm long, 0.7–0.8 mm wide, stramineous. *Caryopsis* ellipsoid, 1.4 mm long, 0.6 mm wide, brown; hilum oblong. In flower November to August.

Distribution. Occurring in Mexico and Guatemala in forests between 1,300 and 2,800 m elevation.

Additional specimens examined. GUATEMALA. ALTA VERAPÁZ: Cobán, *von Tuerckheim II 1342* (GH, NY, US), *II 1956* (NY, US); hills between Cobán and Tres Cruces, *Standley 90263* (F, US). SAN MARCOS; near Aldea Fraternidad, between San Rafael Pié de la Cuesta and Palo Gordo, west-facing slope of the Sierra Madre mountains, *Williams et al. 26050* (F, NY, US); barrancas 6 mi. S and W of town of Tajumulco, northwestern slopes of Volcán Tajumulco, *Steyermark 36678* (F, US). MEXICO. CHIAPAS: 2 mi. NE of Pueblo Nuevo Solist, *Lathrop 5820* (US); Laguna Montebello, Montebello National Park, *Breedlove & Dressler 29530* (F, NY); SE of Cerro Baúl on the border with the state of Oaxaca, 16 km NW of Rizo de Oro along a logging road to Colonia Gigaroa, *Breedlove & Smith 21699* (NY); 5 km SE of Jitotol along road to Bochil, *Breedlove 23323* (NY); Montebello, *Carlson 2330* (US), *2332* (MO); Montecristo, *Matuda 2006* (F, GH, NY, US); Mt. Pasitar, *Matuda 316* (RB, US); in the paraje of Kulak'tik, *Ton 1713* (F); 25 mi. E of La Trinitaria, Lago of Monte Bello, *Breedlove 9680* (US); Clínica Yerba Buena, 2 km NW of Pueblo Nuevo Solistahuacán, *Raven & Breedlove 19846* (US); Sierra Madre, *Tateoka 1009* (US).

3. **Panicum brachystachyum** Trin., Gram. Pan. 138. 1826. TYPE: Brazil. Minas Gerais: Serra do Cipó, Jan. 1825, *Langsdorff s.n.* (holotype, LE, not seen, fragment at US; isotype, P). Figure 5.

Perennials ca. 18–35 cm tall. *Culms* erect, branching at the base; internodes cylindric, hollow, sparsely pilose; nodes stramineous,

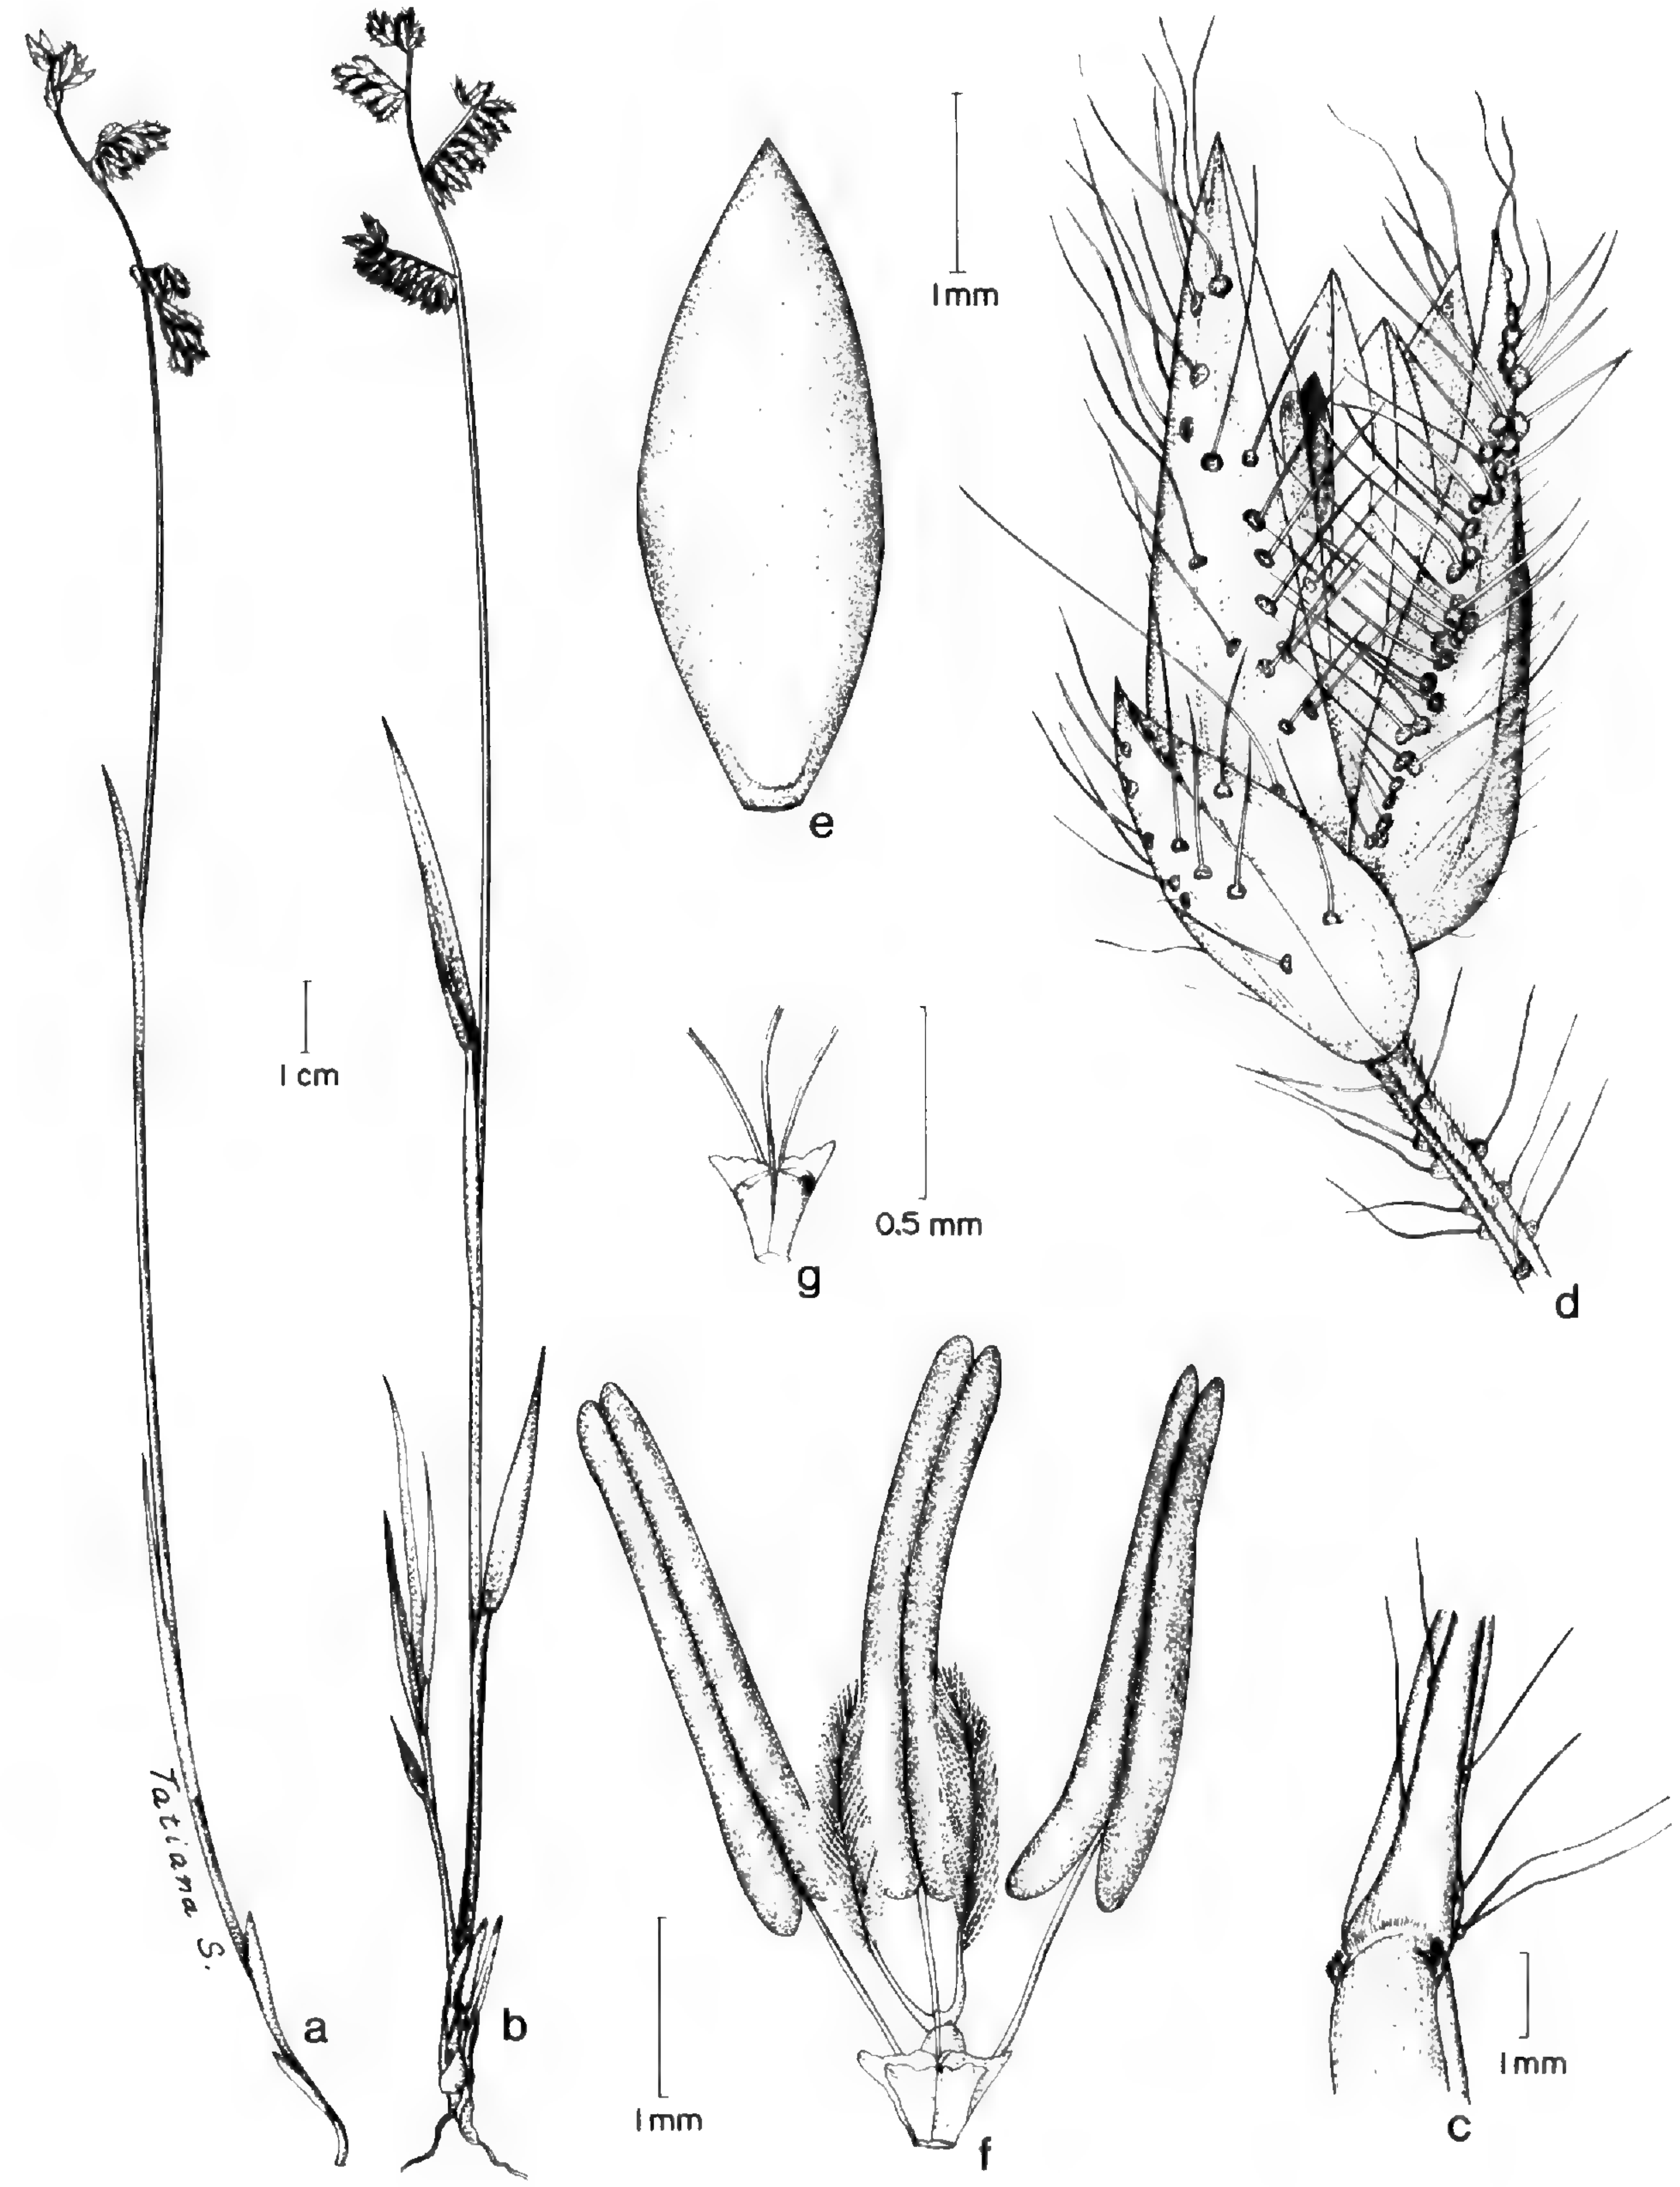

FIGURE 5. Panicum brachystachyum.—*a, b. Habit.—c. Ligule.—d. Spikelet, lateral view.—e. Upper anthecium, dorsal view.—f. Flower.—g. Lodicules. a, c–g based on* Langsdorff s.n. *(US); b based on plate of Trinius (1829).*

glabrous to short-pilose. *Leaf sheaths* stramineous, striate, sparsely pilose, with small auricles, densely pilose, the margins short-ciliate. *Ligule* membranous-ciliate, arcuate, 0.3–0.4 mm long. *Leaf blades* lanceolate, 3–4.5 cm long, 0.2–0.3 cm wide, acuminate, flat or subinvolute, glabrous, subcordate to narrowed basally, the margins scabrous and with sparse, papillose hairs; the midnerve inconspicuous. *Panicles* exserted, formed of 2–4 alternate, densely flowered, distant and spreading racemose branches 1–4 cm long;

peduncle hispid; axis flattened, scabrous and long-hispid, the axils of the branches densely papillose; axis of the branches hispid to scabrous, the pedicels arranged in pairs on one side of the branch, the pedicels triquetrous, hispid and with long papillose-pilose hairs. *Spikelets* broadly ellipsoid, 4.9–5.2 mm long, ca. 3.5 mm wide, grayish, gaping; glumes and lower lemma with long papillose-pilose hairs, the upper glume and lower lemma subequal, acute to acuminate, exceeding the upper anthecium in length. *Lower glume* ovate, acuminate, 2.8–3 mm long, ⅓–½ the length of the spikelet, covered with thick, papillose hairs, 1–3(–5)-nerved, the midnerve scabrous. *Upper glume* broadly ovate, 5-nerved, with thick papillose hairs near the margins, the rest of the surface with fine whitish hairs. *Lower lemma* glumiform, 3–5-nerved, with sparse, irregularly scattered, papillose hairs, these more dense toward the apex, the margins hyaline. *Lower palea* lanceolate, 3.9–4.5 mm long, 1.2 mm wide, membranous, the margins shortly ciliate; male flower present, the anthers dark purple, 3.2 mm long. *Upper anthecium* lanceolate, 4–4.4 mm long, 1.2 mm wide, membranous, acute to acuminate, whitish to stramineous; lemma slightly carinate, 3–5-nerved; anthers ca. 3.3 mm long, lodicules ca. 0.5 mm long, cuneate, with raised distal margins; ovary ovoid; anthers dark purple. *Caryopsis* not seen.

This species has been collected only once, in 1825, by *Langsdorff* "in saxosis montis alti da Lapa," now the Serra do Cipó, Minas Gerais, Brazil. The collection presumably consisted of a single individual, which was divided in three parts. One part is the holotype in LE, from which the plate in Trinius (1829) was probably drawn. The second part is the P isotype. The third part is a fragment of the type (taken from the LE specimen) in US and consists of a single branch without base. The plant from the Trinius plate and the US specimen are illustrated in the present paper to give a more complete view of this rare and probably extinct grass. Many collecting trips have been made to the Serra of Cipó by T. Sendulsky and by other botanists, but this species has never been collected again.

4. **Panicum chapadense** Swallen, Contrib. Science 22: 8, fig. 4. 1958. TYPE: Brazil. Goiás: collected on sandstone outcrop, 7 km south of Veadeiros, region of the Chapada dos Veadeiros, 24 Apr. 1956, *Dawson 14602* (holotype, R; isotype, US). Figure 6.

P. pirineosense Swallen, Phytologia 14: 78. 1966. TYPE: Brazil. Goiás: collected between rocks, at Pirineus, 18 Oct. 1956, *Macedo 4805* (holotype, US; isotypes, BAA, SP, US).

Rather robust perennials with long, creeping, horizontal rootstocks, the *culms* erect, 50–140 cm tall, with a cormlike base, 2 or 3 basal internodes orange-colored, 1–4 cm diam., glabrous, shining, lightly covered with aphyllous, velutinous old scales; new innovations appearing between those thickened internodes and covered by small, hard, yellow, pilose scales; upper internodes cylindric, solid, shortly pilose or glabrous, striate; nodes dark, constricted and shortly pilose, the first node swollen, yellow, glabrous, shining. *Leaf sheaths* stramineous, 5–11 cm long, longer (basal) or shorter than the internodes, densely villous to papillose-pilose all over the surface or pilose toward the apex only; the upper margins ciliate, the lower ones membranous; auricles small, rounded, sometimes densely pilose. *Ligule* membranous, ciliate, ca. 0.5 mm long, with or without long hairs behind the membrane at the base of the blade; external ligule present or absent. *Leaf blades* lanceolate, 12–23 cm long, 1.3–2.5 cm wide, with ciliate to scabrous margins, subcordate basally and velutinous to glabrous on both surfaces, the midnerve not prominent; *pseudopetiole* small. *Panicles* terminal, lax, oblong to pyramidal, with many flowers, 13–26 cm long, 2–6 cm wide, the primary branches racemose, dense and alternate, appressed or slightly divergent from the axis (the lower branches shortly branching at the very base), the spikelets secund and arranged in pairs on

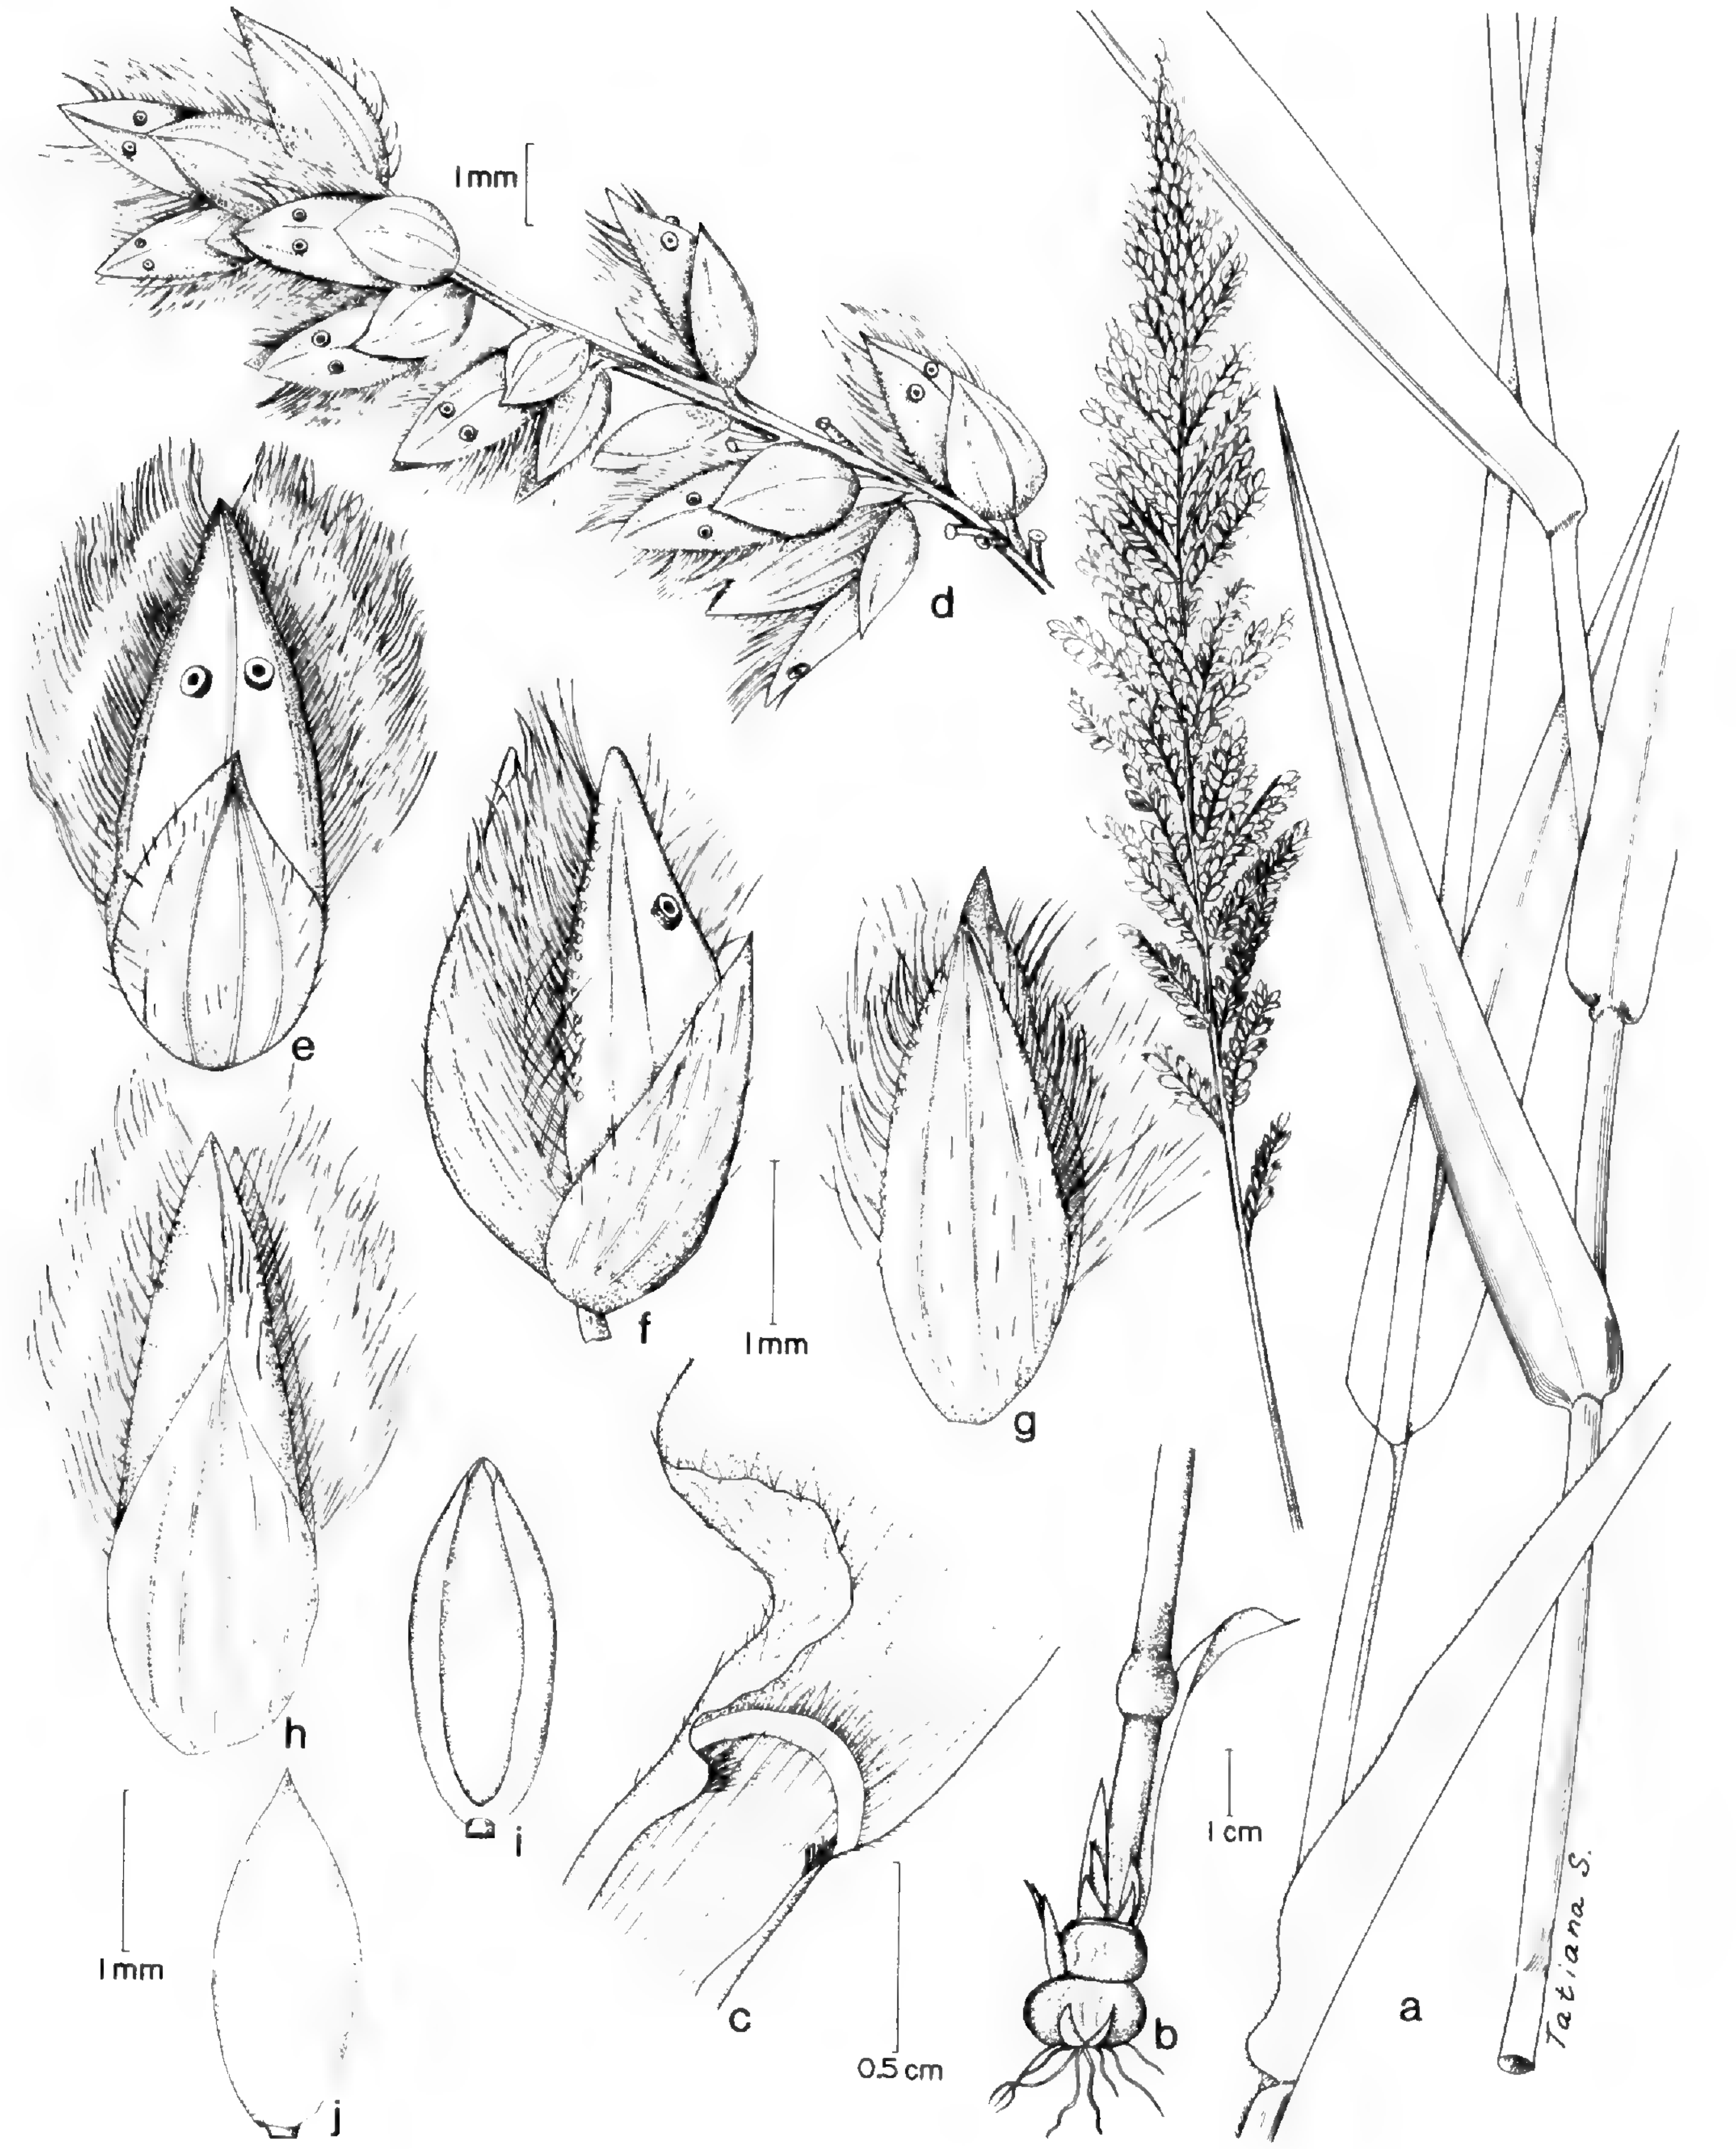

FIGURE 6. Panicum chapadense.—*a. Leafy stems.—b. Culm showing cormlike base.—c. Ligule.—d. Portion of a racemose branch.—e. Spikelet, ventral view, lower lemma with glands.—f. Spikelet, lateral view.—g. Spikelet, dorsal view.—h. Spikelet, ventral view, lower lemma without glands.—i. Upper anthecium, ventral view.—j. Upper anthecium, dorsal view. Based on* Burman & Filgueiras 450 *(SP)*.

short, unequal pedicels, on the lower side of the branches; axis longitudinally ridged, nearly glabrous or finely hispid, the axis of the branches triquetrous, hispid to scabrous, the axils of the branches densely pilose, brownish, sometimes with 1 or 2 long hairs; pedicels hispid and slightly pubescent. *Spikelets* narrowly ellipsoid, 2.5–3(–3.3) mm long, 0.6–

0.8 mm wide, stramineous, with purplish traces, the upper glume and lower lemma subequal and exceeding the upper anthecium in length. *Lower glume* ovate, acute, 1.6–1.9 mm long, ½–¾ as long as the spikelet, 3(–5)-nerved, shortly pubescent on both surfaces (more so on the upper surface). *Upper glume* acute, 2.2–2.8 mm long, 5-nerved, the midnerve scabrous, densely hispid on the outer surface, with long, papillose, whitish and fringed hairs toward the margins, the inner surface pilose toward the apex. *Lower lemma* glumiform, 2.2–2.8 mm long, 5-nerved, with a pubescence similar to that of the upper glume, with or without 2–4 crateriform glands on the middle portion. *Lower palea* lanceolate, 1.8–2.2 mm long, 0.5–0.7 mm wide, stramineous, shortly pubescent, the margins ciliate; male flower present. *Upper anthecium* narrowly ovoid, 1.5–1.9 mm long, 0.5–0.7 mm wide, acute, stramineous. *Caryopsis* not seen. In flower March to October.

Distribution. Endemic to Goiás, Brazil. Occurring in "campos rupestres" and "cerrados" between stones in rocky habitats at 1,000–1,600 m elevation.

Additional specimens examined. BRAZIL. GOIÁS: 5–15 km S of Veadeiros, road to São João d'Aliança, *Prance & Silva 58824* (MO, NY, US); 22 km N of Alto do Paraíso, *Irwin et al. 32492* (F, NY); 20 km by road N of Alto Paraíso, *Anderson 6760* (NY, UB, US); ca. 15 km S of Goiás Velho, *Anderson 9976* (UB); ca. 15 km N of Corumbá do Goiás, *Anderson 10305* (UB); serra do Pirineus, *Burman & Filgueiras 410, 450* (SP); 12 km NW of Veadeiros, road to Cavalcante, *Irwin et al. 9419* (US); ca. 15 km S of Veadeiros, *Irwin et al. 12782* (MO, NY); Corumbá, Montes Pirineus, *Onishi et al. 98* (R). Without locality, *Macedo 4380* (US).

A remarkable feature of this species is the presence of cormlike structures at the base of each culm, a character occasionally present in other species of *Panicum*, for example, *P. bulbosum* Kunth and *P. paucifolium* Swallen.

When describing *P. chapadense*, Swallen included it in sect. *Laxa*. This species has no affinity with sect. *Laxa*, being distinct by the type of spikelet, presence of glands on the lower lemma, and smooth and glabrous upper anthecium.

5. **Panicum crateriferum** Sohns, J. Wash. Acad. Sci. 46: 378, figs. 10–22. 1956. TYPE: Mexico. Guerrero: on steep grassy slopes and narrow ravine with open pine woods and scattered oaks on granitic soil at km 339–340 between Acahuizotla and Agua de Obispo, on highway to Acapulco, ca. 3,000 ft., 1 Oct. 1949, *Moore Jr. 5148* (holotype, US; isotype, GH). Figure 7.

Perennials, the *culms* decumbent, creeping and rooting at the lower nodes, becoming erect, 20–60 cm tall, branching; internodes hollow, 2.5–6 cm long, glabrous to sparsely pilose with whitish long hairs; nodes dark, densely pilose with whitish hairs. *Leaf sheaths* 0.8–2.5 cm long, shorter than the internodes, glabrous to hispid, more densely so toward the upper portion, the margins long-ciliate toward the apex, otherwise glabrous; collar a nitid, wide rim of dense, whitish, antrorse hairs. *Ligule* membranous-ciliate, ca. 0.4 mm long. *Leaf blades* ovate-lanceolate to lanceolate, flat, 4–6 cm long, 0.6–1.3 cm wide, asymmetrical basally, with the adaxial surface sparsely papillose-strigose, the abaxial surface glabrous to sparsely papillose-strigose, the margins ciliate basally, otherwise glabrous; midnerve inconspicuous, the lateral nerves anastomosing; *pseudopetiole* small, pilose. *Panicles* lax, 5–10 cm long, 1.5–6 cm wide, with 4–6 racemose and alternate branches, distant and divergent from the rachis, the uppermost branch consisting of a long pedicel and a single spikelet only; the spikelets borne in pairs, one subsessile (occasionally abortive), the other shortly pedicellate, arranged along the lower side of the branches; axis longitudinally ridged, glabrous, the axis of the branches triquetrous (one side flattened), scabrous, with or without scarce, long, papillose hairs, the axils of the branches densely pilose with stiff and papillose hairs; pedicels short, scabrous. *Spikelets* narrowly ovoid to lanceolate, 2.5–3.1 mm long, 0.8–1.1 mm wide, sparsely to densely papillose-pilose or hirsute, the glumes and lower lemma subequal or the upper glume a little shorter than the lemma,

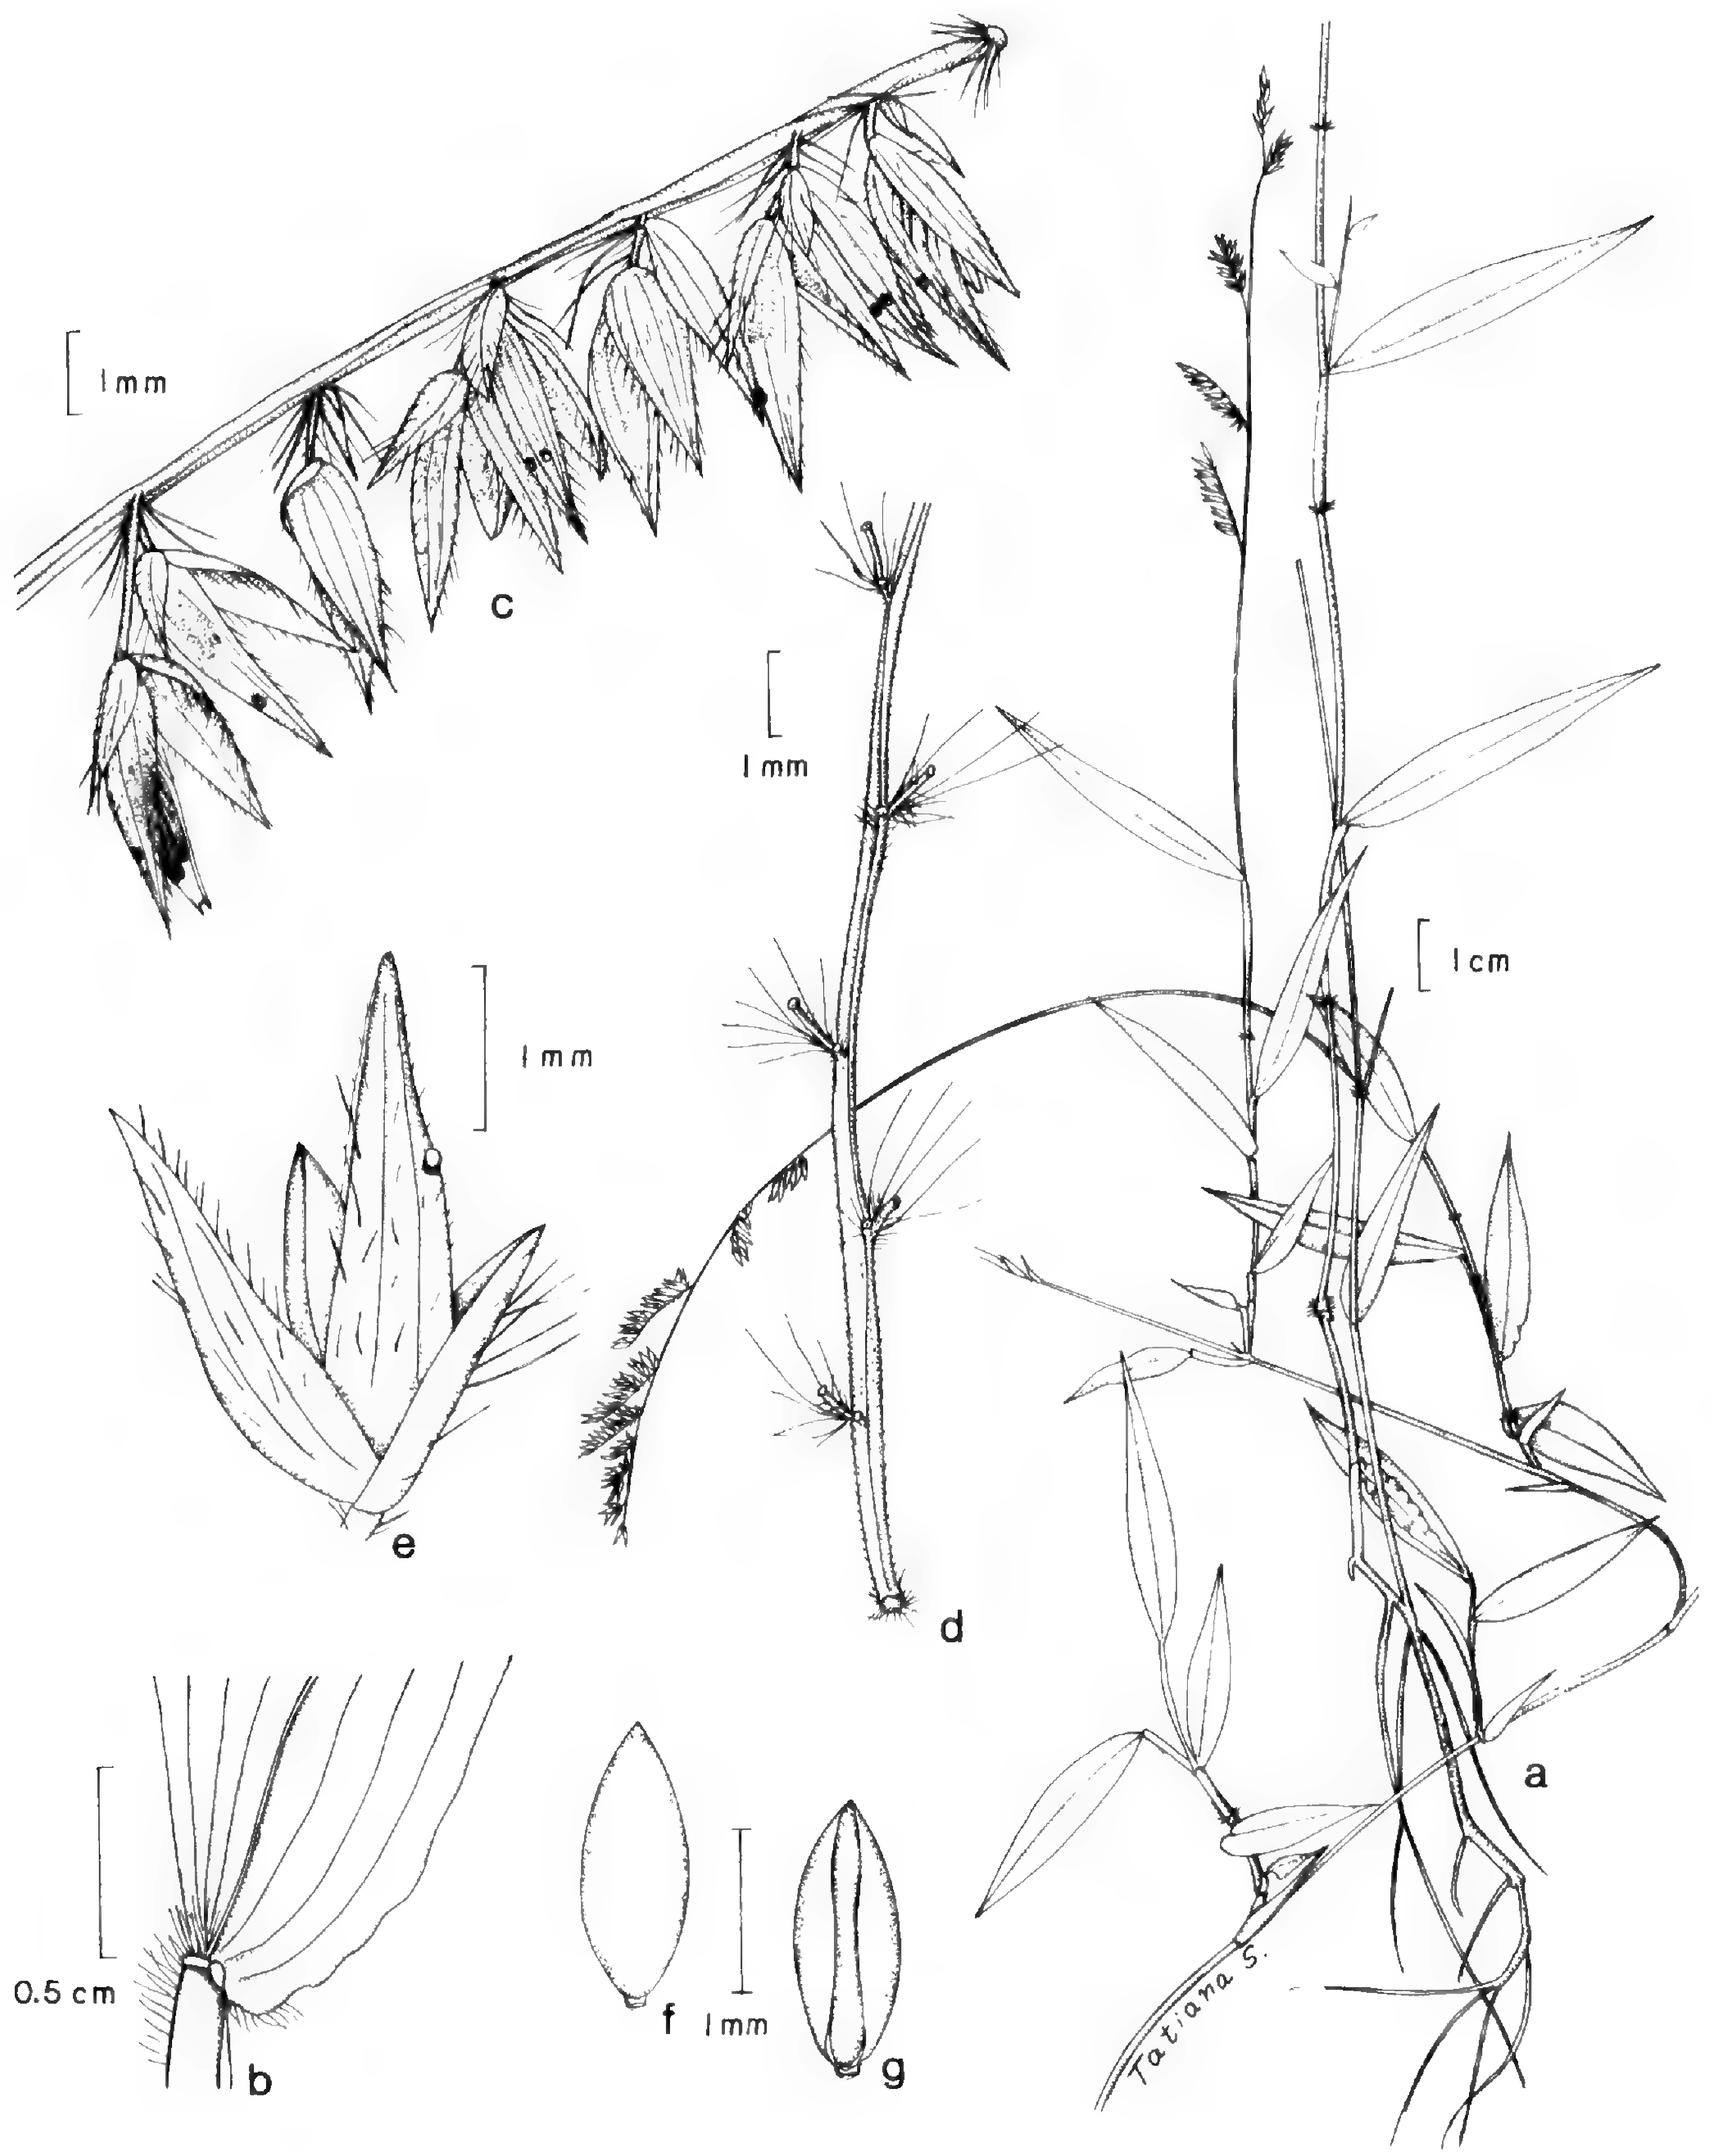

FIGURE 7. Panicum crateriferum.—*a. Habit.—b. Ligule.—c. Portion of a racemose branch.—d. Portion of a branch showing pedicels.—e. Spikelet, lateral view.—f. Upper anthecium, dorsal view.—g. Upper anthecium, ventral view. Based on* Hinton et al. 10801 *(US)*.

acute, the margins hyaline. *Lower glume* ovate-lanceolate, 1.3–2 mm long, ⅓–½ the length of the spikelet, acuminate, with long papillose-pilose hairs toward the apex and margins, the rest of the surface shortly pilose, 3(–5)-nerved, the midnerve scabrous. *Upper glume* 2.1–2.8 mm long, 5(–7)-nerved, papillose-hirsute toward the apex. *Lower lemma* 2.4–3 mm long, glumiform, 5(–7)-nerved, sparsely pilose, long-pilose or glabrous toward the margins, with 2 crateriform glands toward the upper part. *Lower palea* lanceolate, 2.2–

2.6 mm long, 0.5–0.6 mm wide, hyaline, ciliate at the margins, scabrous at the apex; male flower present. *Upper anthecium* ellipsoid, 1.5–2 mm long, 0.5–0.6 mm wide, stramineous. *Caryopsis* not seen. In flower October to November.

Distribution. Endemic to Guerrero and Oaxaca, Mexico; up to 1,000 m elevation.

Additional specimens examined. MEXICO. GUERRERO: Carrizo–Santo Domingo, *Hinton et al. 14725* (paratype, US); Plan del Carrizo, *Hinton et al. 14646* (paratype, US); Montes de Oca, *Hinton et al. 10801* (paratype, US). OAXACA: region of Chinantla, Santa María de Lovaoi, San Juan de Petlapa, *Vera Santos 3437* (US); La Soledad, *Ernst 2593* (US).

A few three-flowered spikelets were found on the collection *Hinton et al. 10801*; here the spikelets had two lower flowers, one neuter and the other with stamens, and one hermaphrodite flower in the upper anthecium. These spikelets have two lemmas, both with crateriform glands, one neuter (the lower without a palea) and the other, in an intermediate position, with its corresponding palea and male flower.

This characteristic three-flowered spikelet has been found previously and consistently in *P. quadriglume* (Doell) A. Hitchc.

6. **Panicum irregulare** Swallen, J. Wash. Acad. Sci. 30: 216. 1940. TYPE: Costa Rica. San José: vicinity of El General, 760 m, Feb. 1939, *Skutch 4115* (holotype, US; isotypes, GH, MO, NY). Figure 8.

Probably perennials. *Culms* decumbent, rooting and branching at the lower nodes, becoming erect, 60–80 cm tall; internodes cylindric, 4.3–11 cm long, glabrous, hollow; nodes glabrous. *Leaf sheaths* 3.2–4.8 cm long, shorter than the internodes, auriculate, the auricles pilose, the margins glabrous, membranous. *Ligule* membranous-ciliate, 0.3–0.5 mm long, with long hairs toward the base of the blade; adaxial surface of the collar shortly and densely pilose. *Leaf blades* ovate-lanceolate, 7–13 cm long, 1.5–3.3 cm wide, narrowed and somewhat asymmetrical basally, finely scabrid and with strigose hairs to nearly glabrous on the adaxial surface, the abaxial surface finely scabrid to nearly glabrous, the midnerve conspicuous, the lateral nerves anastomosing; *pseudopetiole* pilose, stramineous, ca. 1 mm long. *Panicles* terminal, oblong, exserted, 14–28 cm long, 3–7 cm wide, with 15–30 racemose branches ± divergent from the axis, alternate, and distant, usually drooping, the spikelets borne in pairs, one subsessile (occasionally abortive), the other shortly pedicellate arranged along one side of the branch; axis cylindric, finely scabrid, the axis of the branches somewhat flattened, scabrous, sparsely hirsute, the axils of the branches pilose; pedicels triquetrous, scabrous, pilose toward the base. *Spikelets* long-ellipsoid, biconvex, 1.8–2.3 mm long, 0.7–1 mm wide, greenish, scabrous to short pilose, the upper glume and lower lemma subequal (or the upper glume occasionally shorter), both with long hairs toward the margins to glabrous. *Lower glume* ovate, acute, 0.7–1.1 mm long, ¼–½ the length of the spikelet, 3-nerved, the midnerve scabrous. *Upper glume* 5-nerved, acute, pilose to finely scabrid toward the apex. *Lower lemma* glumiform, 5-nerved, acute, scabrous toward the apex. *Lower palea* elliptic, 1.4–1.5 mm long, 0.5 mm wide, hyaline, membranous, scabrous on the wings. *Lower flower* hermaphrodite; anthers ca. 1 mm long; stigmas 2, plumose. *Caryopsis* of the lower anthecium a little smaller than that present in the upper anthecium, 0.8–0.9 mm long, 0.4–0.5 mm wide, free from its lemma and palea. *Upper anthecium* ovoid, 1.3–1.5 mm long, 0.5–0.6 mm wide, stramineous, brown at maturity. *Caryopsis* ovoid, 0.8–1.2 mm long, 0.4–0.6 mm wide, the hilum punctiform to oblong. In flower November to April.

Distribution. Costa Rica to Colombia and Venezuela at 650–2,000 m elevation.

Additional specimens examined. COSTA RICA. ALAJUELA: Río Grande, cerca de San Ramón, *Brenes 19683* (NY). SAN JOSÉ: Basin of El General, *Skutch 4816* (GH, NY). COLOMBIA. Without locality: *Smith 2571* (GH). VENEZUELA. ARAGUA: slopes of mountainside near stream, between Choroní and Maracay, *Soderstrom 978* (US);

Parque Nacional Henry Pittier, NW of Maracay, Rancho Grande, *Davidse 3017* (US).

Although having the diagnostic characters of sect. *Stolonifera*, *P. irregulare* differs by the presence of an hermaphrodite flower in the lower floret, a character unknown elsewhere in the genus. This lower flower develops a normal caryopsis similar to the one present in the upper floret, only a little smaller. Unlike the upper anthecium, in the lower floret the lemma and palea are membranous, and the caryopsis is completely free from these bracts. Pohl (1980) suggested that this species may be a hybrid between genus *Panicum* and *Pseudechinolaena*, but we could find no evidence to support this. As previously stated, the species matches the characters that differentiate sect. *Stolonifera* from the other sections in subg. *Phanopyrum*.

7. **Panicum latissimum** Mikan ex Trin., in Sprengel, Neue Entdeck. Pflanzenk. 2: 87. 1821. TYPE: "*Panicum latissimum* Mikan detexit in Brasil et comm. an Mikan, sub cujus nom specium descripsi in Spr. gl. n. Entdx" (holotype, LE, not seen, fragment at US (974701)). Figure 9.

P. macrophyllum Raddi, Agrost. Bras. 46. 1823. TYPE: Brazil. Without locality: *Raddi s.n.* (holotype, PI, not seen, fragment at US (80732)).

Robust perennials up to 2.5 m tall. *Culms* decumbent and rooting at the lower nodes to erect, branching at the upper nodes; internodes cylindric, hollow, glabrous, up to 1.5 cm diam.; nodes brown, constricted, glabrous. *Leaf sheaths* 12–14 cm long, striate, stramineous, densely pilose, with long, whitish, caducous hairs or glabrous. *Ligule* membranous-ciliate, small, 0.2–0.3 cm long, external ligule absent. *Leaf blades* 30–35 cm long, 6–12 cm wide, flat, acuminate, glabrous, cordate and amplexicaul basally, the margins conspicuously ciliate to glabrous, the midnerve prominent or not prominent, the lateral nerves anastomosing; *pseudopetiole* brownish, glabrous, 0.6–1.3 cm long. *Panicles* pyramidal, lax and diffuse, many-flowered, 30–45 cm long, 10–18 cm wide, with alternate, distant, hirsute to scabrous branches diverging from the axis, sometimes with secondary and tertiary branchlets; spikelets short- to long-pedicelled, along the lower side of the branches; axis longitudinally ridged, minutely scabrous, the branches hirsute to scabrous, triquetrous; axils of the branches short- to long-pilose; pedicels pilose. *Spikelets* ellipsoid, acute, 2.7–3.1 mm long, 0.9–1.1 mm wide, stramineous to brownish or purplish, the glumes and lower lemma shortly pilose and scabrous, the upper glume and lower lemma subequal, acuminate, both with long hairs toward the margins. *Lower glume* narrowly ovate, acute, 2.5–2.7 mm long, ½–¾ the length of the spikelet, acuminate, shortly pilose to scabrous on the outer surface, densely pilose toward the apex of the inner surface, 5-nerved, the midnerve scabrous. *Upper glume* 2.5–2.9 mm long, 5(–7)-nerved, the midnerve scabrous. *Lower lemma* 2.7 mm long, glumiform, 5-nerved. *Lower palea* elliptic, 1.8–2.3 mm long, 0.6–0.8 mm wide, stramineous, shortly pilose, the margins ciliate; male flower present, the anthers ca. 1.7 mm long. *Upper anthecium* ellipsoid, acute, 2–2.2 mm long, 0.8 mm wide, stramineous. *Caryopsis* not seen. In flower October to April.

Distribution. Brazil. In mountains, humid and rocky habitats at 500–1,000 m elevation.

Additional specimens examined. BRAZIL. ESPÍRITO SANTO: Municipio de Alfredo Chaves, Vila São Bento de Urânio, mata higrófila, *Zuloaga et al. 2410* (RB, SI, US). RIO DE JANEIRO: between Alto Boa Vista and Silvestre, *Chase 8377* (F, MO, NY, US); vicinity of Paineiras, Corcovado, *L. Smith 1205* (F, GH, US); Corcovado, *Riedel 329* (US); without collector, *Oct. 1836* (R); estrada do Sumaré, *Pabst et al. 127* (MO); Petrópolis, *Goes & Dionisio 451* (RB), *Peixoto s.n.* (R); Serra dos Orgãos, perto do Veu das Noivas, *Carauta 712* (F); Serra dos Orgãos, *Vidal II-5580* (R), *Pereira 187* (RB); Parque Nacional da Tijuca, Bom Retiro, *Soderstrom et al. 1855* (US); Bico do Papagaio, *Landrum 2201* (RB), *Ule 4158* (R, US); Tijuca, *Chase 12159* (US), Oct. 1883, *Schwacke & Saldanha s.n.* (R); Pico da Tijuca, *Chase 8486* (US); Estrada da Guanabara, Mata do Sumaré, *Sucre 1748* (RB); Guanabara, Alto da Boa Vista, *Sucre 2091* (R); Sumaré, *Sucre 4071* (RB); Alto da Pedra da Gavea, *Sucre 4297* (RB); Teresópolis, *Vidal 18, 374* (R); estrada Teresópolis–Friburgo, Canoas, *Braga 1532* (RB); Rio de Janeiro, *Riedel 464* (R). Without locality: *Burchell 1110, 1381, 2158* (US); *Gardner 210* (GH, US); *Glaziou 504, 6973* (US), *17928* (P, US); *Riedel s.n.* (P); *Gaudichaud s.n.* (P).

Panicum latissimum is clearly distinguished from other species of sect. *Stolonifera* and from the rest of the genus by having leaves up to 12 cm wide.

8. Panicum piauiense Swallen, Sellowia 18: 110. 1966. Based on *P. blepharophorum* Mez, Bot. Jahrb. Syst. 56, Beibl. 125: 4. 1921. Not *Panicum blepharophorum* J. S. Presl. TYPE: Brazil. Piauí: without locality, July–Sep. 1839, *Gardner 2016* (holotype, BM, not seen, fragment at US; isotypes, GH, NY, P, US). Figure 10.

Ichnanthus gardneri Mez, Feddes Repert Spec. Nov. Regni Veg. Beih. 15: 132. 1918. TYPE: Brazil. Goiás: without locality, 1841, *Gardner 3512* (holotype, B, not seen; isotypes, BR, P, fragments at US).

Cespitose, moderately robust, short-rhizomatous perennials, 40–80 cm tall, with conspicuous, fusiform, long root tubers up to 3–5 mm thick, the cataphylls lanate. *Culms* erect, branching, many-noded, the internodes cylindric, densely to sparsely pilose or glabrous, hollow; nodes brown, constricted, shortly pilose. *Leaf sheaths* 4–6 cm long, longer than the internodes, stramineous, glabrous or scarcely pilose, one of the margins densely ciliate, with short, whitish hairs, the other glabrous. *Ligule* membranous-ciliate, 0.5 mm long, sometimes with long hairs toward the back at the base of the blade; external ligule a row of antrorse whitish hairs, the collar stramineous, pilose. *Leaf blades* lanceolate, 9–13 cm long, 1–1.5 cm wide, acuminate, flat, cordate to subcordate basally, scabrous to densely villous on both surfaces, the adaxial surface shortly pilose at the base, the margins white and cartilaginous, long-ciliate or glabrous basally, otherwise minutely scabrous; *pseudopetiole* small, shortly pilose. *Panicles* lax, oblong, 7–22 cm long, 2–4.5 cm wide, with the branches alternate and diverging from the axis, rarely with short, appressed secondary branchlets; axis longitudinally ridged, sparsely hispid, scabrous, the branches triquetrous, scabrous and sparsely hispid, bearing spikelets in pairs: one subsessile, the other shortly pedicellate, the lower one distant; axils of the branches long-pilose to villous; pedicels pilose or scabrous. *Spikelets* narrowly ellipsoid, 2.4–2.8 mm long, 0.8 mm wide, stramineous to purplish, sparsely pilose or with long hairs at the margins of the glumes and lower lemma. *Lower glume* ovate, acuminate, 1.8–2.5 mm long, ½–¾ the length of the spikelet, scabrous to sparsely pilose on the outer surface, densely pubescent toward the apex on the inner surface, 3-nerved, the midnerve scabrous. *Upper glume* acute to acuminate, 2.3–2.7 mm long, pilose to scabrous, with long, stiff and whitish hairs toward the margins on the outer surface, the inner surface shortly pilose, 5-nerved, the midnerve scabrous. *Lower lemma* glumiform, acute, 2.3–2.6 mm long, 5-nerved, with pubescence similar to that of the upper glume, with or without 2–4 prominent, ocellate and crateriform glands on the middle portion. *Lower palea* elliptic, 1.7–2 mm long, 0.6 mm wide, stramineous, shortly pilose, the margins ciliate; male flower absent. *Upper anthecium* narrowly ovoid, 1.7–2 mm long, 0.6 mm wide, stramineous. *Caryopsis* ellipsoid, 1.3 mm long; hilum oblong. In flower January to April.

Distribution. Brazil, in cerrados of Bahia and Piauí at 800 m elevation.

Additional specimens examined. BRAZIL. BAHIA: Chapadão do Panair, Serra do Mimo, *Black 55-17982* (IAN); Espigão Mestre, ca. 100 km WSW of Barreiras, *Anderson et al. 36751* (F, MO, R, US); Serra de Teririco, Gruta do Pequeño, *Zehntner 67* (R); Serra do Teririco, *Zehntner 3746* (RB, US); Serra do Sincorá, 15–20 km from Andaraí, along the road to Itaeté, *Harley et al. 18652* (MO, P).

This species can be mistaken for poorly developed plants of *P. rude,* but the latter normally reaches greater size (2 or 3 m high). *Panicum piauiense* differs further from *P. rude* by having food-storing thickened roots and by having culms that branch from the base up to the upper part of the plant. The

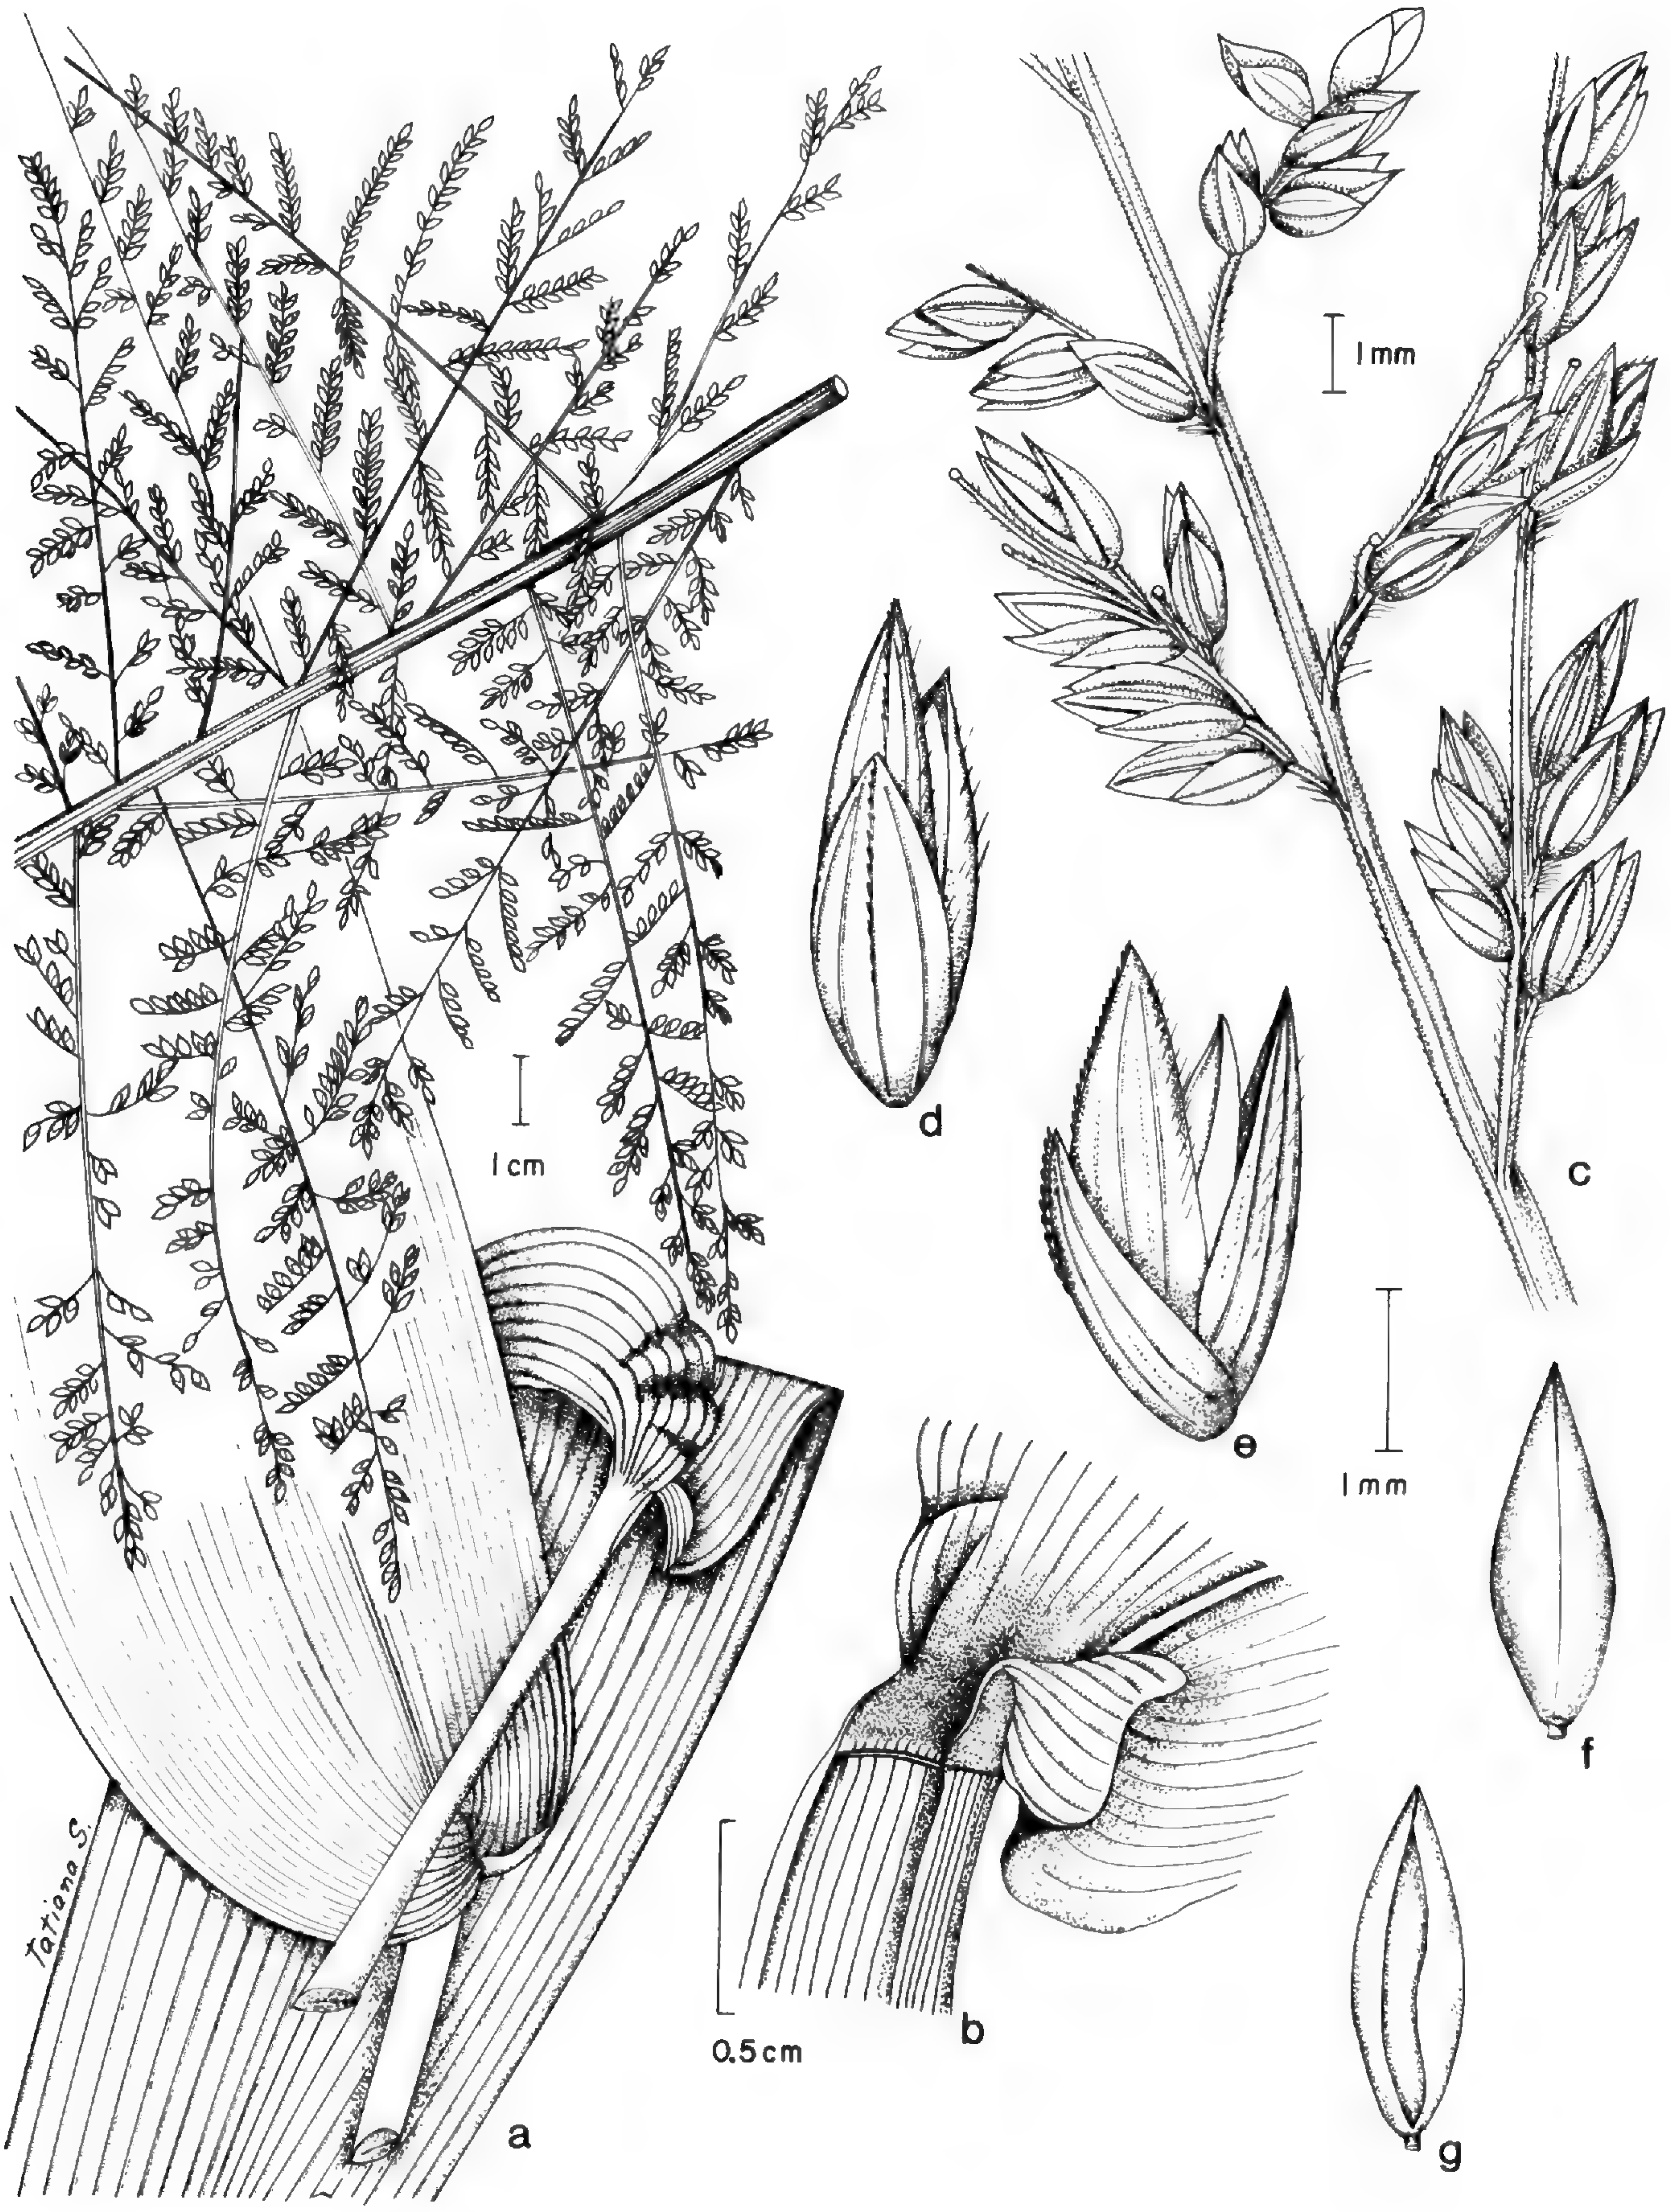

FIGURE 9. Panicum latissimum.—*a. Blades and portion of the panicle.—b. Ligule.—c. Portion of the panicle showing racemose branches.—d. Spikelet, ventral view.—e. Spikelet, lateral view.—f. Upper anthecium, dorsal view.—g. Upper anthecium, ventral view. Based on* Chase 8486 *(US)*.

two species also have different distributions, *P. piauiense* occurring only in Bahia and Piauí, *P. rude* from Espírito Santo to Rio Grande do Sul. The fusiform root tubers of *P. piauiense* are unique within *Panicum*. Soderstrom (1981) reported tubers in the nonpanicoid grasses *Puelia ciliata* Franch., *Lophatherum gracile* Brongn., *Molinia cae-*

9. **Panicum pulchellum** Raddi, Agrost. Bras. 42. 1823. *Eriochloa pulchella* (Raddi) Kunth, Rev. Gram. 1: 30. 1830. TYPE: Brazil. Rio de Janeiro: in sylvaticis prope Catumby, non procul ad urbe Rio de Janeiro, *Raddi s.n.* (holotype, PI, not seen, fragments at BAA, US). Figure 11.

P. leptostachyum J. S. Presl, Rel. Haenk. 1: 311. 1830. *Hymenachne leptostachya* (J. S. Presl) Fourn., Mex. Pl. 2: 36. 1886.
P. bipustulatum Schldl., Linnaea 26: 135. 1853.

Probably perennial. *Culms* decumbent, extensively creeping and rooting, geniculate at the lower nodes, then becoming erect, freely branching, 10–65 cm tall; internodes long, compressed, pilose to glabrous; nodes obscure, densely villous with whitish hairs. *Leaf sheaths* 0.7–2.5 cm long, shorter than the internodes, striate, membranous, densely pilose, with long, whitish hairs to glabrous, the margins ciliate. *Ligule* membranous-ciliate, ca. 0.4 mm long, the collar densely pilose. *Leaf blades* ovate-lanceolate, acuminate, 2.5–5.5 cm long, 1–2 cm wide, asymmetrical and cordate basally, strigose to glabrous on both surfaces, the basal margins long-ciliate with thick, caducous hairs, otherwise scabrous to ciliate, the abaxial surface often purplish; midnerve prominent, the lateral nerves anastomosing; *pseudopetiole* densely pilose, with long, thick hairs. *Panicles* terminal, 4–18 cm long, 1.5–4 cm wide, short- to long-exserted, the peduncle hispid, formed by 5–20 secund, alternate or occasionally opposite and racemose branches, these distant, ascending or reflexed, divergent from the axis; axis longitudinally ridged, hispid, the branches triquetrous, flattened on one side, densely hispid toward the base, hispid to scabrous on the rest of the surface, with spikelets borne in pairs, one subsessile, the other short-pedicellate (the subsessile spikelet frequently abortive), the axils of the branches pilose. *Spikelets* narrowly ellipsoid, 1.8–2.3 mm long, 0.6–0.7 mm wide, greenish, the glumes and lower lemma hirsute, the hairs papillose, rigid, short; upper glume and lower lemma subequal (or the upper glume shorter), acuminate. *Lower glume* ovate, acute, 0.8–1.1 mm long, ⅓–½ the length of the spikelet, short-pilose on the middle portion, hirsute toward the margins, separated from the upper glume by an internode, 3-nerved, the midnerve scabrous. *Upper glume* 1.8–2 mm long, 5-nerved, hirsute. *Lower lemma* 1.7–2.1 mm long, 5-nerved, short-pilose on the middle portion and long-pilose toward the margins, bearing 2 crateriform ocellate glands between the midnerve and the 2 immediate lateral nerves, or the glands occasionally absent. *Lower palea* 1.4–1.6 mm long, 0.4–0.6 mm wide, lanceolate, hyaline, short-ciliate at the margins, glabrous in the rest of the surface; male flower usually absent. *Upper anthecium* ellipsoid, acute, 1.2–1.5 mm long, 0.7–0.9 mm wide. *Caryopsis* ellipsoid, 1–1.2 mm long, 0.5–0.6 mm wide; hilum oblong. In flower all year.

Distribution. This species occurs from Mexico, Guatemala, Belize, Honduras, Nicaragua, Costa Rica, and Panama to Colombia, Venezuela, Ecuador, Peru, Boliva, and Brazil. It grows in humid and shaded places from sea level to 2,000 m elevation.

Chromosome number. $n = 10$ (Davidse & Pohl, 1974); $2n = 20$ (Gould & Soderstrom, 1970; Pohl & Davidse, 1971).

Robust, cespitose, short-rhizomatous perennials. *Culms* decumbent and rooting at the lower nodes to erect or leaning among branches of trees, 60–200(–300) cm tall, usually simple, the internodes cylindric, glabrous, hollow; nodes obscure, compressed, glabrous. *Leaf sheaths* 7–20 cm long, longer than the internodes, stramineous, auriculate, striate, papillose-pilose with caducous hairs to densely or sparsely hispid with whitish and appressed hairs, otherwise completely glabrous, the margins pilose to glabrous. *Ligules* membranous-ciliate, 0.5–2.5 mm long; external ligule conspicuous, similar to the inner ligule but smaller; collar brown, pilose to glabrous. *Leaf blades* lanceolate to long-lanceolate, acuminate, flat, 15–45 cm long, 1.6–5 cm wide, cordate to subcordate basally, hispid on both surfaces with appressed short hairs to glabrous, the margins scabrous, ciliate or glabrous; *pseudopetiole* brownish, 0.5–1 cm long and with ciliate margins. *Panicles* lax, pyramidal to oblong, many-flowered, 20–65 cm long, 5–25 cm wide, with secund branches alternate to subopposite, diverging toward the base of the panicles and contracted toward the apex, the spikelets short-pedicelled and disposed in pairs in the branches; axis longitudinally ridged, scabrous to densely hispid; branches and branchlets longitudinally ridged, scabrous and long- to short-pilose, the axils of the branches brownish, shortly pilose; pedicels scabrous, sometimes with long hairs. *Spikelets* ellipsoid, 2.3–3 mm long, 0.8–1.1 mm wide, stramineous or nearly purplish, the glumes and lower lemma sparsely to densely pilose, upper glume and lower lemma subequal and longer than the upper anthecium. *Lower glume* shortly pilose on both surfaces, acute, 1.4–2.5 mm long, ½–¾ the length of the spikelet, 3(–5)-nerved, the nerves anastomosed apically, the midnerve markedly scabrous. *Upper glume* 5(–7)-nerved, acute to acuminate, scabrous, pilose toward the margins and the base or with whitish hairs on the entire surface. *Lower lemma* 5(–7)-nerved, acute to acuminate, with pubescence similar to that of the upper glume, occasionally with one pair of glands on the middle portion. *Lower palea* lanceolate to elliptic, 1.8–2.5 mm long, 0.6–0.7 mm wide, hyaline, with long-ciliate margins; male flower present or absent. *Upper anthecium* ellipsoid, 1.7–2.3 mm long, 0.6–0.8 mm wide, stramineous to brownish at maturity. *Caryopsis* ovoid, light brown, 1.4–1.7 mm long, 0.8–1 mm wide; hilum oblong. In flower September to April.

Distribution. Brazil. Common in interior or edges of forests at 0–1,900 m elevation.

Common names. Papanduva, capim-papanduva, papua, capim papua, cana-de-macaco (Smith et al., 1982); capim de anta (*Pereira 2281*).

The polymorphous nature of *Panicum rude* lies behinds its numerous descriptions under different names. Its pilosity is variable on the vegetative and floral parts, with leaf sheaths, leaf blades, and inflorescences varying from densely pilose with different types of pubescence to glabrous.

The spikelets can be densely pilose on the glumes and lower lemma to glabrescent (only minutely scabrous on the glumes). The lower glume varies from ½ to about ⅘ the length of the spikelet, even in the same specimen (as for example in *Irwin et al. 29321*).

The crateriform glands on the middle portion of the lower lemma may be present or absent on the same specimen, but they are most often absent. These glands are present in the type specimens of "*P. bambusaefolium*" and "*P. secundum*," and they occur in *Irwin et al. 13196*. In the voluminous recently collected material in the Instituto de Botânica of São Paulo studied by T. Sendulsky, glands were not detected.

The illustration of *P. secundum* in Trinius (1836, pl. 324) draws attention to the peculiar one-sided position of the leaves. *Panicum rude* grows mostly at the borders of forests; when the culms develop in more or less open and uniformly lighted areas, they bear leaves distichously or alternately arranged. On the other hand, when the culms grow at forest margins and lean against dense vegetation, they receive light only from one side, which promotes unilateral arrangement of the leaves due to the twisting of the culm (Fig. 12).

Swallen (1966) treated five species closely related to *P. rude* within the Latissima group. The characters used by Swallen to separate these species were mainly pubescence of the leaf sheaths and blades and the sizes of plants and spikelets. We conclude that these characters do not justify separation of species.

Swallen cited *Chase 8165* as type of "*P. pompale*" and *Reitz & Klein 7043* as type of "*P. kleinii.*" It should be noted that these specimens are divided into two sheets each: *Chase 8165 I, Chase 8165 II, Reitz & Klein 7043 I,* and *Reitz & Klein 7043 II.* In both cases, *Chase 8165 I* and *Reitz & Klein 7043 I* contain the upper portion of a culm (including the panicle), and *Chase 8165 II* and *Reitz & Klein 7043 II* contain the vegetative part of the plant only. Consequently, *Chase 8165 I* and *Reitz & Klein 7043 I* should be considered as holotypes of the two names.

11. Panicum soderstromii Zuloaga & Sendulsky, sp. nov. TYPE: Brazil. Bahia: Município de Mucujê, 3 km ao S de Mucujê, na estrada para Jussiape, 1,000 m de alt., 13°00'S, 41°24'W, campo rupestre, 26 July 1979, *S. A. Mori, R. M. King, T. S. dos Santos & J. L. Hage 12652* (holotype, CEPEC; isotype, MO). Figure 13.

Gramen probabiliter perenne (basis non visa), 45–95 cm altum, *culmis* erectis, caespitosis, cylindricis, pilosis. *Foliorum vaginae* internodis superantie, sparse et longe pilosae, basilitex pilis papillosis instructae. *Ligula* brevissima, membranacea, arcuatae, breviter ciliata. *Foliorum laminae* anguste lanceolatae, acutae, 2–13 cm longae, utrinque breviter pilosae, basidus angustis, truncatis, marginibus rotundatis. *Paniculae* terminales, racemosae, pyramidales, effusae, 8–18 cm longae, 2–3(–4.5) cm latae; ramis adscentibus. *Spiculae* late ellipticae, plerumque hiantae, 2–2.8 mm longae, 1–1.5 mm latae, stramineae vel violaceae; *gluma inferior* ovata, ½–¾ longitudinis spiculae aequans, 3-nervis, pilis longis, albis, ad apicem, crassis; *gluma superior* acuta, spiculae subaequans, 3–5-nervis, marginibus subtiliter ciliatis. *Anthoecium inferum*: lemma ovatum, spiculam aequans, 5-nerve, marginibus subtiliter ciliatis, 2–4 glandulis crateriformibus, ocellatis, infra apicem sitis; palea acuta, ad apicem pilosa. *Anthoecium superum* ellipsoideum, stramineum, atrofuscum ad fructus maturitatem. *Caryopsis* ellipsoidea, 1.5 mm long, 1 mm lata, succinea; hilum ovatum sub-basale; embryo longitudine ca. ⅓ caryopsis aequans.

Cespitose, rather robust probable perennial, 45–70(–95) cm tall (base not seen), the lower nodes covered with small, pubescent sheaths. *Culms* erect, branching at the median and upper nodes; internodes cylindric, hard, solid or hollow, pilose, striate, the nodes

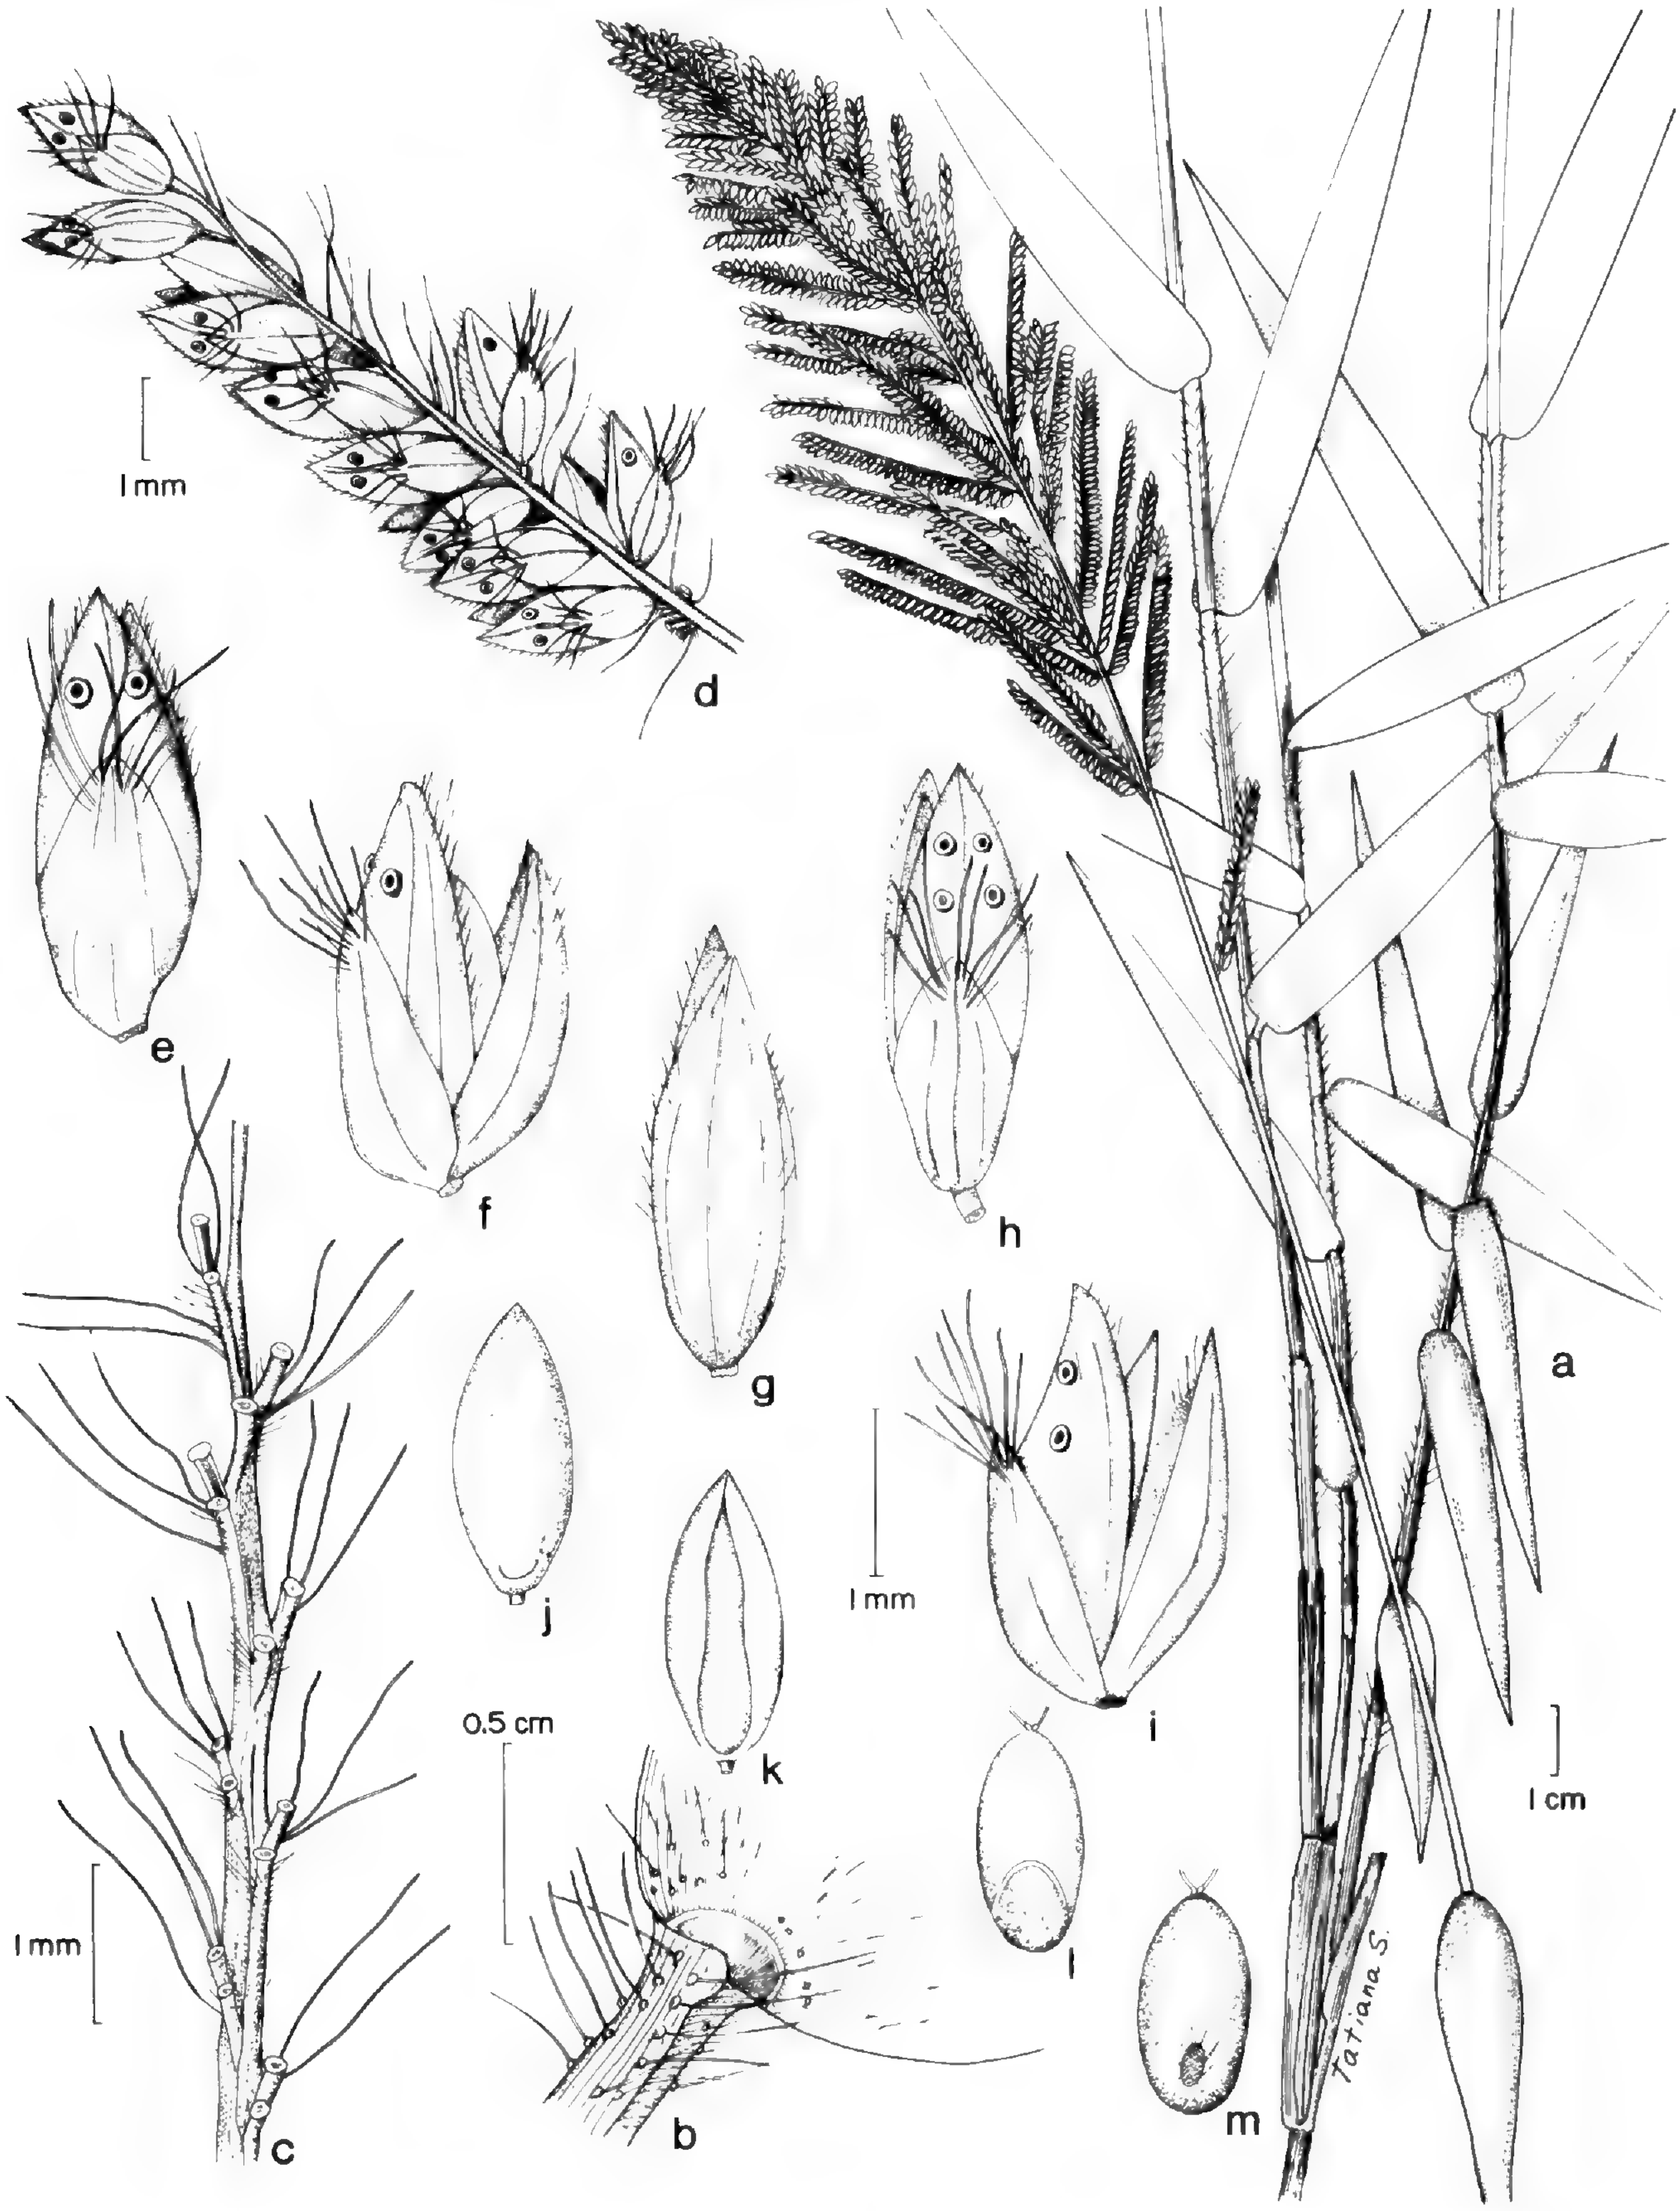

FIGURE 13. Panicum soderstromii.—*a. Leafy stems.—b. Ligule.—c. Portion of a branch showing pedicels.—d. Racemose branch.—e. Spikelet, ventral view.—f. Spikelet, lateral view.—g. dark, constricted, pilose. *Leaf sheaths* longer than the internodes, slightly auriculate, tightly embracing the culms, with long, papillose, pilose hairs; the lower sheaths approximate, short. *Ligule* membranous-ciliate, ca. 0.5 mm long; collar area densely pubescent, dark. *Leaf blades* long-lanceolate, 2–13 cm long, 0.7–1.3 cm wide, stiff, attenuate toward the apex, a little narrowed and truncate basally, with rounded margins, velutinous on both surfaces; the midnerve not prominent; the basal leaves ca. 2–3 cm long, smaller than the uppermost leaves; *pseudopetiole* short. *Panicles* terminal, pyramidal, 8–18 cm long, 2–3(–4.5) cm wide, with numerous, many-flowered, upwardly appressed or spreading racemose branches bearing spikelets in pairs on unequal pedicels; axis glabrous, longitudinally ridged, finely hispid along the ridges; axils of the branches slightly swollen, dark brown, pilose; pedicels with 2 or 3 papillose-pilose whitish and thickened hairs, these longer than the spikelet. *Spikelets* broadly ellipsoid, 2–2.8 mm long, 1–1.5 mm wide, laterally compressed, usually gaping, stramineous or purplish. *Lower glume* ovate, acute, 3-nerved, ½–¾ the length of the spikelet, with a tuft of long, white, papillose-pilose hairs at the apex, otherwise scaberulous. *Upper glume* ovate, acute, 3–5-nerved, a little shorter than the lower lemma, finely ciliate at the margins, otherwise scaberulous. *Lower lemma* ca. 2 mm long, ca. 1 mm wide, 5-nerved, finely ciliate at the margins, otherwise scaberulous, with 2–4 crateriform, ocellate glands; the inner surface pilose. *Lower palea* acute, finely pilose at the apex and scabrid at the keels; male flower present, anthers 0.8–1.1 mm long. *Upper anthecium* ovoid, 1.1–1.4 mm long, 0.4–0.7 mm wide, stramineous or dark brown at maturity, smooth, shining. *Caryopsis* broadly ovoid, ca. 1.5 mm long, 1 mm wide, amber; hilum ovate, sub-basal; embryo ca. ⅓ the length of the caryopsis. In flower July to September.

Distribution. Brazil. Bahia, on rocks, in open and sunny habitats on "campo rupestre" at 1,000 m elevation.

Paratypes. BRAZIL. BAHIA: Serra da Jacobina, *Andrade-Lima 70-6159* (IPA, SP); Morro do Chapeu, 1,000 m, *E. Pereira 2138* (RB, US); Jacobinas, Serra do Brite, 11°09'S, 40°01'W, *H. P. Bautista & R. P. Orlandi 1000* (HRB, US).

The number of glands is generally constant for the same individual, two or four. Sometimes there is a third pair of rudimentary glands. This species is related to *P. chapadense* Swallen, from which it differs mainly by having hairs on the pedicels, pilose lower glumes (with long hairs toward the apex), and smaller spikelets.

None of the specimens was collected with its base, so it is not possible to know if cormlike bases as found in *P. chapadense* are present in the new species.

We have the pleasure of naming this species in honor of the late Dr. Thomas R. Soderstrom, our friend, colleague, and renowned North American agrostologist.

shorter than the internodes, sparsely pilose to glabrous, the upper margins ciliate, the lower margins membranous. *Ligule* membranous, short, 0.2–0.4 mm long, laciniate at the apex; external ligule conspicuous, formed by a row of dense, whitish hairs. *Leaf blades* ovate-lanceolate to lanceolate, flat, 1.5–13 cm long, 0.3–3.5 cm wide, acuminate, contracted and asymmetrical basally, shortly pilose to minutely scabrid or glabrous on both surfaces (with long hairs toward the base or glabrous), the abaxial surface mostly purplish, the midnerve prominent, the lateral nerves usually anastomosing; *pseudopetiole* dark, shortly pubescent. *Panicles* exserted, (1.5–)4–9(–22) cm long, (0.8–)1.5–3(–6) cm wide, formed by numerous, dense, spikelike, alternate to subopposed racemose branches, ± divergent from the axis, the spikelets borne in pairs, densely congested along the lower side of the branches; peduncles hispid to glabrous; axis longitudinally ridged, hispid to scabrous or glabrous; axis of the branches triquetrous (one side flat), scabrous to glabrous, the axils shortly and densely pilose; pedicels short, 0.5–1 mm long, pilose to glabrous. *Spikelets* lanceolate, 2.2–3.2 mm long, 0.5–0.8 mm wide, glabrous, dark green, the upper glume shorter than the lower lemma, occasionally subequal. *Lower glume* ovate, 0.7–1.3 mm long, glabrous, ⅓ the length of the spikelet, 3-nerved, the midnerve scabrous. *Upper glume* gibbous, acute, 1.9–2.8 mm long, 5(–7)-nerved, the midnerve scabrous or glabrous apically. *Lower lemma* acuminate, 2.4–3 mm long, 5(–7)-nerved, the midnerve scabrous. *Lower palea* elliptic, 1.4–1.9 mm long, 0.3–0.5 mm wide, brownish, glabrous, the margins finely ciliate to glabrous; male flower absent. *Upper anthecium* ellipsoid, 1.3–1.9 mm long, 0.4–0.6 mm wide, stramineous, brownish at maturity; lemma 5-nerved; anthers brown, 0.5 mm long. *Caryopsis* ellipsoid, 1–1.5 mm long, 0.5–0.8 mm wide; hilum oblong. In flower all year.

Distribution. A widely distributed species found in Mesoamerica, Lesser Antilles, and South America, from Colombia to Argentina. The plants form dense and weedy ground vegetation in the moist and shaded forests at 150–1,400 m elevation.

Common names. Capim-do-Mato, capim-do-brejo (Smith et al., 1982).

Hitchcock & Chase (1910, 1915) distinguished *P. stoloniferum* from *P. frondescens* by the sizes of the plants and the panicles and by the length of the upper glume compared with the lower lemma. Abundant material showed a complete gradation in these characters. Therefore, we are treating *P. frondescens* as a synonym of *P. stoloniferum*.

13. Panicum venezuelae Hackel, Oesterr. Bot. Z. 51: 368. 1901. *Brachiaria venezuelae* (Hackel) Henrard, Blumea 3: 435. 1940. TYPE: Venezuela. Without locality: *Eggers 13471* (holotype, W, not seen, fragment at US). Figure 15.

P. ineptum A. Hitchc. & Chase, Contr. U.S. Natl. Herb. 17: 509. 1915.

P. berteronianum Mez, Bot. Jahrb. Syst. 56, Beibl. 125: 5. 1921. Not *P. berteronianum* Schultes, 1854. TYPE: Venezuela. Federal District: La Guayra, *Zollner s.n.* (holotype, B, not seen, fragment at US).

Stoloniferous, densely and freely branching perennials, with very long, slender, prostrate stolons. *Culms* decumbent to ascending, densely branching mostly at the lower nodes, 40–80 cm tall; internodes 3–8 cm long, cylindric to compressed, hollow, sparsely pilose to glabrous; nodes densely pilose, with long whitish, usually retrorse hairs. *Leaf sheaths* 1–4 cm long, usually shorter than the internodes, stramineous, striate, sparsely to densely pilose with long, whitish hairs, the margins ciliate. *Ligule* membranous-ciliate, ca. 0.5 mm long, with long hairs toward the back at the base of the blade; collar stramineous, pilose. *Leaf blades* ovate-lanceolate to lanceolate, acuminate, flat, 3–9 cm long, 0.5–1 cm wide, cordate basally, densely to sparsely hirsute; the margins long-ciliate toward the base, otherwise ciliate to scabrous, cartilaginous; midnerve inconspicuous; *pseudopetiole* short, ca. 0.2 cm long. *Panicles* lax, long-exserted, 2–11 cm long, 1–3 cm wide, formed by 4–10 distant, alternate, short branches, these divergent from the axis and racemose, with cleistogamous spikelets in pairs arranged along either side of a ventral septum; chasmogamous spikelets occasionally present; axis longitudinally ridged, long-hirsute, the axils of the branches densely pilose, axis of the branches triquetrous, densely hirsute; pedicels short. Axillary panicles similar to the terminal panicle, but short-exserted and few-flowered. *Spikelets* ellipsoid, 2.5–3 mm long, 1.1–1.3 mm wide, stramineous to greenish, the glumes and lower lemma sparsely to densely hirsute. *Lower glume* ovate, 1.5–1.7 mm long, ½ or more the length of the spikelet, 3-nerved, the midnerve scabrous. *Upper glume* 2.6–2.9 mm long, gibbous, 5(–7)-nerved, with thick, papillose hairs over the entire surface or only toward the apex, 2 glands occasionally present on the middle portion of the outer surface, the inner surface scabrous. *Lower lemma* larger than the upper glume, the apex ± inflated, with a few thick hairs, the middle portion flattened and glabrous, the margins inrolled toward the apex, 5-nerved, the lateral nerves remote from the midnerve, 2 glands sometimes present on the middle portion of the outer surface. *Lower palea* elliptic to obovate, 1.6–1.8 mm long, 0.7 mm wide, hyaline, shortly pilose toward the upper margins, glabrous over the rest of the surface; male flower absent. *Upper anthecium* ellipsoid to obovoid, obtuse, 1.6–1.8 mm long, 0.8–1.1 mm wide, stramineous; lemma 5-nerved, strongly convex; anthers 3, those of the cleistogamous spikelets small, 0.2–0.3 mm long; anthers of the chasmogamous spikelets 0.9 mm long. *Caryopsis* 1.3 mm long, 1 mm wide; hilum punctiform. In flower all year.

Distribution. This species occurs in Guatemala, Honduras, Cuba, Haiti, the Dominican Republic, and Venezuela to northern

Henrard (1940) transferred *P. venezuelae* to *Brachiaria* without explanation. Previously, when describing *P. ineptum*, Hitchcock & Chase (1915) did not refer it to any of the groups of *Panicum*. Brown (1977) pointed out that this species, being a C_3 plant, is not actually a *Brachiaria*, since the genus *Brachiaria* is totally C_4 or Kranz. Sendulsky (1978), in her treatment of *Brachiaria* for Brazil, called attention to the size of the anthers and to the unusual form, for *Brachiaria*, of the long-winged lodicules. She suggested retention of this species in *Panicum*.

The panicle, habit, and spikelets (which bear glands on the lower lemma and occasionally on the upper glume also) suggest inclusion of *P. venezuelae* in sect. *Stolonifera*. However, this is the only species in the section with cleistogamous spikelets, a feature otherwise only found in *Panicum* in species of subg. *Dichanthelium* A. Hitchc. & Chase. Also, the glands differ from those in other species of sect. *Stolonifera*; in *P. venezuelae* the glands are bigger and depressed, not crateriform.

A REVISED TREATMENT OF BORAGINACEAE FOR PANAMA[1]

James S. Miller[2]

ABSTRACT

The Boraginaceae known from Panama now number 52 species compared with the 33 that were recognized the last time the family was treated. Eight of these are described as new species, five in the genus Cordia *and three in* Tournefortia. *Among the new records for Panama is* Moritzia lindenii, *the genus being previously unknown in the country. Most genera of Panamanian Boraginaceae are South American in origin. More than half of the species are widespread in the Neotropics, but the remainder show stronger affinities with the rest of Central America than with South America or with the West Indies.*

The Panamanian species of Boraginaceae have been treated numerous times since the turn of the century. Standley's floras of the Canal Zone (1928) and Barro Colorado Island (1933) predate Ivan Johnston's studies of the family, and many of the names Standley used were later placed in synonymy by Johnston, who published extensively on the family from the 1920s to the 1950s. Johnston's book *The Botany of San José Island* (1949b) treated another island flora, but unfortunately all of the works up to this time essentially describe the flora of the Canal Area. Thomas B. Croat's *Flora of Barro Colorado Island* (1978) provides an excellent treatment of the species on the island.

The Boraginaceae of Panama were treated for the entire country by Nowicke (1969) in the *Flora of Panama*. Subsequently, the number of collections from Panama increased, especially from regions then poorly known. Floristic studies in other Central American countries have altered taxonomic concepts of some Panamanian species. Examination of collections while preparing a revision of *Cordia* for Mexico and Central America (Miller, 1985) and of floristic treatments for Nicaragua (Miller, in press) and Mesoamerica (Miller, in prep.) revealed nine previously unrecorded species as well as eight undescribed species for Panama, a significant increase from 33 to 52 species.

Five subfamilies are currently recognized within the Boraginaceae (Johnston, 1951; Cronquist, 1981): Cordioideae, Ehretioideae, Heliotropioideae, and Boraginoideae, all of which have representatives in Panama, and the Wellstedioideae, which consists of two African species. The Cordioideae and Ehretioideae have sometimes been treated together as a separate family, Ehretiaceae (Lindley, 1830; Airy Shaw, 1973; Hutchinson, 1973). They are, however, clearly related to the other three subfamilies and are tied to them by

---

[1] *W. G. D'Arcy suggested this project and provided encouragement throughout. C. W. Hamilton and K. Krager helped during my visit to Panama. J. K. Myers provided the illustrations, J. D. Dwyer helped with the Latin descriptions, M. J. Huft sent information regarding collections at the Field Museum, and W. G. D'Arcy, P. P. Lowry II, and W. D. Stevens read portions of the manuscript. G. D. McPherson and J. W. Nowicke provided valuable review comments and I thank them for their help. The staff of the Missouri Botanical Garden assisted in many ways and their help is greatly appreciated. I also thank the curators of the following herbaria for lending specimens and for hospitality: A, AAU, ARIZ, ASU, B, BM, BR, C, CAS, CFMR, CHAPA, CR, DS, DUKE, ENCB, F, FHO, G, GB, GH, HAL, HNMN, IND, INIF, K, L, LE, LL, MEXU, MICH, NMC, NY, P, PMA, POM, RSA, SCZ, SD, SLPM, TEX, U, UC, US, USJ, WIS. My wife, Leslie, provided encouragement and accompanied me during field studies in Panama.*

ANN. MISSOURI BOT. GARD. 75: 456–521. 1988.

intermediate genera. Recent authors (e.g., Cronquist, 1981) have generally accepted their inclusion in a broadly defined Boraginaceae. Recognition of one family with five subfamilies also provides more information about relationships.

PHYTOGEOGRAPHIC RELATIONSHIPS OF PANAMANIAN BORAGINACEAE

The Boraginaceae of Panama make up an assemblage of species derived from different regions. In order to assess their phytogeographic relationships, the distributions of the constituent genera and species were determined. The genera *Borago* and *Cynoglossum* were excluded from the generic analysis, as both are not indigenous. The remaining seven genera are listed in Table 1 with their presumed centers of origin.

Four of the seven genera are clearly South American in origin. All three species of *Moritzia* occur in South America, with only one ranging north as far as Costa Rica. Although *Cordia*, *Heliotropium*, and *Tournefortia* are pantropical in distribution, they are strongly centered in South America.

Bourreria and *Hackelia* clearly originated in North America. The majority of the species of *Bourreria* occur in Mexico, with an additional group centered in the Greater Antilles; only a few species range south to southern Central America and South America. *Hackelia* is distributed widely in north temperate regions with the greatest concentration of species in the western United States (Gentry & Carr, 1976).

Ehretia is more problematic but certainly seems to be of Old World origin. Most of its species occur in Africa but it is well represented in tropical and subtropical Asia. Whether or not this strong African representation indicates that *Ehretia* originated there or radiated there as the climate became drier at the end of the Oligocene (Raven & Axelrod, 1974) is not clear. Regardless, *Ehretia* is poorly represented in the New World, with only three species, and the southern limit of distribution is in Chiriquí Province of western Panama. The presence of *Ehretia* in Panama, then, probably results from southward migration.

From this it seems clear that the generic affinities of Panamanian Boraginaceae are predominantly South American. Four of the seven genera that account for all but four of the native Panamanian Boraginaceae are centered in South America. *Hackelia* and *Bourreria* are North American in origin and, at least in the New World, so is *Ehretia*. The strong South American tie agrees with other analyses at familial or generic levels. Gentry (1985) reported that 84% of the plant species in Panama were members of Gondwanaland families, and Karr (1985) reported that at least 50% of the bird species in Panama were members of families that were South American in origin.

Distributions of Panamanian species of Boraginaceae are summarized in Table 2 following Davidse's (1985) format. Distributional data were derived from herbarium specimens and literature (Gentry & Carr, 1976; Gibson, 1970; Johnston, 1924, 1927, 1928, 1930, 1935, 1940, 1949a, c, 1950; Miller, 1985, in press; Nash & Moreno, 1981; Nowicke, 1969). Each species was scored for presence in North America, Central America, South America, and the West Indies. In addition, presence in the Old World or cultivated status was noted.

INTRODUCED SPECIES

Two introduced species of Boraginaceae are known from Panama. *Borago officinalis* L. is widely cultivated throughout the world and occasionally is found naturalized, although these populations do not appear to persist for long. *Cynoglossum amabile* Stapf & J. R. Drumm. is a native of China originally imported as an ornamental and has become established in numerous localities at high elevations in the Neotropics.

COSMOPOLITAN SPECIES

Two species, *Heliotropium curassavicum* L. and *H. indicum* L., are widespread in the

TABLE 1. *Native genera of Panamanian Boraginaceae and presumed centers of origin.*

Genus (Number of Species)	Number of Species in Panama	% of Panamanian Species	Center of Origin
Bourreria (50)	2	4	North America
Cordia (300+)	27	54	South America
Ehretia (50)	1	2	Paleotropics
Hackelia (45)	1	2	North America
Heliotropium (150)	4	8	South America
Moritzia (3)	1	2	South America
Tournefortia (150)	14	28	South America

New World and have become widespread in the Old World as introduced weeds (Nowicke & Miller, in press).

NORTHERN SPECIES

Seven species of borages reach their southern limits in Panama. A single species each of *Bourreria* and *Ehretia*, both genera probably northern in origin, are included in this group. Five Central American species of *Cordia* make up the remainder of this group, of which four are Central American species of lowland wet forests. *Cordia diversifolia* Pavón ex A. DC. and *C. megalantha* S. F. Blake range north to Veracruz in southern Mexico; *C. lucidula* I. M. Johnston and *C. porcata* Nowicke range only as far north as Nicaragua. These four belong to Central American species groups. The fifth, *Cordia inermis* (Miller) I. M. Johnston, reaches from Panama north to Sinaloa, Mexico in dry disturbed areas. It is a member of a group of about eight species that is widespread in the Neotropics of which *Cordia foliosa* Martens & Galeotti is the only other species restricted to Central America.

NORTHERN–SOUTHERN SPECIES

Twenty-seven species, comprising slightly more than half of the Boraginaceae known from Panama, range widely in the Neotropics. With two exceptions, all of these are truly widespread species that indicate no particular geographic affinity. The genus *Moritzia* consists of three species and is entirely restricted to South America except for *M. lindenii* (A. DC.) Gürke ex Benth., which ranges north to Costa Rica. *Hackelia* is a northern genus, but *H. mexicana* (Schldl. & Cham.) I. M. Johnston is widespread in Central America

and the Andes. *Cordia* and *Tournefortia* contain 22 of the widespread species, all of which are found in most of Central America, but only about one-third of them range as far south as southern Brazil and Argentina. The majority have southern limits of distribution in northern South America or extend south only in the Andes.

ENDEMICS

Fourteen species of Panamanian borages, all species of *Cordia* and *Tournefortia*, are known only from Panama and adjacent Colombia or Costa Rica. Seven are known only from Panama (Table 3); three range slightly into Colombia, and four others extend into Costa Rica. All are relatively rarely collected. Eight are described as new in this paper. All of the species of *Tournefortia* and three of *Cordia* occur at mid to high elevations, while the widespread taxa generally inhabit lowlands.

More than half of the Panamanian species of Boraginaceae are widespread or introduced and are not helpful in indicating geographic affinity. The pattern of the lowland Panamanian flora being composed primarily of South American elements has been reported for other groups (Davidse, 1985; Raven & Axelrod, 1974, 1975). Hammel (1986) found a similar pattern for a subset of the flora of La Selva in lowland Costa Rica. The fourteen endemic elements indicate that the Panamanian flora is old enough to have become distinct from that of surrounding areas. The relationships of the endemics are poorly understood but the majority are probably with species of Colombia and Ecuador. Seven species have distributions extending to the north, and many are members of species complexes restricted to Mexico and Central America. These species, and the absence of southern elements, indicate that Panamanian borages have a stronger relationship at the species level with Central America than with South America. Although most of the species belong to originally South American genera, a significant portion of these seem to have reached Panama from the north, perhaps as a result of secondary radiations of *Cordia* and *Tournefortia* in Mexico and northern Central America.

SYSTEMATIC TREATMENT

Boraginaceae Juss., Gen. Pl. 128. 1789.

Trees, shrubs, lianas, vines, or herbs, often conspicuously pubescent, the hairs often with a basal cystolith. Leaves estipulate, simple, alternate or rarely opposite. Inflorescence cymose to paniculate, the branches often scorpioid, helicoid, or reduced and capitate to glomerate. Flowers perfect or imperfect, usually 5-merous; calyx usually persistent, tubular to campanulate, usually 5-lobed; corolla gamopetalous, usually 5-lobed; stamens usually as many as the corolla lobes and alternate with them; ovary superior, 2-carpellate but often becoming falsely 4-locular; ovules usually 4, anatropous; style 1, terminal or gynobasic, simple or branched; stigmas 1–4. Fruits drupaceous and 1–4-seeded, sometimes dry at maturity, or of 4 nutlets.

The Boraginaceae are worldwide in distribution and comprise about 100 genera with approximately 2,000 species. Nine genera are known from Panama containing 52 species. Although no collections of the genus *Borago* are known from Panama, the European species *Borago officinalis* L. is often cultivated in gardens in other parts of Tropical America and is included here as it undoubtedly occurs in Panama.

KEY TO THE GENERA OF BORAGINACEAE IN PANAMA

1a. Plants trees or shrubs; stigmas 2 or 4; fruits fleshy at least when young.
  2a. Style twice divided into 4 stigmas .... *Cordia*
  2b. Style once divided into 2 stigmas.
    3a. Calyx lobes valvate; corolla fleshy, longer than 8 mm .... *Bourreria*
    3b. Calyx lobes imbricate or open in bud; corolla thin, shorter than 5 mm .... *Ehretia*
1b. Plants herbs, lianas, vines, or clambering shrubs, rarely small trees; stigma 1; fruits dry except in *Tournefortia*.
  4a. Fruits entire to shallowly 4-lobed; style terminal; corolla white, green, or yellow-green, rarely purple.
    5a. Plants woody; fruits fleshy .... *Tournefortia*
    5b. Plants herbaceous; fruits dry .... *Heliotropium*
  4b. Fruits deeply 4-lobed, consisting of 4 separate nutlets or the nutlets solitary by abortion in *Moritzia*; style gynobasic; corolla blue.
    6a. Calyx campanulate to rotate.
      7a. Nutlets with glochidiate spines; calyx lobes less than 4 mm long.
        8a. Cauline leaves clasping at base; nutlets spreading, the spines ca. 0.5 mm long .... *Cynoglossum*
        8b. Cauline leaves cuneate to decurrent but not clasping at base; nutlets erect, the spines 1–4 mm long .... *Hackelia*
      7b. Nutlets lacking spines, shallowly ribbed; calyx lobes more than 10 mm long .... *Borago*
    6b. Calyx cylindrical .... *Moritzia*

Borago L., Sp. Pl. 137. 1753; Gen. Pl. ed. 5. 67. 1754. TYPE: *Borago officinalis* L., Sp. Pl. 137. 1753.

Annual or perennial herbs, the stems hirsute. Leaves alternate, the basal ones petiolate, the cauline ones sessile. Inflorescence a corymbose group of racemes, bracteate. Flowers bisexual; calyx with 5 lobes, these free to nearly the base; corolla broadly campanulate to rotate, the 5 lobes imbricate, the tube short, appendaged in the throat; stamens 5, exserted, the filaments broad, the anthers linear; ovary 4-lobed, the ovules 4, the style gynobasic, filiform, the stigma emarginate. Nutlets 4, obovoid or oblong, the gynobase flat or nearly so.

Borago comprises three species from southern Europe and the Mediterranean region, one of which, *Borago officinalis*, is widely cultivated.

Borago officinalis L., Sp. Pl. 137. 1753. TYPE: without locality or collector (holotype, LINN (Savage Catalog number 188.1), not seen; microfiche, MO).

Annual herb, 30–60 cm tall, the stems coarsely hirsute. Basal leaves petiolate, obovate to oblong, 6–12 cm long, 2–6 cm wide, the apex acute to obtuse, the base cuneate and decurrent along the petiole, the margin entire to irregularly undulate, the adaxial surface hirsute to scabrous, the veins prominent, the lower surface pubescent with most of the hairs restricted to the veins, the uppermost leaves sessile, lanceolate. Inflorescence loosely racemose, bracteate, the rachis hirsute. Flowers borne on pedicels 1–5 cm long; calyx rotate, with 5 lanceolate lobes to 10–18 mm long, 2–3 mm wide, hirsute; corolla blue, yellow in the throat, rotate, 18–22 mm long, the 5 lobes ovate to lanceolate, 8–11 mm long, the tube to 3 mm long; stamens 5, the filaments to 2 mm long, broad, the anthers lanceoloid, 5–7 mm long, with an appendage to 3 mm long at the base; ovary ca. 2 mm broad, the 4 lobes globose, the style 5.5–7.5 mm long. Fruits with the calyx and style persistent, the 4 nutlets obovoid, 4–6 mm long, 2–3 mm broad, finely ribbed, tuberculate at the apex.

Distribution. *Borago officinalis* is native in Europe, north Africa, and adjacent Asia but is widely cultivated and occasionally becomes naturalized.

Although *Borago officinalis* has not been collected in Panama, it seems almost certain that it is present in Panamanian gardens. It is often cultivated as a culinary or medicinal herb and is known from most neotropical countries, often as an adventive.

Bourreria P. Browne, Civ. Nat. Hist. Jamaica. 168. 1756; nom. cons. TYPE: *Bourreria succulenta* Jacq., Enum. Syst. Pl. 14. 1760; Select. Stirp. Amer. Hist. 44. 1763.

Trees or shrubs. Leaves alternate, petiolate, the margin usually entire. Inflorescences terminal cymes. Flowers bisexual, actinomorphic; calyx campanulate, 2–5-merous, the lobes valvate in bud; corolla relatively large, salverform, white to yellow in the Central American species, usually 5-merous, the lobes imbricate in bud; stamens 5, the filaments adnate to the base of the tube, the anthers ovate to oblong; ovary 4-locular, the style terminal, bifid; stigmas 2, flattened. Fruits drupaceous, enclosing 4 bony nutlets, the endosperm carnose, the cotyledons flat.

Bourreria has been considered to comprise about 50 species (Airy Shaw, 1973); however, Gibson's (1970) estimate of 15–20 species is probably more realistic. This poorly understood genus needs revision. Numerous species have been published based upon minor variations in leaf shape and indument—resolution of the problems this has created will necessitate field study of these characters. *Bourreria* ranges from Mexico and southern Florida through the West Indies and Central America to northern South America, with the majority of the species occurring in Mexico and the West Indies. About seven species are known from Central America, although only two have been found in Panama. Despite considerable confusion about delimitation of species, the two known from Panama are among the most distinct and easily recognized members of the genus.

De Candolle (1845) placed the species currently recognized as belonging to *Bourreria* in *Ehretia* sect. *Bourreria* (P. Browne) DC. All recent authors have, however, accepted *Bourreria* as distinct generically on the basis of its valvate calyx lobes and corollas that are larger and more fleshy than those in *Ehretia*. Miers (1869) pointed out that *Bourreria* has fruits that dry at maturity and separate into four single-seeded pyrenes with an apical attachment, whereas species of *Ehretia* have drupaceous fruits that usually remain entire at maturity, probably until they are dispersed. They later divide into two 2-seeded pyrenes.

KEY TO THE SPECIES OF *BOURRERIA* IN PANAMA

1a. Corollas 28–48 mm long; most leaf blades greater than 12 cm long .... *B. costaricensis*
1b. Corollas 8–12 mm long; most leaf blades less than 12 cm long .... *B. oxyphylla*

Bourreria costaricensis (Standley) A. Gentry, Phytologia 26: 67. 1973. *Schlegelia costaricensis* Standley, Publ. Field Mus. Nat. Hist., Bot. Ser. 18: 1128. 1938. TYPE: Costa Rica. Alajuela: cataratas de San Ramón, Mar. 1931, *A. M. Brenes 13570* (holotype, F 857116; isotype, NY).

Bourreria superba var. *glabra* Schery, Ann. Missouri Bot. Gard. 29: 366. 1942. *Bourreria panamensis* I. M. Johnston, J. Arnold Arbor. 29: 229. 1948. TYPE: Panama. Bocas del Toro: Chiriquí Lagoon, Isla Colón, 3 June 1941, *H. von Wedel 2472* (holotype, MO, not seen).

Tree 10–15 m tall, the twigs glabrous. Leaves persistent; petioles 10–25 mm long, glabrous; leaf blade elliptic to obovate, 6.5–

23.5 cm long, 3.7–10.5 cm wide, the apex obtuse to rounded and sometimes mucronate, the base acute to cuneate, the margin entire, the adaxial and abaxial surfaces glabrous. Inflorescence a small terminal cyme. Flowers sessile, bisexual; calyx campanulate, 13–18 mm long, 10–18 mm wide at the mouth, glabrous, the 5 lobes triangular; corolla white, broadly funnelform, 2.8–4.8 cm long, 5-merous, the lobes depressed ovate; stamens 5, the filaments 18–20 mm long, the upper 14–18 mm free, slightly puberulent at the point of insertion, the anthers narrowly ellipsoid, 4 mm long. Fruits green, globose, 2–2.5 cm diam.

Distribution. This species occurs in wet to moist forests from sea level to 1,700 from Nicaragua to Panama. In Panama it is known from Bocas del Toro and Colón.

This is one of the most distinctive species of *Bourreria* with its large, funnelform corollas more than 2.5 cm long. It is quite similar to *Bourreria superba* I. M. Johnston of western Mexico in general appearance but is widely separated geographically and grows in a very different habitat. *Bourreria costaricensis* differs further from *B. superba* by having glabrous twigs, leaves, and staminal filaments.

Additional specimens examined. PANAMA. BOCAS DEL TORO: Chiriquí Lagoon, Isla Colón, *Wedel 2974* (MO). CHIRIQUÍ: Fortuna Dam area, 1,200 m, *McPherson 6782* (MO); Fortuna Dam Region, near forestry experimental station, S of lake, 1,150 m, *McPherson 7873* (MO). Bourreria oxyphylla Standley, Trop. Woods 16: 40. 1928. TYPE: Belize. El Cayo: San José, Nov. 1927, *J. B. Aitken 4* (holotype, F 572622).

Beureria wagneri Standley in Yuncker, Publ. Field Mus. Nat. Hist., Bot. Ser. 9: 328. 1940. TYPE: Honduras. Atlántida: foothills back of La Ceiba, 23 July 1938, *T. G. Yuncker, J. M. Koepper & K. A. Wagner 8608* (holotype, F 941533).

Shrub or small tree to 5(–15) m tall, and ca. 1 m diam., the twigs glabrous to puberulent or sparsely strigillose. Leaves persistent, the petioles 7–17 mm long, glabrous to puberulent, the blades elliptic to elliptic-oblong, 4.5–10.5 cm long, 2–5 cm wide, the apex acute to obtuse and often abruptly short acuminate, the base acute to obtuse, the margin entire, the adaxial surface glabrous, the abaxial surface essentially glabrous but sparsely puberulent along the major veins. Inflorescence terminal, cymose, to 9 cm broad, the branches sparsely to evenly strigillose to puberulent. Flowers sessile, bisexual; calyx narrowly campanulate, 5–6 mm long, strigillose to puberulent, the 3–5 lobes deltate and often bifid at the apex; corolla white to pale green, tubular with spreading lobes, 8–12 mm long, 5-merous, the lobes oblong-obovate, 5–6 mm long, the tube 5–6 mm long; stamens 5, exserted, the filaments 3–4 mm long, glabrous, the anthers oblong, 2–3 mm long; ovary ovoid, 1.5–2 mm long, the disc annular, the style 6–8 mm long, the stigmas discoid. Fruits yellow to orange and later turning black, ovoid to subglobose, 6–12 mm long, 5–11 mm broad.

Distribution. *Bourreria oxyphylla* is known from southern Mexico through Belize to Nicaragua with a single collection from San Blas in Panama and a few collections from Colombia. It occurs in wet forests, where it ranges from sea level to nearly 800 m in elevation.

Bourreria oxyphylla is distinctive and is one of only two members of the genus in Central America with glabrous, elliptic leaves; the other, *Bourreria costaricensis*, is readily separated by its larger leaves, some to 10.5 cm wide, and corollas more than 2.8 cm long. *Bourreria wagneri* was described from a population in Honduras with slightly more puberulent twigs but is otherwise identical to other populations and is not recognized as distinct. The southern populations from Panama and Colombia have slightly larger, less lustrous leaves than the populations from northern Central America, but the differences are slight and they do not seem to warrant taxonomic recognition.

Additional specimens examined. PANAMA. SAN BLAS: island of Soskatupu, west end, *Kirkbride 195* (MO).

Cordia L., Sp. Pl. 190. 1753; Gen. Pl. ed. 5. 87. 1754. TYPE: *Cordia sebestena* L., Sp. Pl. 190. 1753.

Trees or shrubs. Leaves alternate, deciduous or persistent, petiolate, the petioles usually adaxially canaliculate. Inflorescence cymose, paniculate, spicate, capitate, or glomerate. Flowers perfect, or unisexual by abortion, with the plants then dioecious; calyx 3–5(–10)-lobed or rarely circumscissile; corolla funnelform, campanulate, or tubular with reflexed or spreading lobes, (4–)5(–18)-lobed, or sometimes the lobes nearly lacking and the corolla apically undulate to frilled or nearly truncate; stamens as many as corolla lobes, the lower part of the filaments adnate to corolla tube, often with hairs at or near insertion, the anthers oblong to ellipsoid; ovary entire, falsely 4-locular; disc annular to crateriform; style terminal, twice bifid, the 4 stigma lobes clavate, filiform, or discoid. Fruits borne with the calyx persistent, variable, dry with a fibrous wall and capped by the persistent, cartilaginous base of the style (sect. *Gerascanthus*), dry and bony-walled (sect. *Rhabdocalyx*), or with a thin exocarp, juicy to mucilaginous mesocarp, and bony endocarp (sects. *Varronia*, *Myxa*, and *Cordia*), usually 1-locular and 1-seeded, the endosperm lacking, the cotyledons plicate.

The pantropical genus *Cordia* is the largest in the family: there are about 300 species, mostly neotropical. Species of *Cordia* are found in a wide variety of habitats, but, although many species can be found in wet forests, those found in dry, disturbed areas are a more important component of the vegetation.

Cordia is the only Panamanian genus of the Cordioideae. The South American genera, *Auxemma* Miers and *Patagonula* L., differ from *Cordia* in the unusual form of their fruiting calyces and by having short styles and monomorphic flowers. Although clearly related to *Cordia*, they seem to represent a distinct lineage. *Cordia*, however, is a very diverse assemblage, and a number of authors have suggested dividing it into 3–12 segregate genera (Mez, 1890; Friesen, 1933; Nowicke & Ridgway, 1973). Nevertheless, *Cordia* sensu lato appears to be a distinct monophyletic group and its division into narrowly defined genera seems unwarranted. Johnston (1930, 1940, 1949a, b, 1950, 1951) treated the genus in a broad sense and recognized five to seven sections in his various works. Recent authors (Nowicke, 1969; Gibson, 1970; Nowicke & Ridgway, 1973; Opler et al., 1975; Miller, 1985) have recognized five sections. Twenty-seven species in four of the sections are known from Panama.

KEY TO THE SPECIES OF *CORDIA* IN PANAMA

1a. Corolla bright red-orange; fruit drupaceous and totally enclosed in the accrescent calyx at maturity (sect. *Cordia*) .... *C. sebestena*
1b. Corolla white to yellow; fruit not totally enclosed by the calyx at maturity or if enclosed, then not drupaceous.
  2a. Corolla marcescent; fruit with a fibrous wall (sect. *Gerascanthus*).
    3a. Ant domatia present at the base of the inflorescences; leaves and twigs with stellate hairs; corolla lobes oblong .... *C. alliodora*
    3b. Ant domatia absent; leaves and twigs glabrous; corolla lobes deltate or ovate .... *C. megalantha*
  2b. Corolla deciduous; fruit with a bony wall.
    4a. Trees or shrubs with few stems; leaf margin entire or denticulate; inflorescences cymose to paniculate, branching more than twice; fruits generally asymmetrical (sect. *Myxa*).
      5a. Corolla yellow to almost white; calyx circumscissile and striate .... *C. dentata*
      5b. Corolla white; calyx opening with valvate lobes or if circumscissile than not striate.
        6a. Calyx costate; leaf margin with short, filiform teeth toward the apex or entire .... *C. diversifolia*

6b. Calyx smooth or striate, not costate; leaf margin entire.
7a. Ovary and fruit strigillose ..... *C. bicolor*
7b. Ovary and fruit glabrous.
8a. Adaxial leaf surface evenly strigillose or scabrous to strigose; plants usually dioecious.
9a. Corolla tube 1.5–3.9 mm long; fruits ovoid, 6–10 mm long.
10a. Stems and peduncles with simple hairs; the larger leaves generally 6.5–13.5 cm wide ..... *C. panamensis*
10b. Stems and peduncles with echinate hairs; the larger leaves generally 11.2–20.4 cm wide ..... *C. cymosa*
9b. Corolla tube ca. 10–12 mm long; fruits ellipsoid, 8.5–16.5 mm long ..... *C. anisophylla*
8b. Adaxial leaf surface glabrous or nearly so; plants usually with bisexual flowers, these usually distylous, dioecious only in *C. collococca* and *C. tacarcunensis.*
11a. Leaf margin distinctly revolute.
12a. Stems sub-alate; abaxial leaf surface glabrous; leaves not bullate ..... *C. leslieae*
12b. Stems not winged or ridged; abaxial leaf surface velutinous; leaves bullate ..... *C. dwyeri*
11b. Leaf margin not or only slightly revolute.
13a. Corolla campanulate ..... *C. eriostigma*
13b. Corolla tubular, with reflexed or spreading lobes.
14a. Calyx distinctly 5-lobed.
15a. Inflorescences axillary, numerous on a single stem; plants dioecious ..... *C. tacarcunensis*
15b. Inflorescences terminal or subterminal, few per stem; plants with bisexual flowers.
16a. Fruits white; leaf blades falcate ..... *C. protracta*
16b. Fruits red or orange; leaf blades flat, not falcate ..... *C. correae*
14b. Calyx (2–)3(–4)-lobed, circumscissile or dehiscing irregularly.
17a. Plants hermaphroditic; leaves persistent; flowers borne on current season's growth.
18a. Apex of the leaf caudate, the caudex 1–3.5 cm long ..... *C. lasiocalyx*
18b. Apex of the leaf acuminate.
19a. Leaf blade elliptic to elliptic-ovate, less than 5 cm wide, usually less than 8 cm long ..... *C. croatii*
19b. Leaf blade ovate to narrowly elliptic or lance-elliptic, usually more than 5 cm wide, usually more than 8 cm long.
20a. Fruit red, the stone not rostrate; anthers 1.1–1.2 mm long; calyx 3–4 mm long ..... *C. lucidula*
20b. Fruit white, the stone not rostrate; anthers 1.9–2.3 mm long; calyx 5.2–6.5 mm long ..... *C. porcata*
17b. Plants dioecious; leaves deciduous; flowers usually borne below the current season's growth ..... *C. collococca*
4b. Shrubs, usually multistemmed; leaf margin serrate to minutely denticulate; inflorescences condensed, spicate, capitate, or if cymose, then less than 2.3 cm broad, dichotomous, and branching only twice; fruits symmetrical or nearly so (sect. *Varronia*).
21a. Inflorescences spicate.
22a. Leaf blade lanceolate; inflorescences terminal ..... *C. curassavica*
22b. Leaf blade ovate; inflorescences axillary, the peduncle adnate to the petiole ..... *C. spinescens*
21b. Inflorescences cymose or capitate.
23a. Inflorescence branched, cymose ..... *C. bifurcata*
23b. Inflorescence capitate.
24a. Calyx lobes with prolonged filiform tips.
25a. Peduncles 0.5–2 cm long; corolla 5–10 mm long ..... *C. globosa*
25b. Peduncles 3–7 cm long; corolla 3–6 mm long ..... *C. bullata*
24b. Calyx lobes acute to acuminate but lacking prolonged tips.
26a. Inflorescences terminal or internodal ..... *C. inermis*
26b. Inflorescences axillary ..... *C. linnaei*

Cordia alliodora (Ruíz Lopez & Pavón) Oken, Allg. Naturgesch. 2(2): 1098. 1841. *Cerdana alliodora* Ruíz Lopez & Pavón, Fl. Peruv. 2: 47, pl. 184. 1799. TYPE: Peru. Huanuco: Pozuzo, *Hipólito Ruíz & José Pavón* (holotype, B, not seen; photo, MO).

Tree to 20(–25) m tall, the twigs stellate-pubescent when young, ending in obovoid ant domatia. Leaves deciduous; petioles (5–)8–28(–35) mm long, stellate-pubescent; blade elliptic to narrowly elliptic or slightly obovate, (3.5–)5–17(–20.5) cm long, (1.4–)2–7(–8.5) cm wide, the apex acuminate or acute, the base acute to obtuse, the adaxial surface glabrous to sparsely stellate-pubescent, the abaxial surface sparsely to densely stellate-pubescent. Inflorescence terminal, usually arising from an obovoid ant domatium, paniculate, to 25(–30) cm broad, the branches usually densely stellate-pubescent. Flowers borne on short spurs to 1.5 mm long, bisexual, monomorphic; calyx tubular, (4–)4.5–5.5(–6.5) mm long, 10(–12)-ribbed, stellate-pubescent, with (4–)5(–6) small teeth; corolla marcescent, white, (8.5–)9.5–12(–14) mm long, (4–)5(–6)-merous, the lobes oblong, (4.5–)5–7(–8.5) mm long, the tube (3.5–)4.5–6(–8.5) mm long; stamens (4–)5(–6), the filaments 9–12 mm long, the upper (3.5–)5.5–7.5 (–9) mm free, sparsely pubescent at insertion, the anthers oblong, 1.5–2(–2.5) mm long, borne at the same height or above the stigmas; ovary ovoid to very broadly ovoid, (0.7–)1–2(–2.5) mm long; disc depressed obovoid to very broadly obovoid, 0.5–1 mm tall; style 4.5–6.5 mm long, the stigma lobes clavate. Fruits enclosed by the persistent corolla and calyx, ellipsoid, (4.5–)5–7(–8) mm long, (1–) 2–2.5 mm broad, the wall thin, fibrous.

Distribution. *Cordia alliodora* occurs in dry to wet forests from sea level to 1,100 m in elevation and ranges from Mexico to South America and to the West Indies. This species is known from all provinces in Panama.

Cordia alliodora is the widest-ranging species of the genus. Its ant domatia and stellate indument are distinctive. It is also one of only two homostylous species in sect. *Gerascanthus*, the other being *Cordia trichotoma* (Vell.) Arráb. ex Steudel of southern South America (Gibbs & Taroda, 1983). This condition is derived in the section, and these two species form a monophyletic group further characterized by stellate hairs on the stems and leaves and by flowers considerably smaller than those of their relatives. The flowers of *Cordia alliodora* vary from short-style to forms with the stigmas and anthers borne at about the same height, but individual plants appear to be constant in the ratio of anther and stigma height. No plants have been found with styles exceeding the stamens considerably.

Cordia alliodora is valued as a timber tree and, for this reason, there has been a great deal of interest recently in establishing plantations of it throughout Central America (Stead, 1980). Flowering occurs at the onset of the dry season with fruits maturing and being dispersed during mid dry season. Common names include Laurel, Laurel Blanco, and Laurel Negro.

Additional specimens examined. PANAMA. BOCAS DEL TORO: Almirante region, *Cooper & Slater 22* (CFMR, F, US); Changuinola Valley, *Dunlap 291* (F, GH, US); vicinity of Chiriquí Lagoon, Old Bank Island, *Wedel 1877* (MO, US). Cordia anisophylla James S. Miller, sp. nov. TYPE: Panama. Colón: Santa Rita Ridge Road, 9 km from Boyd–Roosevelt Highway, 350 m, Premontane Wet Forest, 15 Mar. 1975, *S. Mori & J. Kallunki 5076* (holotype, MO 2664952; isotypes, MO, US). Figure 1.

Arbor ad 8 m alta. Folia persistentia, petiolis (4–)6–12 mm longis; laminae anisophyllae, foliis maioribus ovatis ad lanceolato-ovatis, 10.5–21(–26) cm longis, (3–)5–12.5 cm latis, minoribus ovatis ad cordatis, (3.5–)7.5–8.5 (–13.5) cm longis, 4.5–7.3(–14) cm latis, apice acuminatis ad acutis, basi obtusis, superficie strigillosa, pagina inferiore strigillosa ad pilosa. Inflorescentiae terminales in axillis ramorum dispositae, cymosae. Flores heterostyli; calyx tubuliformis, 7–9 mm longus; corolla alba, tubuliformis, 10–12 mm longa, 5-lobata; stamina 5, antheris oblongis. Fructus drupaceus, putamine inaequilateraliter ovoideo, 8.5–16.5 mm longo, 6–7.5 mm lato.

Small erect tree or large shrub to 5(–8) m tall, the bark brown, smooth, lateral branching dichotomous in a horizontal plane, the twigs strigillose to pilose. Leaves persistent; petioles (4–)6–12 mm long, canaliculate adaxially, strigillose to pilose; blades anisophyllous, the larger ones ovate to ovate-lanceolate, 10.5–21(–26) cm long, (3–)5–12.5 cm wide, the smaller ones orbicular, (3.5–) 7.5–8.5(–13.5) cm long, 4.5–7.3(–14) cm wide, the apex acuminate, the base subobtuse to obtuse, the margin entire, the adaxial surface evenly strigillose, the abaxial surface strigillose to unevenly pilose. Inflorescences terminal or borne in the axils of branches, rarely internodal, loosely branched cymes, the peduncle 5–10(–13.5) cm long, strigillose to nearly pilose. Flowers sessile, distylous; calyx tubular, 7–9 mm long, 3 mm wide at mouth, the 5 lobes ± deltate, 1.8 mm long, ribs absent, strigillose, densely pilose on interior surface; corolla white, tubular with reflexed lobes, ca. 10–12 mm long, 5-merous, the lobes 2.7 mm long, 1.8 mm wide, the tube 9.3 mm long; stamens 5, the filaments 10.5 mm long, the upper 2.6 mm free, villose at and above insertion, the anthers oblong, 2 mm long; ovary oblong, 1.8 mm long, 1.1 mm broad, glabrous; disc small, not evidently distinct from the base of the ovary; style 5.3 mm long, the stylar branches 0.9 mm long, the stigma lobes clavate. Fruits seated in the cupulate calyx, drupaceous, glabrous, the stone slightly inequilaterally ovoid, 8.5–16.5 mm long, 6–7.5 mm broad, the endocarp bony.

Distribution. *Cordia anisophylla* occurs in wet forests from sea level to 1,000 m in elevation and is known only from Panama in the provinces of Colón, Darién, Panamá, and San Blas.

Cordia anisophylla is closely related to *C. panamensis* and to *C. cymosa* but differs from them by having corollas more than 10 mm long and fruits more than 8.5 mm long. This species is also one of only two distylous Central American members of sect. *Myxa*, the other being *C. dentata*. While the *Cordia panamensis* species complex is one of the most taxonomically confusing within sect. *Myxa*, *Cordia anisophylla* is probably the most distinctive species of the group in its elongate, distylous flowers and ellipsoid fruits.

Additional specimens examined. PANAMA. COLÓN: Santa Rita Ridge, *Croat 13895* (MO); Santa Rita lumber

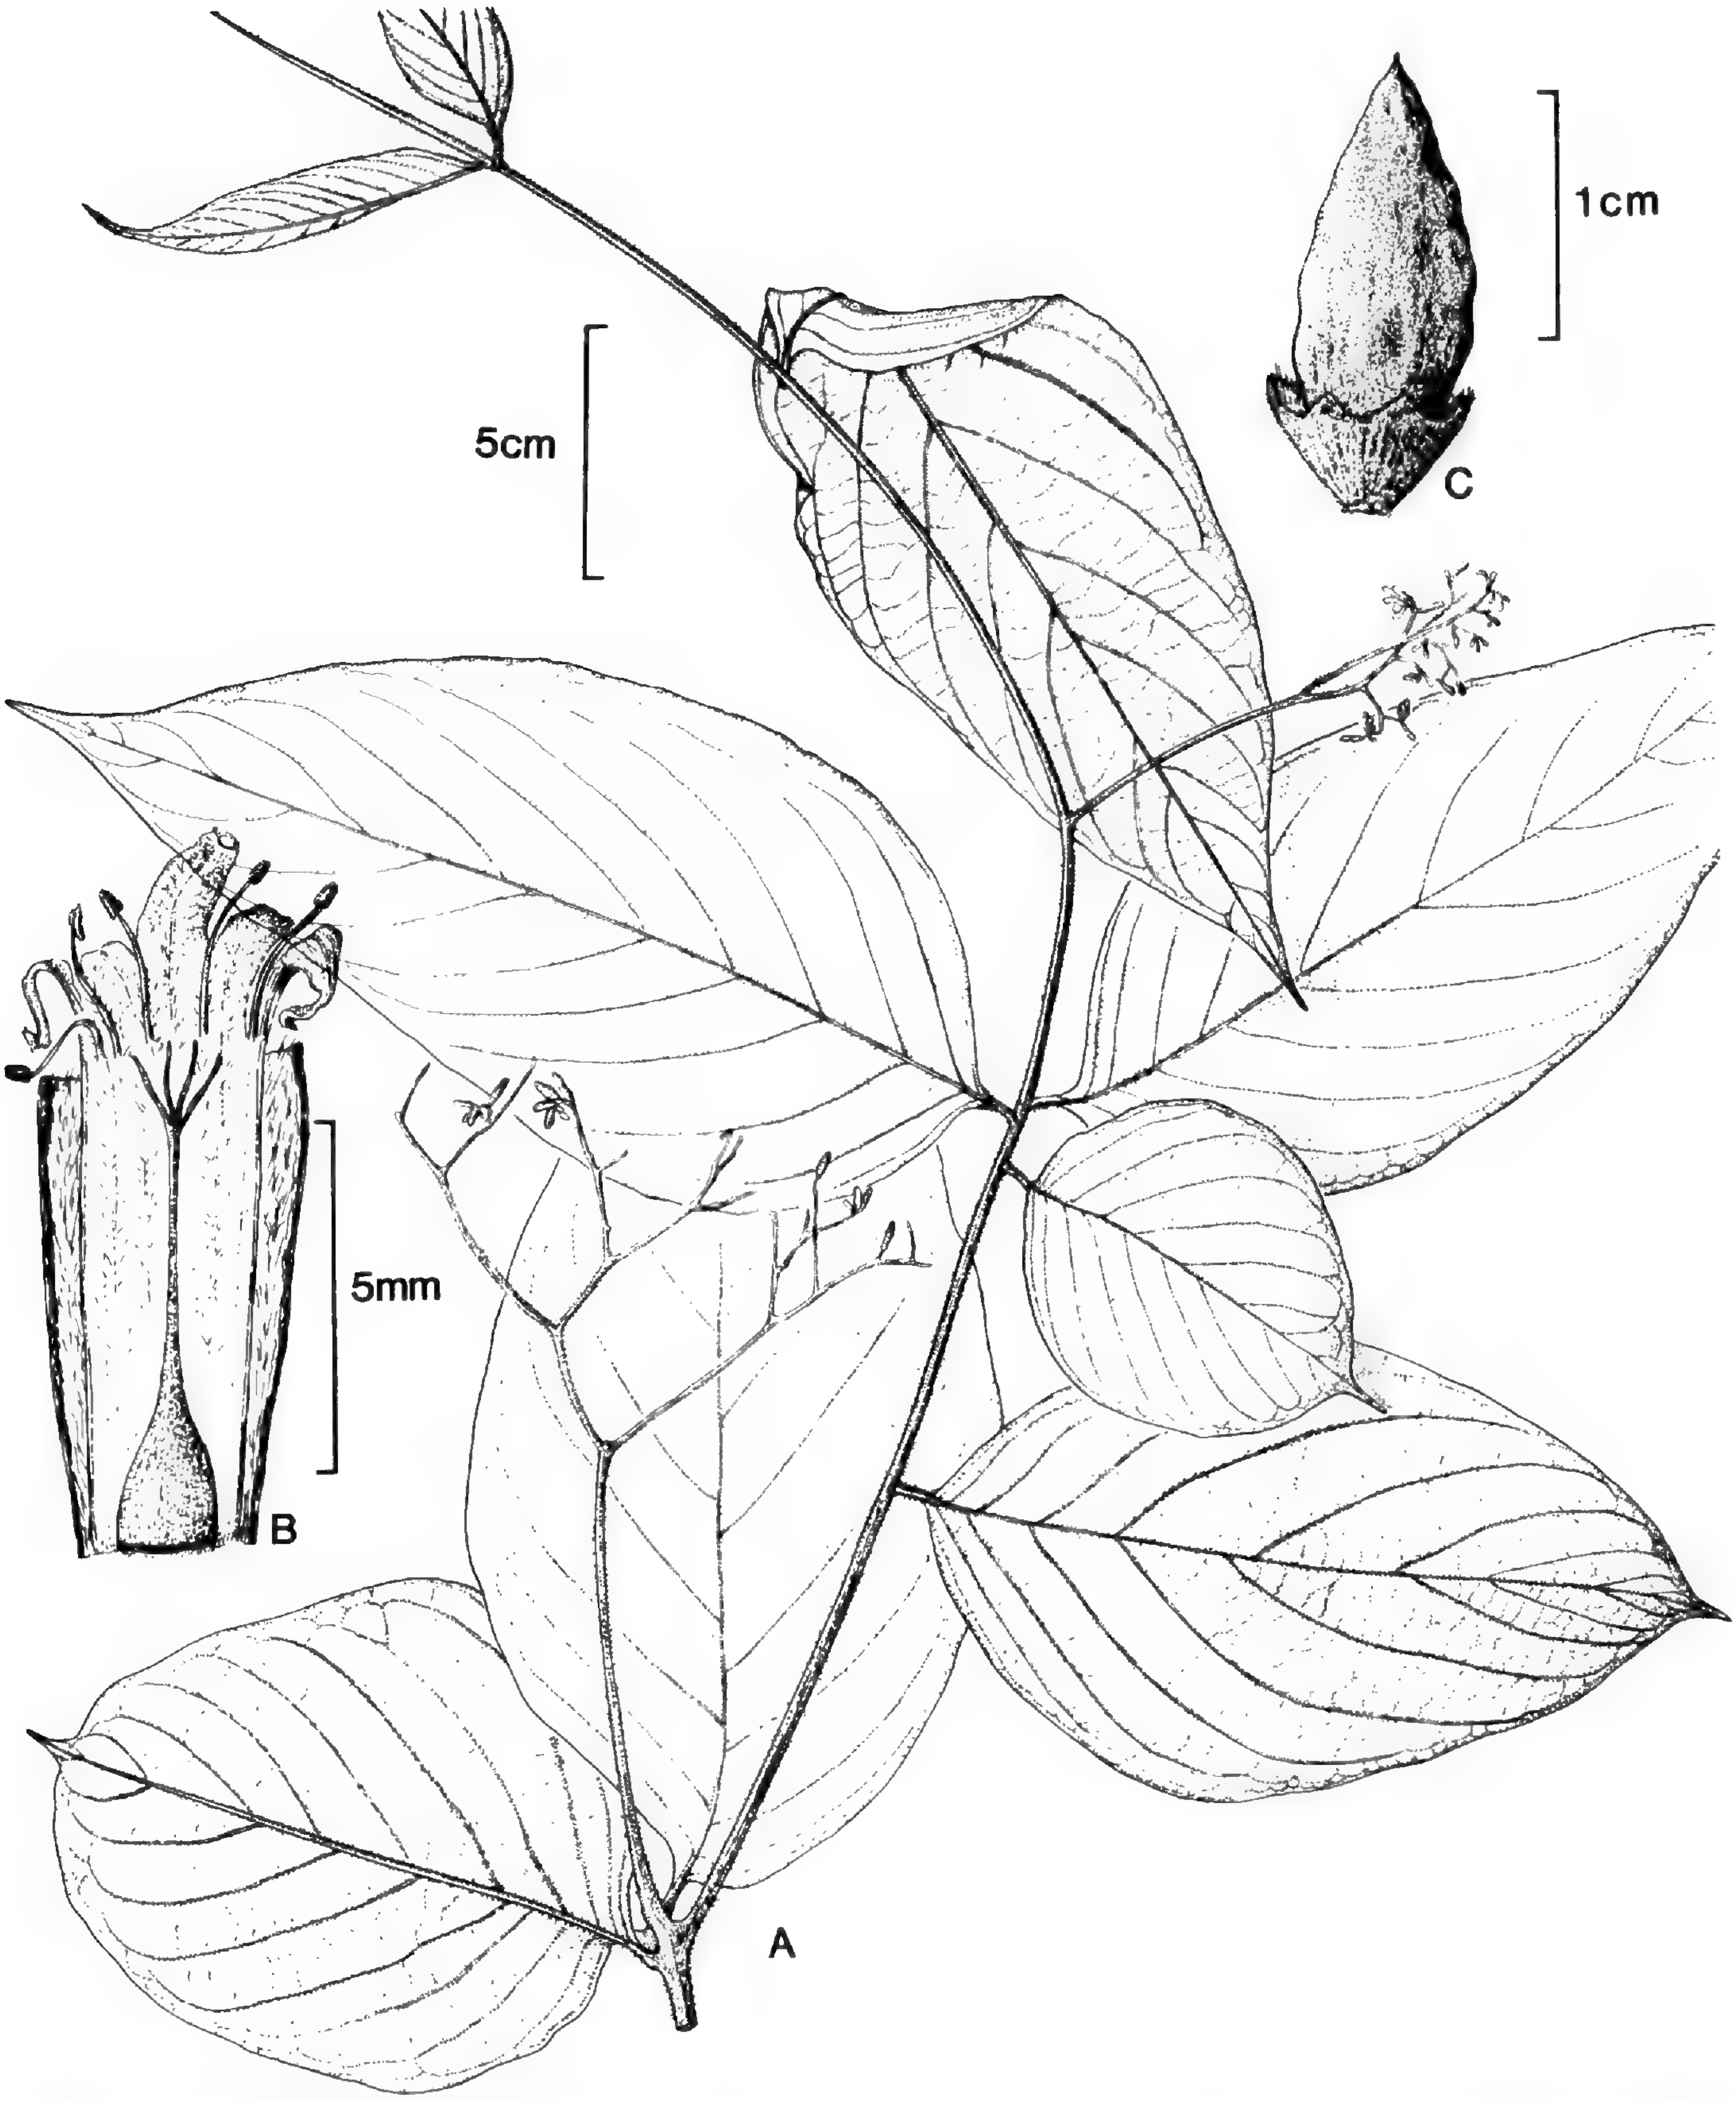

FIGURE 1. Cordia anisophylla.—*A. Flowering branch.—B. Flower with corolla opened.—C. Fruit. A, B from* Mori & Kallunki 5076 *(MO), Colón, Panama; C from* Mori & Kallunki 6373 *(MO), Panamá, Panama.*

SAN BLAS: near Nusigandi on Llano–Carti Road, 300–350 m, *McPherson 10796* (MO).

Cordia bicolor A. DC. in DC., Prodr. 9: 485. 1845. TYPE: Surinam: *Hostmann 406* (holotype, G-DC, not seen; microfiche, MO; isotype, P).

Cordia trichostyla Pittier, Contr. U.S. Natl. Herb. 18(6): 252. 1917. TYPE: Guatemala. Alta Verapaz: vicinity of Secanquim, 550 m, 30 Apr. 1905, *H. Pittier 189* (holotype, US 472845).

Cordia belizensis Lundell, Amer. Midl. Naturalist 29: 488. 1943. TYPE: Belize. Toledo: Monkey River, in high ridge between Swacey Branch and Wahaleaf Creek, 5 July 1942, *P. H. Gentle 4045* (holotype, MICH; isotypes, GH, NY).

Tree to 20 m tall, the young twigs velutinous to puberulent. Leaves persistent; petioles (2–)3–8(–16) mm long; blades elliptic to ovate or narrowly elliptic, (8–)10–19(–22) cm long, (3.3–)4–9(–11.5) cm wide, the apex acuminate, the base obtuse to rounded, the margin entire, the adaxial surface sparsely strigillose to scabrous, the abaxial surface pale, puberulent to strigillose. Inflorescence terminal or borne in the axils of branches, cymose, to 13(–20) cm long, 14(–28) cm broad, the branches velutinous. Flowers sessile, bisexual, monomorphic with the stamens as long or longer than the stigmas; calyx tubular-campanulate, (3.3–)3.6–4.3(–4.9) mm long, ribs absent, densely strigillose, the 5 lobes deltate to attenuate; corolla white, tubular with reflexed lobes, 6.2–7 mm long, 5-merous, the lobes oblong, (2.3–)2.7–3(–3.8) mm long, the tube (2.5–)3.6–4.6(–5) mm long, pubescent in the mouth; stamens 5, the filaments (3.8–)4.8–6(–6.4) mm long, the upper (1–)1.8–3 mm free, pubescent at the point of insertion, the anthers oblong, 1–1.6 mm long; ovary ellipsoid, 0.8–1.6 mm long, strigillose; disc crateriform, 0.3–1 mm tall; style 3–3.7 mm long, the stigma lobes discoid to broadly clavate. Fruits seated in the cupulate calyx, white, drupaceous, the stone inequilaterally ovoid, (7.3–)10.5–13 mm long, (4.5–)7.5–9.5 mm broad, the exocarp densely strigillose, the endocarp bony.

Distribution. *Cordia bicolor* occurs in wet forests from sea level to 500 m in elevation and ranges from Mexico to South America. In Panama this species is known from the Canal Area, Chiriquí, Colón, Darién, Panamá, and Veraguas.

Cordia bicolor is perhaps most closely related to the *C. panamensis* complex in that it also has dichotomous lateral branching, anisophyllous leaves, and similar indument. However, it differs from the other Central American species in its strigillose fruits, a relatively rare character found in several unrelated South American species. *Cordia toqueve* Aubl. of South America is the only other species of this complex that shares this trait.

Additional specimens examined. PANAMA. CANAL AREA: Barro Colorado Island, *Aviles 21* (F); *Croat 5630* (DUKE, F, MO, NY, SCZ), *5823* (DUKE, F, NY, SCZ (2)), *7705* (DUKE, F, MO, NY), *8004* (F, MO, NY, SCZ), *8804* (DUKE, MO), *8809* (F (2), DUKE, MO, NY), *9447* (MO), *14855* (MO, SCZ, UC); *Duke 8379* (NY); without definite locality, *Epplesheimer s.n.* (F (2)); Barro Colorado Island, *Foster 1778* (DUKE, F); area W of Limón Bay, Gatún Locks and Gatún Lake, *Johnston 1588* (A); Barro Colorado Island, *Kenoyer 656* (US); Pipeline Road between mile marker 0 and 11.1 ca. 16 mi. N of Gamboa, *Lewis et al. 5446* (F, MO, NY); near Fort Randolph, *Maxon & Harvey 6520* (US); Barro Colorado Island, *Oppenheimer 252* (MO); near old Fort Lorenzo, mouth of Río Chagres, *Piper 5964* (US). Cordia bifurcata Roemer & Schultes, Syst. Veg. 4: 466. 1819. *Varronia dichotoma* Ruíz Lopez & Pavón, Fl. Peruv. 2: 23, t. 146. 1799, not *Cordia dichotoma* G. Forster, Fl. Ins. Austr. 18 n. 110. 1786. TYPE: Peru. Huánuco: Chacahuasi, *Hipólito Ruíz & José Pavón s.n.* (holotype, B-W, not seen; microfiche, MO).

Shrub to 3 m tall, the twigs sparsely strigillose, the hairs shorter than 0.5 mm, appressed, white translucent. Leaves deciduous, on short spurs 1.5–2 mm long; petioles 2–8 mm long, sparsely strigillose; blade ovate to lanceolate, (2.5–)3.7–9(–12) cm long, (0.8–)1.2–4(–4.7) cm wide, the apex acuminate, the base acute, the margin slightly serrate to entire, the adaxial surface sparsely puberulent with short, erect hairs, the abaxial surface sparsely pubescent. Inflorescence terminal or lateral, a small forking cyme with 4 or more branches, 0.8–2.3 cm broad, the peduncle 1.4–6 cm long, strigillose. Flowers sessile, distylous; calyx short-tubular, 2–2.7 mm long, strigillose, the 5 lobes deltate to shallowly deltate; corolla white, tubular, (2.7–)3.2–3.7 mm long, truncate at the apex, canescent in the middle of the tube; stamens 5, the filaments (2.2–)2.7–3.5 mm long, the upper 0.6–1(–1.3) mm free, canescent at insertion, the anthers broadly ellipsoid, 0.5–0.6 mm long; ovary very broadly obovoid to broadly depressed obovoid, 0.6–1 mm long; disc thin, cuplike, nearly completely adnate to the ovary; style (2.2–)3–3.5 mm long, the stigma lobes flattened. Fruits drupaceous, ⅓–½ enclosed in the slightly accrescent calyx, bright red, the stone ovoid, 4–4.5 mm long, 2.2–3 mm broad, the endocarp bony.

Distribution. Cordia bifurcata occurs in wet forests from sea level to 600 m in elevation and ranges from southern Nicaragua south to Peru. In Panama this species is known from the provinces of Bocas del Toro, Colón, and Darién.

Cordia bifurcata is distinctive in its small, shrubby habit and small, cymose inflorescences and has no close relatives in Panama. It is a member of a taxonomically difficult group of mostly South American species that are all similar in general aspect. The only other member of this group found in Central America is *C. foliosa* Mart. & Gal. of southern Mexico and Guatemala, which differs from *C. bifurcata* in its elliptic, firm-textured leaves with a scabrous upper surface, apiculate flower buds, and acuminate calyx lobes. Two other species of Central America, *C. inermis* and *C. linnaei*, are also closely related to this group, but neither of these has a branched inflorescence.

Additional specimens examined. PANAMA. BOCAS DEL TORO: region of Almirante, *Cooper 83* (F, NY); Changuinola Valley, *Dunlap 90* (GH). COLÓN: vicinity of San Juan near Cement Plant Lake, *Blum & Tyson 537* (MO). DARIÉN: on trail from Punta Guayabo Grando to Río Jaqué, 50–200 m, *Antonio & Hahn 4415* (MO); vicinity of Paya, Río Paya, *Stern et al. 268* (G, MO, US).

Cordia bullata (L.) Roemer & Schultes, Syst. Veg. 4: 462. 1819. *Varronia bullata* L., Syst. ed. 10: 916. 1759. TYPE: Jamaica, *P. Browne s.n.* (holotype, LINN, not seen (Savage Catalog number 255.2); microfiche, MO).

Cordia bullata var. *angustata* DC., Prodr. 9: 496. 1845. TYPE: Guadalupe, 1818, *Krause s.n.* (holotype, G-DC, not seen; microfiche, MO).

Cordia asperrima DC., Prodr. 9: 498. 1845. *Varronia asperrima* (DC.) Friesen, Bull. Soc. Bot. Genève, Ser. 2, 24: 155, t. 1, f. 5. 1933. TYPE: Jamaica, 1822, *Bertero ex herb. Balbis* (holotype, G-DC, not seen; microfiche, MO).

Shrub to 1(–3) m tall, the twigs hirsute to hirtellous, the hairs erect to spreading. Leaves deciduous, on short spurs to 1 mm long; petioles 2–7(–10) mm long, shallowly canaliculate to flattened adaxially, hirsute to hirtellous, the hairs erect to spreading; blade ovate to narrowly ovate, (1.5–)2–8(–9.2) cm long, (0.8–)1.2–4.7(–6.3) cm wide, the apex acute to slightly attenuate, the base subobtuse to obtuse or acute and abruptly decurrent along the petiole, the margin serrate, usually unevenly so, the teeth usually sharp and often short-apiculate, the adaxial surface usually bullate, strigose, the lower surface coarsely pubescent, the hairs ± restricted to the veins. Inflorescence internodal or less commonly subterminal or terminal, a dense, often slightly ellipsoid head, 8–12(–15) mm broad, the peduncle (1.5–)3–6.5(–13.5) cm long, hirsute, the hairs erect to spreading. Flowers distylous, sessile; calyx campanulate, (2–)2.5–3.3(–3.8) mm long, (2–)2.5–3.5 mm wide at the mouth, ribs absent, strigillose, the 5 lobes deltate to triangular, 0.5–1 mm long, with a prolonged filiform tip 1–3(–3.5) mm long; corolla white, tubular, 3–5.3(–6) mm long, undulate, the lobes scarcely distinct, the tube 1.2–2.8 (–3.2) mm long; stamens 5, the filaments (3.3–) 3.8–4.3(–5) mm long, the upper 1–1.7(–2) mm free, puberulent in a ring in the mouth of the corolla tube, the anthers ellipsoid, 0.6–1 mm long; ovary ovoid, 1–1.8 mm long, glabrous; disc usually indistinct from the base of the ovary; style 0.6–4.3 mm long, the stylar branches 0.4–1 mm long, the stigma lobes clavate to discoid. Fruits drupaceous, red, the stone ovoid, 3.7–5.3 mm long, 2.5–3.2 mm broad, the mesocarp thin, the endocarp bony.

Distribution. *Cordia bullata* occurs in dry forests from sea level to 1,400 m in elevation. It is known from Nicaragua to southern Mexico, northern South America, the Greater Antilles, and a single collection from the province of Veraguas in Panama.

Cordia bullata is closely related to and often confused with *C. globosa* (Jacq.) Kunth but differs by having peduncles greater than 3 cm long and corollas less than 6 mm long. Both are common in northern Central America, and populations with interspecific hybrids are known from Nicaragua and Honduras.

Additional specimens examined. PANAMA. VERAGUAS: El Cuchillo, near Cerro Tute, up from Santa Fe, 1,300 m, *Hamilton et al. 1203* (MO).

Cordia collococca L., Sp. Pl. ed. 2. 274. 1762; excluding *Cordia glabra* L. = *Bourreria succulenta* Jacq.; I. M. Johnston, J. Arnold Arbor. 21: 345. 1940. TYPE: without definite locality, collector unknown (holotype, LINN, not seen (Savage Catalog number 253.8); microfiche, MO).

Cordia micrantha Sw., Prodr. 47. 1788. TYPE: "habitat in Jamaica," not seen.

Small tree to 8(–15) m tall, the twigs sparsely to evenly strigillose, later waxy. Leaves deciduous; petioles 5–12(–15) mm long, sparsely strigillose; blade oblong-obovate to elliptic or obovate, (4.7–)5.5–14(–15.2) cm long, (2.5–)3–6.5(–7) cm wide, the apex acute, often with short-acuminate tip, rarely acute, the base cuneate to acute, the margin entire, the adaxial surface glabrous or nearly so but with numerous small papillae, the abaxial surface evenly strigillose to hirtellous. Inflorescence terminal, borne on old wood just before the new vegetative shoots appear, or axillary, cymose, (6–)7–14(–18) cm broad, the branches sparsely strigillose. Flowers sessile, unisexual by abortion, the plants dioecious; female flowers with small, nonfunctional anthers; male flowers with shortened, reduced styles; calyx cupulate, (1.7–)2–2.6 (–3) mm long, ribs absent, evenly strigillose, circumscissile or unevenly 3-lobed; corolla white, tubular with reflexed lobes, (4.5–)4.8–6.3(–6.9) mm long, 5-merous, the lobes oblong-ovate to ovate, (2.3–)2.8–3.7(–4) mm long, the tube 1.7–2.9(–3.3) mm long; stamens 5, the filaments 2.5–5 mm long, the upper (0.8–)1.7–2.2 mm free, puberulent to pubescent below insertion, the anthers oblong to ellipsoid, 0.5–1.6 mm long; ovary ovoid to oblong, 0.8–1.2 mm long, glabrous; style 0.4–2 mm long, the stigma lobes clavate to filiform. Fruit borne with the small calyx persisting at the base, bright red, drupaceous, glabrous, the stone inequilaterally ovoid, 7.5–9.3 mm long, 5.5–7.3 mm broad, the endocarp bony.

Distribution. *Cordia collococca* occurs in dry forests from sea level to 200(–900) m in elevation from Mexico south to northern South America and the West Indies. In Panama this species is known from Bocas del Toro, Canal Area, Chiriquí, Colón, Herrera, Los Santos, Panamá, and San Blas.

Cordia collococca is a relatively common species throughout much of its range, although it has not been collected frequently in Panama. It is easily confused with *Cordia eriostigma* but can be distinguished by being a smaller tree with an even indument of short appressed hairs on its abaxial leaf surface, deciduous leaves, and flowers that are unisexual by abortion. *Cordia collococca* is generally found at elevations below 200 m in dry forests, while *C. eriostigma* usually grows at 600–1,400 m in moist forests.

Cordia micrantha is clearly a synonym of *C. collococca*, but Swartz specified no type other than "habitat in Jamaica," and the choice of a lectotype will require study of material in European herbaria. The name *Cordia glabra* has been improperly applied to this species; Johnston (1940) showed that this name should be considered a synonym of *Bourreria succulenta.*

Additional specimens examined. PANAMA. BOCAS DEL TORO: Almirante, *Cooper 406* (CFMR, F, NY, US); on lower Changuinola River, *Stork 273* (UC, US). CANAL AREA: between Farfan beach and Vera Cruz, *Duke 11733* (MO). CHIRIQUÍ: Progresso, *Cooper & Slater 300* (CFMR, F, US); without definite locality, *Cooper & Slater 307* (CFMR, F, NY, US). COLÓN: Santa Rita Ridge, 500 m, *McPherson 8456* (MO). HERRERA: carretera a Pesé, *Lao 585* (MO). LOS SANTOS: Punta Mala, *Croat 9756* (DUKE), *9763B* (MO (2)). Cordia correae James S. Miller, sp. nov. TYPE: Panama. Coclé: La Mesa, 4 km north of El Valle, disturbed tropical wet forest and roadside, 875 m, 3 Jan. 1974, *M. Nee & J. D. Dwyer 9164* (holotype, MO 2414635; isotype, DUKE). Figure 2.

Arbor vel frutex ad 8 m alta, ramunculis glabris ad strigillosis. Folia persistentia, petiolis 5–10(–14) mm longis, strigillosis; laminae anisophyllae, coriaceae, foliis maioribus ovatis ad anguste ovatis, 10.3–17.6 cm longis, 4.8–8.8 cm latis, apice acuminatis, basi rotundatis ad obtusis, superficie sparsim strigillosa, pagina inferiore minute strigillosa. Inflorescentiae internodales vel axillares, cymosae, ad 5.5 cm latae. Flores sessiles; calyx urceolatus, 5.6 mm longus, rufostrigillosus. Fructus drupaceus, aurantiacus, putamine inaequilateraliter ovoideo, 8.4–13 cm longo, 6.2–9 mm lato, ruminato.

Tree or shrub 4(–8) m tall, the twigs nearly glabrous to strigillose. Leaves persistent; petioles 5–10(–14) mm long, canaliculate adaxially, unevenly and often sparsely strigillose; blades anisophyllous, coriaceous, the larger ones ovate to narrowly ovate, 10.3–17.6 cm long, 4.8–8.8 cm wide, the smaller ones ovate, 7–8 cm long, 4–5.5 cm wide, the apex acuminate, the base rounded to obtuse or rarely acute, the margin entire, the adaxial surface with widely scattered appressed hairs, the abaxial surface minutely strigillose. Inflorescences subterminal, internodal or axillary, few per stem, cymose, to 5.5 cm broad, expanding somewhat in fruit, peduncle 1.8–5.3 cm long, strigillose, the hairs brown. Flowers sessile; calyx urceolate, 5.6 mm long, 3 mm wide at the mouth, the 5 lobes deltate, 0.7–1.4 mm long, ribs absent, rufous-strigillose; corolla white, tubular with reflexed lobes, 8.5 mm long, 5-merous, the lobes oblong, 3.6 mm long, 1.9 mm wide, the tube 7.8 mm long; stamens 5, the filaments 10.5 mm long, the upper 6 mm free, glabrous, the anthers oblong, ca. 1 mm long; ovary ovoid, glabrous; style ca. 4 mm long, the stylar branches 2.3 mm long, the stigma lobes clavate. Fruits borne in the slightly expanded, saucer-shaped calyx, orange at maturity, drupaceous, glabrous, the stone inequilaterally ovoid, 8.4–13 mm long, 6.2–9 mm broad, ruminate, the endocarp bony.

Distribution. Cordia correae occurs in wet forests from 800 to 1,000 m in elevation and is known only from Panama in the provinces of Coclé, Panamá, and Veraguas.

Cordia correae is known from only a few collections from Panama in the region of El Valle and from Cerro Jefe. Its closest relative is probably *C. protracta* I. M. Johnston, a species of low elevations along the Atlantic coast of San Blas and adjacent Colombia. The two species share similar habits of growth, branching patterns, anisophyllous leaves, and distinctly five-lobed calyces. The fruits of *C. correae,* however, are orange, subglobose, and have a ruminate surface, while those of *C. protracta* are white, elongate, and ridged longitudinally. *Cordia correae,* which is endemic to Panama, is named in honor of Profesora Mireya D. Correa A., who has done much to advance the study of Panamanian plants.

Additional specimens examined. PANAMA. COCLÉ: La Mesa above El Valle, along road which ends in pasture, 810 m, *Croat 25310* (MO, NY); vicinity of La Mesa, N of El Valle, 1,000 m, *Gentry 6813* (AAU, MO, NY); Cerro Pilón, El Valle Site Area of WEPCOR, *Kirkbride 1071* (NY); La Mesa, 4 km N of El Valle, 850–875 m, *Nee & Dwyer 9214* (MO (2), NY). PANAMÁ: along road, 18.9 km N of Cerro Azul, *Mori & Kallunki 4998* (AAU, DUKE, NY, (2)). VERAGUAS: vicinity of Cerro Tute, forested slopes along trail to summit, 850–1,000 m, *McPherson 10684* (MO).

Cordia croatii James S. Miller, sp. nov. TYPE: Panama. Verguas: 5 mi. west of

Santa Fe on road past Escuela Agricola Alto Piedra on Pacific side of divide, 800–1,200 m, *T. B. Croat 23059* (holotype, MO 2198065; isotypes, AAU, BR, C, CAS, CR, DUKE, F, L, LL, MEXU, NY, RSA, US, WIS). Figure 3.

Arbor ad 20 m alta, ramunculis glabris ad strigillosis. Folia persistentia, petiolis 6–12 mm longis, laminae ellipticae ad elliptico-ovatae, (4.5–)5.7–8.2(–11.2) cm longae, (2–)3–4.3(–4.8) cm latae, apice acuto ad leviter acuminato, basi acuta ad obtusa. Inflorescentiae terminales, cymosae (3–)8–12(–15) cm latae. Flores bisexuales; calyx campanulatus, 3–4.3 mm longus, glaber, 3(–4)-lobatus; corolla alba, tubularis, 5–7.2 mm longa, 5-lobata, lobis reflexis, ovatis; stamina 5, filis 4–6.5 mm longis, villosis, antheris oblongis, 1.1 mm longis. Fructus drupaceus, putamine inaequilateraliter ovoideo, 8–11 mm longo, 6–8(–11) mm lato.

Tree to 20 m tall, the twigs nearly glabrous to sparsely strigillose, often with considerable waxy deposits. Leaves persistent; petioles 6–12 mm long, deeply canaliculate adaxially, nearly glabrous to sparsely strigillose; blades

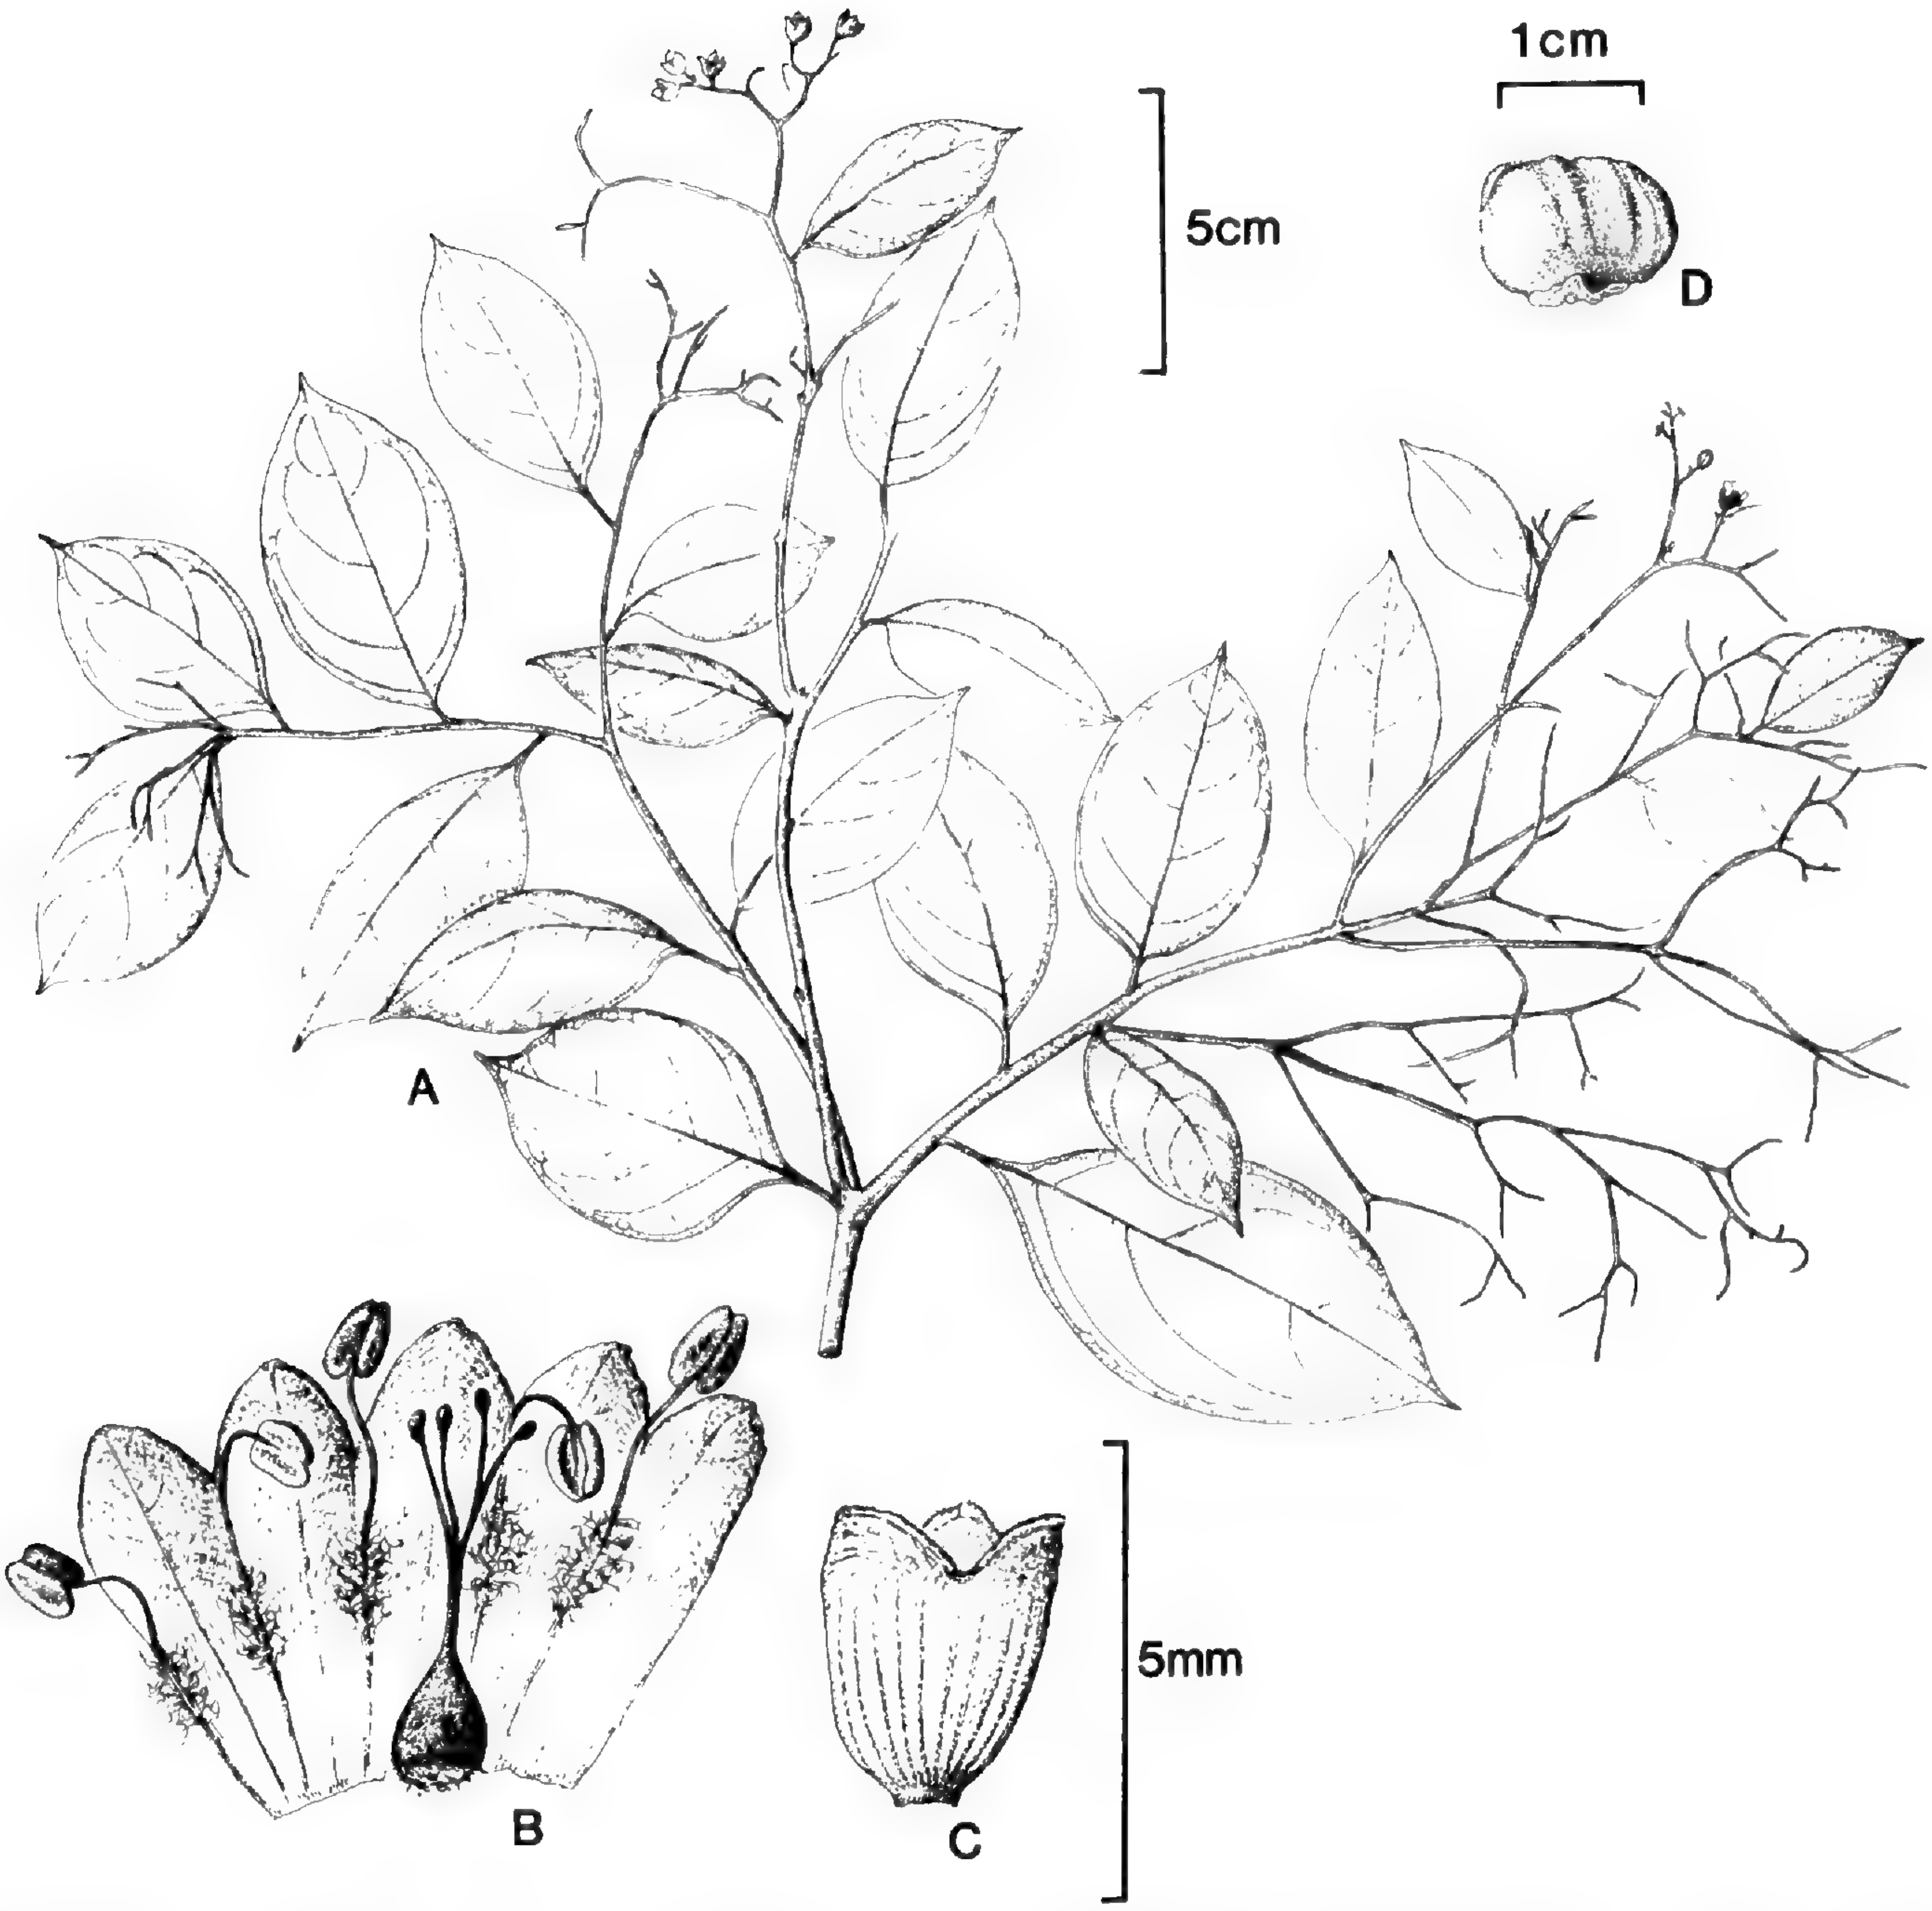

FIGURE 3. Cordia croatii.—*A. Flowering branch.—B. Flower with corolla opened.—C. Calyx.—D. Dried fruit.—A–C from* Croat 23059 *(MO), Veraguas, Panama; D from* Tonduz 12520 *(US), Alajuela, Costa Rica.*

elliptic to elliptic-ovate, (4.5–)5.7–8.2(–11.2) cm long, (2–)3–4.3(–5) cm wide, the apex acute to slightly acuminate, the base acute or less commonly obtuse and slightly decurrent, the margin entire, the adaxial surface glabrous to papillose with widely scattered appressed hairs, the abaxial surface glabrous. Inflorescence terminal, cymose (3–)8–12 (–15) cm broad, the branches sparsely brown-strigillose to ferruginous-puberulent. Flowers sessile, monomorphic, the stamens longer than style; calyx campanulate, 3–4.3 mm long, 3.4–4 mm wide at mouth, the 3(–4) lobes ovate, rounded at apex, 1–1.8 mm long, ribs absent, glabrous; corolla white, tubular with reflexed lobes, 5–7.2 mm long, 5-merous, the lobes ovate, 2–4.3 mm long, 1.5–3 mm wide, the tube 2.2–3 mm long, glabrous; stamens 5, the filaments 4–6.5 mm long, the upper 2–2.5 mm free, villous along the lower free portion, the anthers oblong, 1.1 mm long; ovary ovoid to conical, 1–1.6 mm long, 1–1.4 mm broad, glabrous; disc crateriform, 0.4–0.5 mm tall, 1–1.1 mm broad, glabrous; style 2–2.3 mm long, the stylar branches 1.7–2.5 mm long, the stigma lobes discoid. Fruits borne in the saucer-shaped calyx, drupaceous, glabrous, the stone inequilaterally broadly ovoid, 8–11 mm long, 6–8(–11) mm broad, the endocarp bony.

Distribution. *Cordia croatii* occurs in cloud forests from 800 to 1,200 m in elevation and is known from the San Ramón region of Costa Rica and the provinces of Coclé and Veraguas in Panama.

Cordia croatii is distinct in its small elliptic leaves. It is known only from a few Panamanian collections and several from the San Ramón region of Costa Rica, although further collecting efforts may reveal it in cloud forests in between. This species is somewhat unusual in sect. *Myxa* in that it occurs at relatively high elevations, unlike the majority of its relatives, which are usually found in lowland wet forests. *Cordia croatii* shares a three-lobed calyx with *Cordia lasiocalyx* Pittier, *C. lucidula* I. M. Johnston, and *C. porcata* Nowicke and is probably closely related to these species. *Cordia croatii* is named in honor of Dr. Thomas B. Croat who collected the type material and has contributed greatly to the study of Panamanian botany.

Additional specimens examined. PANAMA. COCLÉ: Cerro Pilón, 2,900 ft., *Lallathin 1F* (MO); *1-1* (MO).

Shrub to 2(–4) m tall, the twigs glabrous to strigillose or puberulent or rarely hirsute but always with small, globose wax particles. Leaves deciduous, on short spurs to 1 mm long; petioles 1–8(–21) mm long, strigillose or puberulent to hirsute; blades lanceolate to narrowly elliptic or elliptic-ovate, (1–)2–9.4(–16) cm long, 0.5–4(–7.3) cm wide, the apex acute, the base cuneate to acute and sometimes decurrent, the margin serrate, occasionally merely undulate, the adaxial surface scabrous to papillose, the abaxial surface strigillose with most hairs restricted to the major veins, or tomentulose. Inflorescence terminal, spicate, 1.5–8.8(–15) cm long, the peduncle 1.8 cm long, puberulent or strigillose to nearly glabrous. Flowers sessile, distylous; calyx campanulate, 2–3.2(–3.8) mm long, the 5(–6) lobes deltate; corolla white, tubular with reflexed to spreading lobes, (3.8–)4.8–6.8 (–8.2) mm long, 5(–6)-merous, the lobes ovate to depressed ovate, 1.2–1.8(–2.8) mm long, the tube 2.4–3.4 mm long; stamens 5, the filaments 3.2–5(–6) mm long, the upper 0.8–2 mm free, the free portion glabrous, puberulent to pubescent beneath the point of insertion, the anthers ellipsoid, (0.3–)0.7–1 mm long; ovary ovoid to broadly ovoid, (0.8–)1–1.2(–1.6) mm long; disc crateriform, 0.4–0.6(–0.8) mm tall; style (1.4–)2–4(–5.7) mm long, the stigma lobes clavate. Fruits drupaceous, red, ½–¾ enclosed in the slightly accrescent calyx, the stone ovoid, (3.7–)4–4.5 (–6) mm long, 2.2–3 mm broad, the endocarp bony.

Distribution. *Cordia curassavica* is common in a wide variety of habitats but is found most often in disturbed or dry areas from sea level to 2,000 m in elevation. This species ranges from Sonora and Baja California in northern Mexico south to northern South America and east to the West Indies. It is known from all of the provinces in Panama.

Cordia curassavica is extremely variable, and many of its variants have been recognized as taxonomically distinct by previous authors. Much of the variation throughout the range of *C. curassavica* is in overall size of the plants, size of leaves, and size of inflorescences. Individuals from populations in Baja California and Socorro Island are quite small in stature with leaves much reduced in size; the synonym *C. socorrensis* Brandegee is based on a collection of this sort. The most diminutive plants occur in populations from the Tehuacán region of Puebla, Mexico, the area from which the type of another synonym, *Cordia brevispicata* Martens & Galeotti, was collected.

The other extreme variant of *Cordia curassavica* occurs along the Atlantic coast of Central America, and only in Panama can it be found on the Pacific slope. These plants are more robust and differ from other populations in being larger in all aspects as well as in having broader leaves. Also, the pubescence of the upper leaf surface differs from what is seen in other populations; the hairs are represented only by the persistent bases, lacking shafts. *Cordia chepensis*, based on a type collection from Chepo, and *Cordia littoralis*, based on a population from the Atlantic coast of Costa Rica, are synonyms of this sort. These were referred to as "typical *Cordia curassavica*" by Johnston (1949a), who felt that with further study, several segregate species would be recognized. Numerous collections from all portions of the range indicate that there are no clear morphological discontinuities.

Although populations of *Cordia curassavica* vary over its geographic range, a much greater component of this variation appears to be due to phenotypic response to local climate rather than genetic differences between the populations. While collections made in the field from different regions often vary widely in appearance, most of these differences are not evident in the plants that have been raised in the greenhouse from seed collected in Mexico, Nicaragua, and Panama. Adult plants raised from seed under uniform conditions from morphologically and geographically diverse populations are often virtually indistinguishable.

Cordia curassavica hybridizes with *C. spinescens* L. and with *C. bullata* (L.) Roemer & Schultes and probably hybridizes with several additional species (Miller, in prep.). Observations made on numerous hybrids show that they vary in pollen stainability according to the parentage, but even if sterile, they are capable of persisting by spreading rhizomatously. As a result, these hybrids are represented in herbarium collections, leading to confusion and the long list of synonyms associated with this species. Although interspecific hybridization appears to be relatively uncommon, it may be adding to the variability of populations through rare backcrossing to parent plants.

Data indicate that *Cordia curassavica* is best treated in a broad sense, as much of the variability between populations is phenotypic. While there are considerable differences between the extremes, none of the intermediates exhibit any significant reduction in pollen stainability. Despite this variability, *Cordia curassavica* is a well-marked species easily distinguished from *C. spinescens* by having lanceolate leaves and elongate, terminal, spicate inflorescences. *Cordia curassavica* differs from *Cordia guanacastensis* Standley, the other Central American species with which it could be confused, by having much more elongate spikes generally less than 8 mm broad and by having the peduncles nearly glabrous or puberulent to strigillose rather than hispid as in *C. guanacastensis.*

Additional specimens examined. PANAMA. BOCAS DEL TORO: Santa Catalina River bank and beach, *Blackwell et al. 2710* (MO, SCZ, UC); vicinity of Almirante, Changuinola Canal, *Blum 1389* (MO, SCZ); Chiriquí Lagoon, Isla Colón, 0–120 m, *Wedel 562* (GH, MO, U), *2478* (MO, NY, US); Chiriquí Lagoon, Columbus Island, *Wedel 2608* (MO, US); Chiriquí Lagoon, Isla Colón, *Wedel 2923* (MO, NY, US). CANAL AREA: Ancon Hill, *Bartlett & Lasser 16312* (GH, MICH, MO); Fort Sherman area, *Blum et al. 386* (MO, SCZ); Gamboa Navy Pipe Line along main dirt road, *Correa & Haines 541* (MO); road S-10, north of Escobal, *Croat 12447* (F, MO); near beach at Fort Kobbe, *Duke 4196* (MO (2)); near Coco Solo Weather Station, *Duke 4284* (MO); Summit Gardens, *Dwyer 7190* (MO); Fort San Lorenzo, *Ebinger 457* (F, MEXU, MO); Ancon Hill, 100–200 m, *Killip 12059* (GH, NY, US), *12106* (US); near Fort Randolph, *Maxon & Harvey 6506* (US); low woods E of Bella Vista, a suburb of Panama City, *Maxon & Valentine 6945* (US); Toro Point near Fort Sherman, *McDaniel 4996* (MO); Fort San Lorenzo, bluff above Chagres River, *McDaniel 5179* (MO); Curundu, 30–40 m, *Miller 1033, 1034, 1035, 1036, 1037, 1038, 1039, 1040, 1041, 1042, 1043, 1044* (MO); along Fort Sherman road (S2 or 82), *Mori & Kallunki 2712* (MO); Ancon Hill, *Standley 25207* (US); Balboa, *Standley 25552, 27152* (US); near Fort Randolph, *Standley 28604* (US); Mount Hope Cemetery, *Standley 28786* (US); vicinity of Fort Sherman, *Standley 31220* (US); Fort Sherman near road to Gatún, *Tyson & Dwyer 1206* (MO, SCZ); Howard Air Force Base near Red Devil drop zone, *Tyson 1865* (MO); Fort Clayton, *Tyson et al. 2304* (NY); vicinity of Miraflores Lake, just outside Naval reserve, *White 244* (MO, NY). CHIRIQUÍ: along trail north of Cerro Punta, *Croat 10477* (MO, NY). COCLÉ: vicinity of El Valle, 800–1,000 m, *Allen 100, 753* (F, MO); hills S of El Valle de Antón, 700 m, *Allen 2510* (US (2)); Río Hato Airstrip, *Blum & Dwyer 2474* (AAU, SCZ); *Burch et al. 1148* (K, MO, UC, US); 10 km W of Agua Dulce on the Interamerican Highway, *Correa 87* (MO, SCZ); 3 mi. Cordia cymosa (J. D. Smith) Standley, Publ. Field Mus. Nat. Hist., Bot. Ser., 18: 981. 1938. *Cornutia cymosa* J. D. Smith, Bot. Gaz. (Crawfordsville) 40: 10. 1905. TYPE: Costa Rica. Alajuela: Paturages de la Palma, 1,460 m, 19 Nov. 1898, *A. Tonduz 12555* (holotype, US 1323323; isotypes, K, US (2)).

Tree to 15(–30) m tall, the twigs ferruginous-tomentulose with scattered echinate hairs. Leaves persistent; petioles 15–41 mm long, shallowly canaliculate adaxially, ferruginous-tomentulose with scattered echinate hairs; blades dimorphic, the larger ones elliptic or elliptic-ovate, (15–)18–32(–37.5) cm long, (7.5–)11–20.5(–26) cm wide, the smaller ones orbicular to circular, 9.5–16 cm long, 8.5–17 cm wide, the apex obtuse or less commonly rounded or acute, the base obtuse or less commonly acute, the margin entire, the adaxial surface strigillose, the abaxial surface soft-pubescent, with most of the the hairs restricted to the veins. Inflorescence terminal, cymose, (14.5–)17–29 cm long, 18.5–31 cm broad, the peduncle (1–)3.5–8.2(–11.2) cm long, ferruginous-tomentulose with scattered echinate hairs. Flowers sessile, unisexual by abortion, the plants dioecious, the male flowers with reduced styles, the female flowers with small, nonfunctional anthers. Female flowers with a tubular calyx ca. 3.7 mm long; corolla white, tubular with reflexed lobes, 4.6–5.3 mm long, 5-merous, the lobes oblong-ovate, 2–2.2 mm long, 1–1.2 mm wide, the tube 2.4–3.3 mm long; stamens 5, nonfunctional, the filaments ca. 3.5 mm long, the upper 0.5–1.8 mm free, glabrous or nearly so, the anthers ellipsoid, shriveled, 0.2–0.4 mm long; ovary ellipsoid to ovoid, 1.5 mm long, 0.8–0.9 mm broad, glabrous; disc small, crateriform or indistinct from the base of the ovary; style 2.5–3.5 mm long, the stylar branches 1.2–2 mm long, the stigma lobes clavate to discoid. Male flowers with a campanulate calyx, 2.2–3 mm long, 2–3 mm wide at mouth, strigillose to puberulent, the 3–5 lobes depressed-ovate to deltate, ca. 0.8 mm long; corolla white, tubular-campanulate with reflexed lobes, 3.8–4.7 mm long, the 5 lobes oblong-ovate, 1.9–2.1 mm long, 1–1.4 mm wide, the tube 2–2.7(–3.8) mm long; stamens 5, the filaments (2.5–)4–5 mm long, the upper 1.6–2.4 mm free, pubescent at and just above the point of insertion, the anthers ellipsoid to oblong, 0.8–1 mm long; ovary ovoid, 0.6–1 mm long, 0.4–0.6 mm broad, glabrous; disc crateriform, 0.3–1 mm tall, 0.6–1.2 mm broad, or occasionally not distinct from the base of the ovary, glabrous; style 0.7–1(–1.8) mm long, the stylar branches 0.3–0.5(–1) mm long, the stigma lobes filiform to clavate. Fruits seated in the cupulate calyx, white, drupaceous, glabrous, the stone inequilaterally ovoid, 7.3–10 mm long, 4.8–9 mm broad, endocarp bony, 1-locular.

Distribution. *Cordia cymosa* ranges from Costa Rica south through Panama and

Colombia to Ecuador, mostly in cloud forests and rarely at low elevations in wet forests. In Panama it is known from Bocas del Toro, Canal Area, Coclé, and Panamá.

Cordia cymosa is a member of the *C. panamensis* group, one of the taxonomically most complex species groups of sect. *Myxa.* It is probably most closely related to *C. panamensis* but differs by having larger stature. *Cordia cymosa* is easily distinguished from the other members of the complex by its scattered echinate hairs on the stems, petioles, and peduncles.

Additional specimens examined. PANAMA. CANAL AREA: Mt. Lerio, *Christopherson 152* (US (2)). BOCAS DEL TORO: region of Cerro Colorado, 4.3 mi. above Camp Chami, 1,500 m, *McPherson 9595* (MO). COCLÉ: El Valle de Antón, *Alston 8809* (US). PANAMÁ: Cerro Campana, *Folsom et al. 2312* (MO); Cerro Campana, trails just inside entrance to Parque Nacional, 850 m, *Miller & Miller 998* (MO); along the Panamerican Highway 6.5 mi. E of highway checkpoint at turnoff to Chepo, *Miller et al. 1018* (MO).

Cordia dentata Poiret, Encycl. 7: 48. 1806. TYPE: Curasao: *Von Rohr 1799* (holotype, P in herb. Jussieu, not seen; microfiche, MO).

Cordia calyptrata Bertero ex Sprengel, Syst. Veg. 1: 649. 1825. *Varronia calyptrata* (Bertero ex Sprengel) DC., Prodr. 9: 469. 1845. TYPE: Mexico, Veracruz: near Vera Cruz, 1,000 ft., 1839, *J. J. Linden 284* (holotype, BR; isotypes, K, MICH).

Cordia tenuifolia Bertol., Rendiconto Sess. Ordinarie Accad. Sci. Ist. Bologna 1860–1861: 63. 1860; Mem. Reale Accad. Sci. Ist. Bologna, 11: 199, t. 11. 1861. TYPE: Guatemala: In Volcano d'acqua a Valasquezio (not seen).

Cordia leptopoda K. Krause, Bot. Jahrb. Syst. 37: 628. 1906. TYPE: Colombia: in planitiebus ad flumen Magdalena, prope Purificacion, 200–500 m, *Lehmann 7347* (not seen).

Cordia ovata Brandegee, Univ. Calif. Publ. Bot. 10: 187. 1922. TYPE: Mexico. Veracruz: Remudadero, *C. A. Purpus 8937* (holotype, UC; isotypes, GH, MO, NY, US).

Tall shrub or tree to 7(–10) m tall, the twigs puberulent to nearly glabrous. Leaves semideciduous; petioles 8–20 mm long; blades elliptic to widely elliptic or ovate, occasionally obovate, 4.6–10 cm long, 3–7 cm wide, the apex obtuse, or less commonly acute or rounded, the base obtuse to rounded, rarely acute, the margin entire or slightly denticulate, the adaxial surface strigillose to scabrous, the hairs arising from a distinct cystolith, the abaxial surface nearly glabrous to puberulent with dense tufts of curly hairs in the axils of the major veins. Inflorescence terminal, cymose-paniculate, 15–20 cm broad, the branches puberulent to sparsely strigillose. Flowers sessile, distylous; calyx campanulate, 3–3.8 mm long, circumscissile and tearing open somewhat unevenly, faintly 10(–12)-ribbed; corolla yellow to almost white, campanulate, 9–12 mm long, 5(–6)-merous, the lobes depresssed ovate, 1.8–4 mm long; stamens 5(–6), the filaments 4.7–9.4 mm long, puberulent at the point of insertion, the anthers ellipsoid to oblong, 1.2–2 mm long; ovary ellipsoid to globose, 1–1.5 mm long; style 3.5–5.3 mm long, the stigma lobes clavate. Fruits borne in the saucer-shaped calyx, translucent white, drupaceous, the stone ellipsoid, symmetrical or nearly so, 9–11 mm long, 5.5–7.2 mm broad, the endocarp bony.

Distribution. Cordia dentata occurs in dry forests from sea level to 400(–1,400) m in elevation from Mexico to northern South America and the West Indies. In Panama this species is known from the Canal Area and the provinces of Chiriquí, Herrera, Los Santos, Panamá, and Veraguas.

Cordia dentata is the most distinctive member of sect. *Myxa* in Central America. It is the only species with a yellow corolla that is relatively large, campanulate, and rather showy, and it is often cultivated for this reason, as well as for its sweet, edible fruits. It differs further from most other members of the section by having a circumscissile calyx. The unusual calyx and corolla of *C. dentata* suggest that it is not closely related to any of the other Panamanian members of sect. *Myxa*, and its relationships with species from other geographic regions are obscure. Johnston (1940) stated that the type of *C. dentata* was collected by Von Rohr, but the only sheet in the Jussieu herbarium is labeled as a Vahl collection. It was apparently collected by Von Rohr, and the sheet at Paris is a duplicate that Poiret received from Vahl.

Cordia dentata is common throughout

much of Mexico, Central America, the West Indies, and northern South America but has been only rarely collected in Panama. While most species of sect. *Myxa* occur in wet forests, *C. dentata* occurs in drier regions, often in second-growth and disturbed areas. It is frequently found growing along roadside ditches and fencerows from Costa Rica northward.

Additional specimens examined. PANAMA. CANAL AREA: Monte Lirio, *Christopherson 125* (US); between Gorgona and Mamei, 10–30 m, *Pittier 2236* (NY, US). CHIRIQUÍ: vicinity of David, *Pittier 2820* (GH, NY, US); vicinity of San Felix, 0–120 m, *Pittier 5448* (GH, NY), *5458* (US). VERAGUAS: 5 mi. E of Santiago, *Tyson et al. 4289* (MO, SCZ).

Cordia diversifolia Pavón ex A. DC. in DC., Prodr. 9: 474. 1845. TYPE: Nueva España, *Pavón s.n.* (holotype, G-DC, not seen; microfiche, MO; isotype, G).

Cordia johnstonii Cuf., Arch. Bot. Sist. 10: 41. 1934. TYPE: Costa Rica. Atlantida: 28 mi. from Puerto Limón, *Cufodontis 365* (not seen).

Cordia petenensis Lundell, Wrightia 4: 49. 1968. TYPE: Guatemala. Petén: Remate, 26 Apr. 1960, *E. Contreras 894* (holotype, LL; isotypes, F, K).

Shrub to slender tree to 5(–10) m tall, the twigs hispid to hirsute. Leaves persistent; petioles 5–19 mm long, hispid to hirsute; blades narrowly elliptic or sometimes lanceolate or oblanceolate, 10.5–19 cm long, 3.2–6.8 cm wide, the apex acuminate to acute, the base acute, the margin with few, short, filiform teeth toward the apex or entire, the adaxial surface strigose, the abaxial surface soft strigose, the hairs mostly restricted to the veins. Inflorescence terminal, paniculate, 5.5–11 cm broad, the branches hispid to villous. Flowers sessile or on short spurs to 2(–4) mm long, unisexual by abortion, the plants dioecious, the male flowers lacking styles, the female flowers with small, nonfunctional anthers; calyx tubular, 4.5–5.5 mm long, 10-ribbed, 3–4(–5)-lobed; corolla white, tubular with reflexed lobes, 8–9.5 mm long, 5-merous, the lobes oblong to obovate; stamens 5, in male flowers the filaments 7.7–9(–10.7) mm long, the upper (3–)4.5–5.3 mm free, glabrous or the lower free portion pubescent, the anthers oblong, 0.4–1.8 mm long, in female flowers the stamens much reduced, the anthers 0.4–0.7 mm long; ovary ovoid, 0.4–1.2 mm long; disc widely depressed obovoid, 0.5–1 mm tall, style 7–8.5 mm long, absent in male flowers, the stigma lobes filiform. Fruits borne in the expanded, saucer-shaped calyx, white, drupaceous, the stone ovoid to ellipsoid, 7–9 mm long, 4–6 mm broad, the endocarp bony.

Distribution. *Cordia diversifolia* occurs in wet forests of the Atlantic coast from sea level to 600 m in elevation from Mexico to Panama. In Panama this species is known from Bocas del Toro and the Canal Area.

Cordia diversifolia is an uncommon species of Atlantic lowland forests in Central America but is apparently quite common in lowland Bocas del Toro. It is distinctive in its narrowly elliptic to lanceolate leaves, leaf margins with short, filiform teeth, costate calyx, and filiform stigma lobes. This is the most widespread member of a small complex of closely related Central American species that is defined by the presence of denticulate leaf margins, costate calyces, and consistent dioecy. The group also includes *C. cordiformis* I. M. Johnston, *C. salvadorensis* Standley, and *C. skutchii* I. M. Johnston, all of which occur from Nicaragua northward.

Additional specimens examined. PANAMA. BOCAS DEL TORO: Almirante, out along the road to the "Bomba," *Blum 1314* (MO, SCZ); Lincoln Creek, *Carleton 40* (NY, US); Changuinola Valley, *Cooper & Slater 61* (CFMR, F), *112* (CFMR, F, US); region of Almirante, *Cooper 342* (CFMR, F (2), NY, US); Changuinola, *Croat 16309* (F, MO, NY); Changuinola Valley, *Dunlop 175* (F, US); Changuinola to 5 mi. S at junction of ríos Changuinola and Terebe, 100–200 ft., *Lewis et al. 795* (MO, UC, US), *937* (K, MO, US), *938A* (MO), *946* (F, MO, NY, UC, US); Chiriquí to 5 mi. S along Río Guarumo, *Lewis et al. 1994* (F, MO (2), US); Almirante, near road to Chiriquí, *McDaniel 5077* (MO); Shepherd Island, *McDaniel 5077*, *5161* (MO); on lower Changuinola River, *Stork 284* (UC, US); Almirante region, *Taylor & Slater 61* (US); Chiriquí Lagoon, Water Valley, *Wedel 632* (MO); Chiriquí Lagoon, *Wedel 1070* (MO); Chiriquí Lagoon, Old Bank Island, *Wedel 1894* (GH, MO, US), *2051* (MO, US); Chiriquí Lagoon, Pumpkin River, *Wedel*

2580 (MO, US); Chiriquí Lagoon, *Wedel 2595* (MO, US); vicinity of Nievecita, ca. 0–50 m, *Woodson et al. 1824* (F, MO, NY); Río Cricamola, between Finca St. Louis and Konkintoe, ca. 10–50 m, *Woodson et al. 1895* (MO, NY). CANAL AREA: Gamboa Naval Reservation, *Ebinger 482* (BR, ENCB, F, GH, MO).

Cordia dwyeri Nowicke, Phytologia 18: 419. 1969. TYPE: Panama. Colón: Santa Rita Ridge, 19 km from the Transisthmian Highway, 28 Jan. 1968, *J. D. Dwyer 8857* (holotype, MO 2518567; isotypes, F, GH, MO).

Sparsely branched tree to 10(–20) m tall, the twigs reddish-brown villous. Leaves persistent; petioles (2–)4–8(–14) mm long, thick, villous; blades coriaceous, bullate, ovate to elliptic, (9–)19–35(–60) cm long, (5–)8–16 (–25) cm wide, the apex acuminate to acute, the base rounded to obtuse or rarely subcordate, the margin entire, revolute, the adaxial surface distinctly bullate, often drying with a silver cast, nearly glabrous with a few scattered, appressed hairs, the abaxial surface brown pubescent to densely brown pilose. Inflorescence axillary or terminal, cymose, 4–15(–23) cm broad, the branches densely velutinous to tomentose, the hairs reddish brown. Flowers sessile, bisexual, monomorphic; calyx cupulate, 6–7 mm long, ribs absent, densely strigillose, with 2–3 unevenly deltate lobes; corolla white, cupulate with reflexed lobes, 8–9.5(–10.6) mm long, 5-merous, the lobes ovate to widely elliptic, 3–4 mm long, the tube 4.5–7 mm long; stamens 5, the filaments (5–)8–11(–13) mm long, the upper (2–)4.5–6.5 mm free, densely pubescent just above the point of insertion, the anthers ellipsoid to oblong, 1.4–1.8 mm long; ovary ovoid to conical, 1–1.7 mm long, glabrous; disc transversely oblong, 0.4–0.8 mm long; style 5–7.4 mm long, the stigma lobes clavate. Fruits half enclosed in the slightly accrescent calyx, white, drupaceous, inequilaterally ovoid, the stone ca. 1.7 cm long, ca. 1.3 cm broad, the endocarp bony, pebbled on the surface.

Distribution. *Cordia dwyeri* occurs in wet forests from sea level to 450 m in elevation and ranges from southern Nicaragua to northern South America. In Panama this species is known from the provinces of Bocas del Toro, Colón, and Panamá.

Cordia dwyeri appears to have no close relatives in Central America and is very distinctive in its habit of growth and in its extremely large, bullate leaves. Its closest relative is probably *C. trichoclada* DC. of South America, a species that has large bullate leaves but differs in having a costate calyx. *Cordia dwyeri* is apparently common throughout lowland wet forests of Costa Rica and Panama, although it is not often collected. This may be due to relatively rare flowering or may relate to the difficulty of preparing specimens from such bulky plants.

Additional specimens examined. PANAMA. BOCAS DEL TORO: Palo Blanco, *Gordon 95c* (MO). COLÓN: East Santa Rita Ridge, *Correa & Dressler 663* (MEXU, MO); Santa Rita Ridge, *Croat 13856* (MO). PANAMÁ: El Llano-Carti Highway, about 8 km N of El Llano, *Dressler 4573* (ENCB, F, MO); forest and roadside between 6–12 km N of El Llano on Carti Road, 1,200 ft., *Hammel 866* (MO); El Llano–Carti Road, 7.9 km from Interamerican Highway, 400 m, *Miller et al. 872* (MO); El Llano–Carti Road, 7.9 km from Interamerican Highway, 350 m, *Mori & Kallunki 5608* (AAU, MO, NY); along El Llano–Carti Road, 7 km N of Pan-American Highway at El Llano, 450 m, *Nee 10402* (MEXU, MO, US); El Llano–Carti Road, ca. 9 mi. from Pan-American Highway along newly cut bypass, 350–400 m, *Sytsma 4145* (MO).

Cordia eriostigma Pittier, Contr. U.S. Natl. Herb. 18: 251, fig. 101. 1917. TYPE: Colombia. Cauca: El Paso de la Balsa, on the Cauca River, near Jamundi, 480 m, 10 Feb. 1906, *H. Pittier 1489* (holotype, US 531695).

Tree to 15(–30) m tall, the twigs minutely brown strigillose, later waxy. Leaves persistent; petioles (7–)10–24(–30) mm long, sparsely strigillose; blade elliptic or slightly ovate or obovate, occasionally narrowly elliptic, (5–)6–16(–22.5) cm long, (2.4–)4.3–7.5(–11) cm wide, the apex usually obtuse and acuminate at the very tip, occasionally acute or rounded, the base obtuse to acute, the margin entire, the adaxial surface glabrous or nearly so, usually with small papillae, the abaxial surface with few, small, scattered hairs, some attached medianly. Inflorescence terminal, cymose, 8–13(–17) cm broad, the branches brown strigillose. Flowers sessile, bisexual, monomorphic; calyx cupulate to campanulate, 2.8–3.5(–4.7) mm long, ribs absent, evenly strigillose, opening without distinct lobes or unevenly 3–5-lobed; corolla white, campanulate, 5.7–6.3(–7.3) mm long, 5(–6)-merous, the lobes deltate to shallowly deltate, (2.5–)3–4.3 mm long, the tube 2.4–3.4 mm long; stamens 5(–6), the filaments (4–)5–5.5 mm long, the upper (1.4–)2–2.5 (–3) mm free, puberulent below insertion, the hairs often spreading onto corolla tube; anthers oblong to ellipsoid, 1–1.7 mm long; ovary ovoid to broadly ovoid, 1.3–2 mm long, glabrous or with short bristles on the upper portion; disc crateriform, small; style 1.5–2.6 mm long, the stigma lobes spatulate to discoid. Fruit borne in the saucer-shaped calyx, red to orange at maturity, drupaceous, glabrous, the stone inequilaterally ovoid, 6–7 mm long, 3.5–5.5(–6) mm broad, the endocarp bony.

Distribution. *Cordia eriostigma* occurs in moist to wet forests at 200–1,200 m in elevation and ranges from Mexico to Colombia. In Panama this species is known only from the province of Coclé.

Cordia eriostigma is uncommon and is often confused with *C. collococca*, from which it can be distinguished by having persistent leaves with nearly glabrous abaxial surfaces, bisexual flowers, campanulate corollas, valvate calyx lobes, and ovaries with distinct bristles on the upper portion. *Cordia eriostigma* differs further from *C. collococca* in usually being found above 600 m in elevation.

Additional specimens examined. PANAMA. COCLÉ: El Valle site area of WEPCOR, Cerro Pilón, *Kirkbride 1071* (MO, US); El Valle de Antón, *Lao 281* (F, MO).

Cordia globosa (Jacq.) Kunth in Humb., Bonpl. & Kunth, Nov. Gen. Sp. 3: 76. 1818; *Varronia globosa* Jacq., Enum. Syst. Pl. 14. 1760. TYPE: not seen.

Varronia humilus Jacq., Enum. Syst. Pl. 14. 1760. *Cordia humilus* (Jacq.) D. Don, Gen. Hist. 4: 383. 1838. *Cordia globosa* var. *humilus* (Jacq.) I. M. Johnston, J. Arnold Arbor. 30: 98. 1949. TYPE: not seen.

Cordia jacmeliana K. Krause, Bot. Centralbl. 32: 344. 1914. *Varronia jacmeliana* (K. Krause) Friesen, Bull. Soc. Bot. Genève, Ser. 2, 24: 177. 1933. TYPE: Haiti. Ouest: near Jacmel, *Krause 11808* (not seen).

Varronia humilus var. *mexicana* Friesen, Bull. Soc. Bot. Genève, Ser. 2, 24: 162, t. 1, f. 4. 1933. *Varronia mexicana* Friesen, Bull. Soc. Bot. Genève, Ser. 2, 24: 162. 1933. TYPE: Mexico. Morelos: near Cuernavaca, 5,000 ft., 22 June 1896, *C. G. Pringle 6346* (holotype, G; isotypes, BR, CAS, ENCB, F, K, L, LE, MEXU (2), MO, NY, US (3)).

Shrub to 3(–4) m tall, the twigs strigillose. Leaves deciduous, on short spurs to 1 mm long; petioles (2–)3–12(–25) mm long, strigillose, the hairs appressed to spreading; blades ovate to lance-ovate, (1.3–)2–5.7(–9) cm long, (0.7–)1–2.7(–5) cm wide, the apex acute, the base subobtuse to acute and decurrent along the petiole for a short distance, the margin serrate, usually unevenly so, the teeth usually blunt, occasionally short-apiculate, the adaxial surface usually ± smooth, occasionally slightly bullate, strigose to strigillose, or scabrous, the abaxial surface strigillose to strigose, most of the hairs restricted to the veins, rarely nearly tomentose. Inflorescence subterminal, a dense, globose head, 8–14(–16) mm broad, the peduncle 0.5–1.5 (–3.6) cm long, strigillose. Flowers sessile, distylous; calyx campanulate, (2.3–)3–4(–4.2) mm long, ribs absent, the 5 lobes deltate to triangular with prolonged filiform tips 2–4 mm long; corolla white, tubular, (5–)6–8 (–10) mm long, undulate to shallowly lobed, the lobes scarcely separate to transversely elliptic-oblong, the tube (2.4–)3–4(–4.5) mm long; stamens 5, the filaments (4.5–)5–8(–9) mm long, the upper (1.3–)2–3(–4) mm free, puberulent in a ring in the mouth of the corolla tube, the anthers ellipsoid, 0.8–1.1 mm long; ovary ovoid, 1–1.5(–1.8) mm long; disc crateriform, 0.5–1 mm tall; style (3–)4.5–7 (–7.5) mm long, the stigma lobes filiform to clavate. Fruits drupaceous, red, the stone ovoid, 3.5–4.8 mm long, (1.5–)2–3.8 mm broad, the endocarp bony.

Distribution. *Cordia globosa* occurs in dry to moist forests from sea level to 600 m in elevation and ranges from southern Florida and Mexico to northern South America and the West Indies. This species is known in Panama from one collection.

Cordia globosa is a common weedy shrub throughout Central America, the West Indies, and parts of northern South America, but apparently rare in Panama. *Cordia globosa* is most closely related to *C. bullata*, which ranges from Costa Rica to Mexico and the West Indies, but the former differs in having corollas more than 5 mm long and peduncles less than 3.6 cm long. The leaves of *C. globosa* are also generally smaller and have a less prominent indument. Nevertheless, these two species are often difficult to separate, and interspecific hybridization appears to occur in some populations in Nicaragua, Honduras, and Yucatán (Miller, in prep.).

Jacquin did not specify a type when he published the names *Varronia globosa* and *V. humilus*. None of his collections of this species seem to be present in the Willdenow or Linnaean herbaria. There may be a specimen at BM (Stafleu, 1967), but Johnston (1949c) stated that no type was preserved. Proper lectotypification will have to await examination of specimens in European herbaria. An odd situation exists with *Varronia humilus* var. *mexicana* and *Varronia mexicana*, two names published by Friesen based on the same type for either a new species or a new variety. Friesen did not indicate at which rank he felt it should be treated.

Additional specimens examined. PANAMA. PANAMÁ: Punta Paitilla, *Standley 26268* (US).

Cordia inermis (Miller) I. M. Johnston, J. Arnold Arbor. 30: 95. 1949. *Lantana inerma* Miller, Gard. Dict. ed. 8, 1768. TYPE: Mexico. Veracruz: *Houston s.n.* (holotype, BM, not seen).

Cordia cana Martens & Galeotti, Bull. Acad. Roy. Sci. Bruxelles 11: 331. 1844. TYPE: Mexico. Oaxaca: Bois de la late Pacifique, 1840, *Galeotti 7140* (holotype, BR).

Cordia insularis Greenman, Proc. Amer. Acad. Arts 33: 482. 1898. TYPE: Mexico. Nayarit: Tres María Islands, 3–25 May 1897, *E. W. Nelson 4296* (holotype, GH; isotype, US).

Erect shrub to 2(–3) m tall, the twigs strigillose to puberulent when young, later glabrous and lenticellate. Leaves deciduous; petioles (2–)4–12(–22) mm long, strigillose to puberulent; blades elliptic-ovate to narrowly elliptic or elliptic-lanceolate, (2–)3.5–10(–14) cm long, (0.7–)1–3.5(–6.8) cm wide, the apex acuminate to acute, the base attenuate, the margin serrate, the adaxial surface strigillose to strigose, the abaxial surface strigillose. Inflorescence internodal or terminal, a small globose head, (3–)4–7(–10) mm broad, the peduncle (0.7–)1–5(–9) cm long, strigillose to puberulent. Flowers sessile, appearing unisexual, the plants subdioecious, the male flowers with reduced styles, the female flowers smaller than the males, with small nonfunctional anthers; calyx campanulate, 1.8–3 mm long, ribs absent, strigillose, the (4–)5 lobes deltate, 0.5–1 mm long; corolla white to greenish white, 2.5–3.5(–3.8) mm long, truncate to undulate but lacking distinct lobes, puberulent to pubescent in the middle of the tube; stamens 4–5, in male flowers the filaments (3.3–)3.5–4 mm long, the upper 1–1.6 mm free, puberulent at insertion, the anthers oblong, 0.7–1 mm long, in female flowers the filaments 2–2.5 mm long, the upper 0.3–0.5 mm free, puberulent at insertion, the anthers ellipsoid, ca. 0.3 mm long; ovary ovoid to nearly spherical, 0.5–1 mm long; disc crateriform, 0.2–0.6 mm tall; style in male flowers 0.7–1 mm long, the stigma lobes much reduced, filiform to slightly flattened, the style in female flowers 2–3.5 mm long. Fruits drupaceous, (3–)4–5.5(–6.5) mm long, 2–3(–3.2) mm broad, ⅓–⅔ enclosed in the slightly accrescent calyx, the calyx and fruit bright red at maturity, the stone ovoid, the endocarp bony.

Distribution. Cordia inermis occurs in disturbed areas from sea level to 1,100 m in elevation and ranges from Mexico to Panama. In Panama this species is known from the Canal Area, Chiriquí, and Panamá.

Cordia inermis is one of the most common weedy species of the genus in Central America. It reaches its southern limit in Panama where it is known from relatively few collections. In Panama, *C. inermis* can be confused with *C. linnaei*, from which it differs in having terminal or internodal rather than axillary inflorescences.

Cordia inermis has been described as dioecious (Opler et al., 1975). The female flowers have small nonfunctional anthers, and the male flowers have reduced styles and stigmas. The pollen from anthers of female flowers is small, deformed, and completely nonstainable. The female flowers appear to be 100% male sterile, but there is no indication of complete female sterility in male flowers, even though the gynoecium is reduced. In fact, some collections of male plants have both flowers and fruits on the same branch, and this species is probably subdioecious.

Additional specimens examined. PANAMA. CANAL AREA: Quarry Heights, hilltop, *Dwyer 2610* (MO (2), NY, US). CHIRIQUÍ: 1 mi. W of airport at Puerto Armuelles, near sea level, *Croat 22531* (F, MO); Río San Cristobal, 2 mi. W of David, 150 ft., *Tyson 912* (MO, RSA). PANAMÁ: Taboga Island, *Standley 27039* (US); *Woodson et al. 1478* (F, MO, NY).

Cordia lasiocalyx Pittier, Contr. U.S. Natl. Herb. 18: 251. 1917. TYPE: Panama. Darién: open field around Garachine, sea level, 12 Feb. 1912, *H. Pittier 5694* (holotype, US 715984; isotype, F).

Shrub or small tree to 5(–10) m tall, the branching pattern divaricate, the twigs glabrous. Leaves persistent; petioles (3–)4–7 (–10) mm long, canaliculate adaxially, glabrous; leaf blades elliptic-oblong to slightly obovate, (6–)9–13(–16) cm long, (2–)2.6–5(–5.4) cm wide, the apex abruptly caudate, the caudex (1–)2–3(–3.5) cm long, the base acute and slightly decurrent, the margin entire, the adaxial surface glabrous, the abaxial surface sparsely and minutely strigillose. Inflorescence terminal, cymose, 2.5–6.5(–10) cm broad, the peduncle 2.5–5 cm long, glabrous or with a few widely scattered hairs. Flowers sessile, monomorphic, the stamens exceeding the style; calyx cupulate to campanulate, 3.8–5 mm long, 3.6–4 mm wide at the mouth, ribs absent, glabrous or nearly so, the 3 lobes deltate, 1–2 mm long; corolla white, tubular, 7.6–10 mm long, 5-merous, the lobes oblong, 3.3–4.6 mm long, 2–2.5 mm wide, the tube 4.3–6 mm long; stamens 5, the filaments 6–9.5 mm long, the upper 2.6–3 mm free, pubescent at insertion, the anthers oblong, ca. 1.3 mm long; ovary ovoid to broadly ovoid, 1.3–1.8 mm broad, glabrous; style 3.5–5 mm long, the stylar branches 1.6–2.2 mm long, the stigma lobes clavate. Fruits borne in the cup-shaped calyx, white, drupaceous, glabrous, the stone strongly inequilaterally ovoid, 10–11 mm long, 6.4–9 mm broad, ruminate, the mesocarp mucilaginous, endocarp bony, 1-locular.

Distribution. *Cordia lasiocalyx* occurs in moist forests from sea level to 800 m in elevation and is known only from Panama, where it occurs in Bocas del Toro, the Canal Area, Coclé, Darién, and Panamá.

Cordia lasiocalyx is a member of a taxonomically difficult species complex that is characterized by glabrous leaves, a three-lobed calyx, and white fruit. Its caudate leaf apex readily separates it from its closest Central American relatives, *C. croatii*, *C. lucidula*, and *C. porcata*, all of which have acuminate leaf apices. *Cordia lasiocalyx* is probably most closely related to *C. lomatiloba* I. M. Johnston, a species of Amazonian South America.

Additional specimens examined. PANAMA. BOCAS DEL TORO: Island Potrero, Changuinola Valley, *Dunlap 322* (F, GH, US). Cordia leslieae James S. Miller, sp. nov. TYPE: Panama. Panamá: Cerro Jefe 5.8 mi. above Lago Cerro Azul, 840 m, 30 July 1983, *James S. Miller & Leslie A. Miller 886* (holotype, MO 3386970). Figure 4.

Arbor ad 7 m alta, ramunculis glabris, subalatis. Folia persistentia, petiolis 0.8–2 cm longis, applanatis, basibus continuis secus ramos; lamina coriacea, obovata, 9.2–16.2 cm longa, 5.3–8.4 cm lata, apicibus retusis ad acuminatis, basibus cuneatis, marginibus integris, revolutis. Inflorescentia terminalis, cymo-paniculata. Flores bisexualis; calyx tubulo-campanulatus, 5.5–6 mm longus; corolla alba, 8–10 mm longa, 5-lobata, lobis ovatis, incrassatis ad apices, stamina 5. Fructus drupaceus, aurantiacus, putamine inaequilateraliter ovoideo, 1.4 cm longo.

Tree to 7 m tall, the twigs glabrous, subalate. Leaves persistent; petioles 0.8–2 cm long, flattened in cross section and canaliculate adaxially, the bases continuous along the stem for a short distance; blades coriaceous, obovate, 9.2–16.2 cm long, 5.3–8.4 cm wide, the apex variable, retuse or acuminate, the base cuneate, the margin entire, revolute, the adaxial surface glabrous, slightly papillose, the abaxial surface glabrous. Inflorescence terminal, cymose-paniculate, 5.5–7.5 cm long, 5–9.5 cm broad, with 50–120 or more flowers, the branches sparsely strigillose. Flowers sessile or nearly so, bisexual; calyx tubular-campanulate, 5.5–6 mm long, 3–3.4 mm wide at the mouth, ribs absent, sparsely strigillose, the 5 lobes deltate, 1–1.4 mm long; corolla white, tubular with reflexed lobes, 8–10 mm long, 5-merous, the lobes ovate to oblong with a triangular thickening at the apex, 4 mm long, 2–3 mm wide, the tube 4–6 mm long; stamens 5, the filaments 9.3 mm long, the upper 4.3 mm free, pubescent at insertion, the anthers oblong, 2 mm long; ovary obloid, 1.8 mm long, 0.7 mm broad; style 5.5 mm long, the stylar branches 2 mm long, the stigma lobes clavate to discoid. Fruits seated in the cupulate, slightly accrescent calyx, orange, drupaceous, the stone inequilaterally ovoid, 1.4 cm long, mesocarp mucilaginous, endocarp bony, 1-locular.

Distribution. *Cordia leslieae* occurs in cloud forests at 800–1,000 m in elevation and is known only from Cerro Jefe, in the province of Panamá.

Cordia leslieae is apparently not closely related to any other species of *Cordia* in Central America. This species is distinct in having sub-alate stems and petioles and in having thickened areas at the ends of the corolla lobes. It is named in honor of my wife, Leslie Miller, who assisted me with field studies in Panama and discovered the tree from which the type collection was made.

Additional specimens examined. PANAMA. PANAMÁ: Cerro Jefe, *Dressler 3489* (MO, PMA); Cerro Jefe region roadside and forest, 200–800 m, *Hammel 4850* (MO); Cerro Jefe, NE of Panama City, forested slopes below summit, 850–900 m, *McPherson 9735* (MO); Cerro Jefe, near summit, along road to east about a quarter mile below tower, 750–850 m, *McPherson 11191* (MO); Cerro Jefe, 850–900 m, *Sytsma 2009* (MO).

Cordia linnaei Stearn, J. Arnold Arbor. 52: 627. 1971. TYPE: Jamaica. St. Andrews: pastures behind Hope Gardens, 600–700 ft., 22 Oct. 1956, *Proctor 15789* (holotype, BM, not seen; isotype, IJ).

Shrub to 4 m tall, the twigs coarsely pubescent, the hairs erect, brown. Leaves deciduous, on short spurs 1–1.5 mm long; petioles (1–)1.5–3(–7) mm long, pubescent, the hairs erect, brown; blades ovate to lanceolate, (2–)3.4–9(–10.6) cm long, (0.9–)1.2–2.9(–5.3) cm wide, the apex acute to acuminate, the base cuneate, the margin sharply serrate, the adaxial surface coarsely puberulent, the hairs short, slightly swollen at the base, appressed, the abaxial surface softly pubescent, the hairs wavy, erect. Inflorescences numerous, axillary, capitate, 7–11 mm broad, the peduncle (0.5–)0.8–2.8(–6.4) cm long, pubescent, the hairs erect, brown. Flowers sessile, distylous; calyx cup-shaped, 2–2.5(–2.7) mm long, ribs absent, strigillose, the 5(–6) lobes deltate to shallowly triangular, sometimes with a short apiculate tip; corolla white, tubular, 3–3.8(–4.2) mm long, truncate at the apex; stamens 5, the filaments (2.5–)3–3.5(–3.8) mm long, the upper 0.3–1(–1.2) mm free, glabrous to canescent at insertion, the anthers ellipsoid, 0.4–0.6 mm

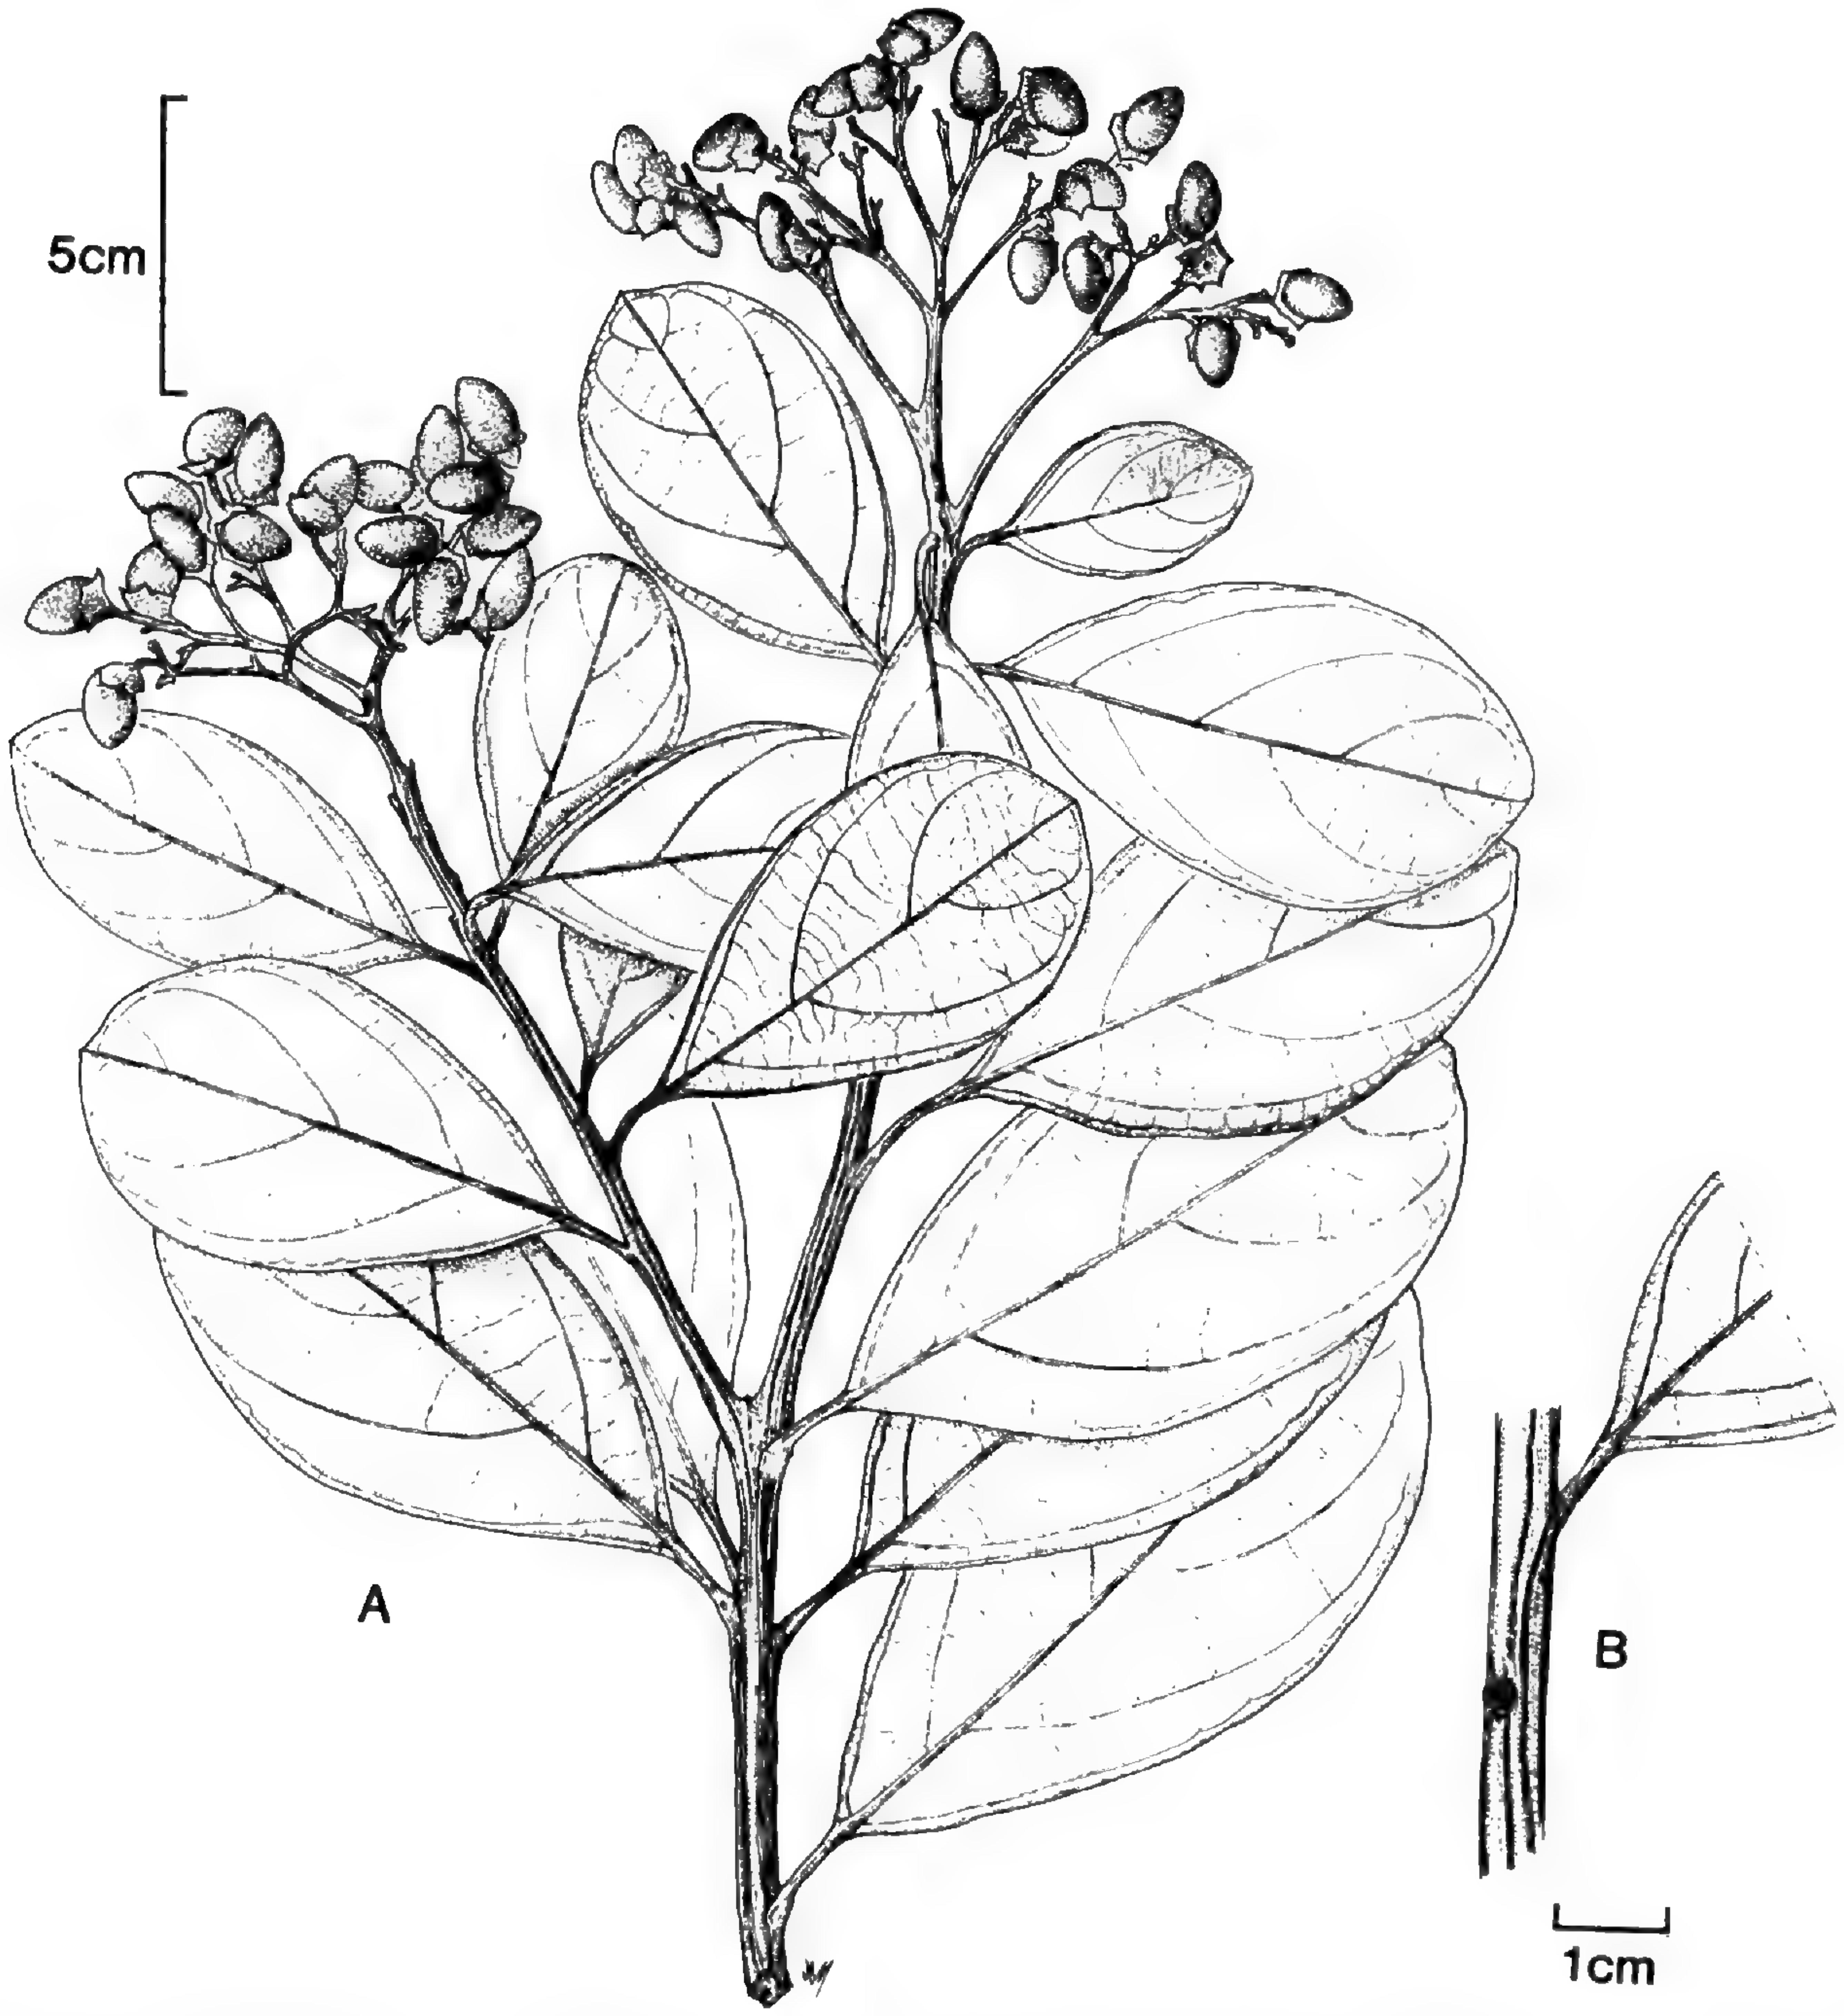

FIGURE 4. Cordia leslieae.—*A. Fruiting branch.—B. Sub-alate twig with petiolar attachment. From* Miller & Miller 886 *(MO), Panamá, Panama.*

long; ovary ellipsoid, 0.6–1 mm long; disc crateriform to nearly flat, thin, ca. 0.2 mm tall; style (2.1–) 2.5–3(–3.5) mm long, the stigma lobes filiform or nearly so. Fruits drupaceous, 3.5–4(–5) mm long, (2.6–)3–3.5(–5) mm broad, ⅔ to nearly totally enclosed in the calyx, red, the stone ovoid to broadly ovoid, the endocarp bony.

Distribution. *Cordia linnaei* occurs in moist to wet forests from sea level to 900 m in elevation from Mexico to Colombia and in the West Indies. In Panama, *C. linnaei* is known from the Canal Area, Colón, Darién, Panamá, San Blas, and Veraguas.

This species was treated as *Cordia lineata* (L.) Roem. & Schultes in the *Flora of Panama* (Nowicke, 1969), as it has been in most recent works, but Stearn (1971) showed that this name is based on a long string of illegitimate names. It is easily recognized by its numerous, small, axillary inflorescences, which never branch cymosely as they do in *C. bifurcata.* The most likely Panamanian species with which *C. linnaei* could be confused is *C. inermis,* which has terminal and internodal, rather than axillary, inflorescences.

Additional specimens examined. PANAMA. CANAL AREA: near beach, at Ft. Kobbe, *Duke 4195* (MEXU, MO); along abandoned road C29 just N of Las Cruces

Trail, 6 km E of Gamboa, 150 m, *Nee 9042* (MEXU, MO, US); Balboa, *Standley 25474, 26068, 29245* (US). COLÓN: 20 km from Transisthmian Highway on Santa Rita Ridge, SE facing slope, 400 m, *Knapp & Schmalzel 1765* (MO); Santa Rita Ridge, ca. 4–5.5 mi. E of Transisthmian Highway, *Lewis et al. 5267* (MO); lumber road at about 8 km NE of Santa Rita Ridge along ridge, 650 ft., *Wilbur & Weaver 10830* (DUKE); wooded slopes on Santa Rita Ridge about 5 mi. from highway at Sabanita, 650 ft., *Wilbur & Weaver 11827* (DUKE). DARIÉN: Chepigana, *Duke & Briston 264* (DUKE, MO); Isla Boca Grande, *Duke 8846* (MO). PANAMÁ: vicinity of Cerro Jefe, Altas de Pacora, 2,400 ft., *Antonio 3218* (MO); vicinity of Río Pacora, E of Panama City on Panama National Highway, *Bartlett & Lasser 16954* (MO); 3 mi. from Interamerican Highway on road to Cerro Campana, *Croat 12057* (F, MO, NY); Cerro Jefe, *D'Arcy 9748* (MO); Panamerican Highway at Río Mamonica, 4 mi. beyond Chepo, *Duke 5580* (GH, MO); grasslands on Cerro Campana, 2,400–2,700 ft., *Duke 8677* (DUKE, MO); end of road near Río Boquerón, road is 2 km N of cement plant on Colón Highway, ca. 26 km E of turnoff to end of road, 500 ft., *Hammel 915* (MO); summit of Cerro Jefe and forests along road beyond summit, *Hayden 1025* (MO); in woods near Panama, *Hayes 559* (K); Punta Paitilla, just E of Panama City, *Heriberto 212* (GH, US); Cerro Jefe, 4.8 mi. above Lago Cerro Azul, 600–800 m, *Miller & Miller 883* (MO); El Llano–Carti Road, 3 mi. from Panamerican Highway, 400 m, *Miller et al. 1016* (MO); El Llano–Carti Road, 5 km N of Panamerican Highway at El Llano, 300 m, *Nee 7902* (MO); Río Tapic, *Standley 28153* (US); Cerro Jefe, 850–900 m, *Sytsma 1959* (MO); slopes of Cerro Jefe beyond Cerro Azul between 4–8 mi. in mostly heavily wooded slopes, *Wilbur & Weaver 11348* (DUKE); between Pacora and Chepo, ca. 25 m, *Woodson et al. 1671* (MO). VERAGUAS: Isla de Coiba, *Dwyer 2323* (MO (2), US); 1–2 mi. above Santa Fe, Gentry 3049 (F, MO, NY).

Cordia lucidula I. M. Johnston, J. Arnold Arbor. 21: 352. 1940. TYPE: Panama. Bocas del Toro: Potrero, Changuinola Valley, 20 Oct. 1923, *V. C. Dunlap 284* (holotype, US; isotypes, F, NY).

Tree to 5(–10) m tall, the twigs glabrous to sparsely strigillose. Leaves persistent; petioles (4–)7–12(–16) mm long, glabrous to strigillose; blades ovate to narrowly ovate, (9–) 11–22(–28) cm long, 5–9(–12) cm wide, the apex acuminate, the base obtuse and slightly decurrent or rarely rounded or acute, the margin entire, the adaxial surface glabrous or rarely strigillose, the abaxial surface minutely strigillose rarely approaching glabrous. Inflorescence terminal or rarely internodal or axillary, cymose, 4.5–8.7 cm broad, the peduncle 1.8–3.7(–7.8) cm long, strigillose. Flowers sessile, monomorphic; calyx cupulate to campanulate, 3–4 mm long, ribs absent, glabrous to strigillose, the 3 lobes ± deltate, 0.8–1 mm long; corolla white, tubular with reflexed lobes, 5–7 mm long, 5-merous, the lobes oblong, 2.3–3 mm long, the tube 2.8–4.2 mm long; stamens 5, exserted, the filaments 4.5–7.5 mm long, the upper 2.4–3 mm free, pubescent at the point of insertion, the anthers ellipsoid to oblong, ca. 1.2 mm long; ovary ovoid, 1–1.3 mm long, glabrous; disc crateriform, ca. 0.7 mm tall; style 1.9–4.1 mm long, the stigma lobes clavate. Fruits 10–13 mm long, 9.5–12 mm broad, borne in the slightly expanded, cup-shaped calyx, drupaceous, red, the stone broadly inequilaterally ovoid, the surface ruminate and slightly ridged, the endocarp bony.

Distribution. *Cordia lucidula* occurs in wet forests from sea level to 1,500 m in elevation and ranges from Nicaragua to Panama. In Panama *C. lucidula* is known from the provinces of Bocas del Toro, Chiriquí, Darién, and Panamá.

Cordia lucidula is extremely variable and is the most commonly collected member of a difficult group of closely related species, including *C. lasiocalyx* and *C. porcata,* found in Panama and Costa Rica. *Cordia lucidula* can be distinguished by its three-lobed calyx, more or less ovate leaves, and bright red fruits without apical prolongation. Leaf shape and texture often vary on a single plant and with time of year and locality. *Cordia lucidula* differs from *C. lasiocalyx* by having an acuminate, rather than caudate leaf apex. *Cordia lucidula* is most likely to be confused with *C. porcata,* which differs in having white fruits and anthers more than 1.9 mm long.

Additional specimens examined. PANAMA. BOCAS DEL TORO: region of Almirante, *Cooper 372* (C, CFMR, F, GH, US); Changuinola Valley, *Dunlap 356* (CFMR, F, US); Río Terebe just below Puerto Palenque, 350 ft., *Kirkbride & Duke 549* (F, MO, NY, SCZ); cloud forest of Cerro Bonyic, above Quebrada Hurón, 500–1,200 ft., *Kirkbride & Duke 596* (F, MO, NY, SCZ); Chiriquicito to 5 mi. S along Río Guarumo, *Lewis et al. 2089* (MO, UC); Chiriquí Lagoon, Fish Creek Hills, *Wedel 2394* (GH (2), MO), *2425* (GH, MO, US). CHIRIQUÍ: San Bartolo Limite near Costa Rican border, 12 mi. W of Puerto Armuelles, 400–500 m, *Croat 22150* (BR, C, CAS, F, LL, MEXU, MO, NY, RSA); Burica Peninsula, 8 mi. W of Puerto Armuelles, 200 m, *Liesner 353* (MO, WIS). COCLÉ: 7 km N of El Copé, *Folsom & Collins 6470* (NY). DARIÉN: primary forest along headwater of Río Tuqueza, ca. 2 km air distance from continental divide, in the vicinity of upper gold mining camp of Tyler Kittredge, *Croat 27126* (MO); trail from Pucuro to Cerro Mali, vicinity of mouth of Tapaliza River, ca. 100 m, *Gentry & Mori 13546* (MO, SCZ, US); 0–2 mi. E of Tres Bocas along the shortest headwater of the Río Cuasi, *Kirkbride & Duke 1184* (MO, NY). PANAMÁ: El Llano–Carti Road, 10.6 mi. from the Pan-American Highway, 400 m, *Miller et al. 871* (MO); El Llano–Carti Road, just south of San Blas border, 400 m, *Miller et al. 1014* (MO); El Llano–Carti Road, 10–12 km from junction with Inter-American Highway, 410 m, *Mori & Kallunki 2881* (AAU, MO, NY, U); El Llano–Carti Road, 8–11 km from Inter-American Highway, 300–400 m, *Mori 7709* (MO, U).

Cordia megalantha S. F. Blake, Proc. Biol. Soc. Wash. 36: 200. 1923; nom. nov. for *Cordia macrantha* S. F. Blake, Contr. U.S. Natl. Herb. 24: 19. 1922, non Chodat, 1921. TYPE: Guatemala. Izabal: Quebrada, 18 May 1919, *S. F. Blake 7498* (holotype, US 989592).

Tree to 30(–60) m tall, the twigs glabrous. Leaves deciduous; petioles (8–)11–33(–55) mm long, glabrous; blades elliptic to obovate, (4.6–)6–19(–21) cm long, 2.9–8(–12.6) cm wide, the apex acute to acuminate or rarely obtuse, the base acute or rarely obtuse to rounded, the margin entire, the adaxial and abaxial surfaces glabrous. Inflorescence terminal, paniculate, to 30 cm broad, the branches glabrous except for puberulent tips. Flowers on short spurs 2–5 mm long, distylous; calyx tubular, (8.5–)9–10(–11) mm long, striate to 10–20 ribbed, glabrous to puberulent, the hairs dark brown, unevenly lobed, tearing upon dehiscence or dehiscing circumscissilly; corolla marcescent, white, funnelform, 28–43(–50) mm long, the 5(–6) lobes deltate to ovate, 11–13 mm long; stamens 5(–6), the filaments 14.5–19 mm long, the upper 5–10(–13) mm free, pubescent at insertion and frequently over the entire free portion, the anthers oblong, 2–4 mm long; ovary ovoid to conical, 1.3–2.5(–4) mm long; disc depressed ovoid, 0.5–1 mm tall; style 16–19 mm long, the stigma lobes clavate. Fruits enclosed by the persistent calyx and corolla, ellipsoid to narrowly ellipsoid, 8–12 mm long, 4–6 mm broad, the wall thin, fibrous.

Distribution. *Cordia megalantha* ranges along the Atlantic coast of Central America in wet forests from sea level to 400 m in elevation. Disjunct populations occur on the Pacific side of Central America on the Osa Peninsula of Costa Rica and the Burica Peninsula in Chiriquí where the only known collection from Panama was made.

Often exceeding 30 m in height, *Cordia megalantha* is the tallest Central American species of *Cordia*. Although there are no reports of *C. megalantha* being cultivated as a timber tree, as is *C. alliodora*, it may have potential in wet regions. It apparently does not flower each year (T. Wendt, pers. comm.) and this, combined with its height, may be responsible for the paucity of collections. *Cordia megalantha* is very distinctive among the Panamanian members of the genus in its large size, marcescent corolla, and deltate corolla lobes.

Additional specimens examined. PANAMA. CHIRIQUÍ: west of San Bartolo Limite near Costa Rican border, *Croat 22175* (MO).

Cordia panamensis Riley, Kew Bull. 1927: 135. 1927. TYPE: Panama. Panamá: secondary growth at sea level near Old Panama, *L. A. M. Riley 143* (holotype, K; isotypes, MO, US).

Tree to 10(–15) m tall, the young twigs hirsute. Leaves persistent; petioles (5–)7–12 (–17) mm long, villous to hirsute or occasionally strigillose and with scattered, erect, longer hairs; blades dimorphic, the larger ones ovate to ovate-elliptic, (12–)17–28(–35) cm long, (5–)6.5–13.5(–15) cm wide, the apex acuminate, the base obtuse to rounded or occasionally somewhat cordate, often somewhat asymmetrical, the smaller ones orbicular, (5–) 6.5–9(–10) cm long, (3.8–)5–8.4(–10) cm wide, the margin entire, the adaxial surface scabrous, the abaxial surface ± pubescent, the hairs stiff but not rough to the touch, nearly erect to spreading. Inflorescence terminal or in the axils of the branches, cymose, (5–)7–13.5(–16) cm broad, the lower portion of the branches villous to hirsute, the tips of the branches densely strigillose. Flowers sessile, unisexual by abortion, the plants dioecious, the male flowers with reduced styles, the female flowers with small, nonfunctional anthers. Female flowers with a tubular calyx 2–3.6 mm long, ribs absent, strigillose, the 3–5 lobes unevenly deltate to triangular, 0.4–0.6(–1) mm long; corolla white, tubular with reflexed lobes, 3.8–4.5(–5.5) mm long, (4–) 5(–6)-merous, the lobes oblong-ovoid, 1–1.8 mm long, the tube (2–)2.5–3(–3.7) mm long; stamens (4–)5(–6), the filaments 3–3.6(–4.3) mm long, the upper 0.4–1.1 mm free, glabrous, the anthers ellipsoid, shriveled and containing only aborted pollen, ca. 0.3 mm long; ovary ellipsoid, 1–1.3(–1.8) mm long, glabrous; disc scarcely distinct from the base of the ovary; style 2–3.4(–4) mm long, the stigma lobes discoid. Male flowers with a campanulate calyx (2.5–)3–4 mm long, ribs absent, strigillose, the 3–5 lobes uneven, deltate to triangular, 0.7–1.1 mm long; corolla white, tubular-campanulate with reflexed lobes, 4.5–6(–6.5) mm long, 5(–6)-merous, the lobes oblong-ovoid, (1.5–)2–2.3(–2.7) mm long, the tube (1.5–)2.5–3.9 mm long; stamens 5(–6), the filaments 4.8–7.2 mm long, the upper 2–3.5(–4.3) mm free, villous at the point of insertion, the anthers ellipsoid, 0.8–1.3 mm long; ovary ovoid, 0.6–1.2 mm long, glabrous; disc crateriform, 0.5–0.7 mm long; style abortive, 1–2(–3.3) mm long, the stigma lobes filiform. Fruits seated in the cupulate calyx, white, drupaceous, glabrous, the stone inequilaterally ovoid, 6–7.5 mm long, (4.3–) 5.5–6 mm broad, the endocarp bony.

Distribution. *Cordia panamensis* occurs in dry to wet forests and ranges from southern Mexico to northern South America from sea level to 1,000 m in elevation. In Panama it is known from all regions except Bocas del Toro.

The *Cordia panamensis* complex is one of the most taxonomically difficult groups in the genus. Its Central American members, which include *C. anisophylla* and *C. cymosa*, are similar in appearance and are sometimes sympatric. The group reaches its greatest diversity in Panama and northern South America. *Cordia panamensis* differs from *C. cymosa* by being smaller in all aspects and by having only simple (vs. echinate) hairs. It differs from *C. anisophylla* in having a shorter corolla and fruits that are nearly as broad as long. *Cordia panamensis* is extremely variable in Panama with individual populations differing considerably in leaf size, shape, and indument. North of Costa Rica, it is more constant morphologically. *Cordia panamensis* is most closely related to *Cordia hebeclada* I. M. Johnston of Colombia, Ecuador, and Peru, which differs only in its evenly velutinous twigs and lower leaf surfaces.

Additional specimens examined. PANAMA. CANAL AREA: Juan Mina, *Bartlett & Lasser 16523* (DUKE, MO); beside railroad tracks along road to Tropic Test Center Miraflores Annex, *Correa 261* (DUKE, MO); Guillard Highway near Paraiso, *Croat 10141* (MO, SCZ); Barro Colorado Island, *Croat 10250* (MO, UC), *10390* (DUKE, F, MO, NY, SCZ, UC); Ancon Hill near gates to Quarry Heights Military Preserve rear gate, *Croat 11950* (F, MO, SCZ); Barro Colorado Island, *Croat 11967* (DUKE, F, MO, NY, SCZ); road S-11, NW of Escobal, *Croat 12460* (MEXU, MO (2)); Road K-2G, *Croat 15142* (MO); roadside in forest between Gatún and Fort Sherman, *Croat 15400* (MO); Pipeline Road 2 mi. from Gamboa gate, *Croat 16612* (MO); vicinity of Madden Lake along Boy Scout Road, less than 100 m, *Croat 38322* (MO); near Pedro Miguel railway station, *D'Arcy & D'Arcy 6021* (CHAPA, MO (2), RSA, US (2)); near beach at Ft. Cordia porcata Nowicke, Phytologia 18: 397. 1969. TYPE: Panama. Colón: Santa Rita Ridge lumber road, 3 Oct. 1968, *M. Correa A. & R. Dressler 1076* (holotype, MO 2062961; isotype, MO).

Shrub or small tree 2–6 m tall, the twigs glabrous. Leaves persistent; petioles 5–11 mm long, broadly canaliculate adaxially, glabrous; blades narrowly elliptic to lance-elliptic, (5–)8.3–21(–24) cm long, 3–7.5(–10) cm wide, the apex acuminate, the base acute or rarely obtuse, slightly decurrent, the margin entire, sometimes slightly revolute, the adaxial surface glabrous, often drying with a silvery sheen, the abaxial surface glabrous to sparsely and minutely strigillose. Inflorescence terminal or internodal, cymose, 2.5–5.5(–10) cm broad, usually with 50–100 flowers, the peduncle 1.8–4.4 cm long, the branches canescent to strigillose, the hairs brown. Flowers monomorphic, sessile; calyx campanulate, 5.2–6.5 mm long, 2.6–5 mm wide at the mouth, ribs absent, nearly glabrous to minutely strigillose, the (2–)3(–4) lobes ± deltate, 1.3–1.8 mm long; corolla white, tubular with reflexed lobes, 6.5–10 mm long, (4–)5-merous, the lobes oblong, 3.1–4.5 mm long, 1.5–2 mm wide, the tube 3.7–6.4 mm long; stamens (4–)5, the filaments (4.5–)7–8.4 mm long, the upper (1.3–) 2.5–4 mm free, the lower free portion pubescent, the anthers narrowly oblong, 1.9–2.3 mm long; ovary ovoid to broadly ovoid, 0.8–1 mm broad, glabrous; style (4–)5.2–5.8 mm long, the stylar branches 2–2.5 mm long, the stigma lobes clavate. Fruits borne in the slightly expanded, saucer-shaped calyx, white at maturity, drupaceous, glabrous, the stone inequilaterally ovoid and sharply apiculate at the apex, 8.7–11 mm long, 4.8–6.5 mm broad, essentially smooth, the endocarp bony.

Distribution. *Cordia porcata* occurs in wet forests and ranges from southern Nicaragua to Panama from sea level to 1,500 m in elevation. In Panama it is known from the provinces of Coclé, Colón, Los Santos, and Panamá.

Cordia porcata differs from *C. lucidula*, the species with which it is most likely to be confused, in having lance-elliptic leaves, anthers more than 1.9 mm long, and smooth, rostrate fruits. Although *C. porcata* is quite common in some areas of Panama, it is known from only a small number of collections in northern Costa Rica and a single collection from Nicaragua.

Additional specimens examined. PANAMA. COCLÉ: region N of El Valle de Antón, 1,000 m, *Allen 3710* (BR, F, G, MO, U); Cerro Pilón, above El Valle de Antón, *Croat 14323* (MO, NY); La Mesa above El Valle, along road which ends in pasture, 810 m, *Croat 25310* (MO, NY); Cerro Pilón, El Valle, 3,000 ft., *Duke & Lallathin 15015* (MO); vicinity of La Mesa, N of El Valle, 1,000 m, *Gentry 6813* (AAU, MO, NY). COLÓN: Cerro Santa Rita, ca. 6 mi. from the Transisthmian Highway, 800–900 ft., *Antonio 1805* (MO); Santa Rita Ridge Road, ca. 1 hour walk from end of road, *Antonio 4490* (MO); East Santa Rita Ridge, *Correa & Dressler 635* (MO, SCZ); Santa Rita Ridge, *Correa & Dressler 1076* (MO), *Croat 13837* (MO), *D'Arcy & D'Arcy 6169* (C, F, MO); Santa Rita lumber road, ca. 15 km E of Colón, *Dressler & Lewis 3702* (F, MO, US); Santa Rita Ridge, *Dwyer 8581* (F, MO); Santa Rita Ridge, highway to 8 mi. east, 800 ft., *Dwyer et al. 9027* (MO (2), NY); Santa Rita Ridge, *Dwyer & Gentry 9366* (MO, NY), *9373* (MO); near Agua Clara rainfall station, Santa Rita Ridge, *Foster 1730* (DUKE); Santa Rita Ridge, 2–3 mi. from Transisthmian Highway, *Gentry 1865* (MO); Santa Rita Ridge, E ridge, *Gentry & Dwyer 4816* (DUKE, F, MO, RSA); Santa Rita Ridge east of Transisthmian Highway, 300–500 m, *Gentry 6546* (F, MO); Santa Rita Ridge, 400–500 m, *Knapp et al. 1680* (MO); end of Santa Rita Ridge Road, 21 km from Transisthmian Highway, 400–500 m, *Knapp & Schmalzel 5243* (MO); Santa Rita Ridge Road, 21–26 km from Transisthmian Highway, 500–550 m, *Knapp 5867* (MO); Santa Rita Ridge, 2 mi. from Transisthmian Highway, 100 m, *Lao et al. 7* (F, MO (2)); Santa Rita Ridge, ca. 5.5–6 mi. E of Transisthmian Highway, *Lewis et al. 5391* (MO, UC); *Lewis 5397* (F, MO, NY); Santa Rita Ridge trail, beyond end of Santa Rita Ridge Road (Panamanian Highway R 20 D), 17–35 km from Boyd-Roosevelt Highway, 400–800 m, *Mori & Crosby 6308* (MO, US); Santa Rita Ridge Road, 7.8 km from the Boyd-Roosevelt Highway, ca. 25 km W of Colón, *Mori & Dressler 7906* (AAU, MO, NY); 2.7 mi. by gravel road, NE of carretera Transisthmica, on the Santa Rita Ridge, *Nee & Mori 3676* (MO, WIS (2)); Santa Rita Ridge, end of road from Transisthmian Highway, ca. 10 mi. from highway, *Porter et al. 4762* (MO); Santa Rita, *Suere & Dressler 4818* (MO); Santa Rita Ridge road, 20 km from Transisthmian Highway, 100–1,200 ft., *Sytsma 1094* (MO); Santa Rita Ridge, 20 km from Transisthmian Highway, *Sytsma 1108* (MO); Santa Rita Ridge Road, 20–22 km from Transismithian Highway, 1,000–1,200 ft., *Sytsma 1311, 1312* (MO); Santa Rita Ridge, *Sytsma 1548* (MO); upper Río Piedras headwaters, along trail from end of Santa Rita Ridge Road, ca. 11 km SW of Cerro Bruja, 600–700 m, *Sytsma et al. 4184* (MO). LOS SANTOS: Cerro Pilón, 2,700 ft., *Dwyer & Lallathin 8586* (MO). PANAMÁ: El Llano–Carti Road, 13.7 km N of Pan-American Highway, *Folsom 3589* (MO).

Cordia protracta I. M. Johnston, J. Arnold Arbor. 21: 349. 1948. TYPE: Panama. San Blas: Permé, *G. P. Cooper 244* (holotype, GH; isotypes, F, MICH, NY, US (2)).

Tall shrub, the twigs sparsely strigillose. Leaves persistent; petioles 4–9 mm long, canaliculate adaxially, sparsely strigillose; blades anisophyllous, falcate, the larger oblong-ovate, 15.6–24.6 cm long, 5.4–10.3 cm wide, the apex long acuminate, the acumen to 3 cm long, the base asymmetrical, rounded to obtuse, the margin entire to slightly undulate, the adaxial surface glabrous, the abaxial surface glabrous but sparsely strigillose along the veins. Inflorescences terminal or borne in the branch axils, few per stem, cymose, to 6.5 cm long, 4.5 cm broad, with 20 or more flowers, the branches strigillose. Flowers sessile or nearly so, bisexual, monomorphic; calyx tubular, 7–7.5 mm long, ca. 4 mm wide at mouth, ribs absent, sparsely strigillose, the 5 lobes deltate, ca. 1 mm long; corolla white, tubular with reflexed or spreading lobes, ca. 12 mm long, 5-merous, the lobes oblong to ovate, 4–4.5 mm long, ca. 2.5 mm wide, the tube 7–7.5 mm long; stamens 5, exserted, the filaments ca. 11 mm long, the upper 4–4.5 mm free, slightly puberulent at insertion, the anthers oblong, ca. 2.2 mm long; ovary narrowly ovoid, ca. 2.0 mm long, ca. 1.1 mm broad, glabrous; style ca. 7.5 mm long, the stylar branches ca. 2.5 mm long, the stigma lobes clavate. Fruits borne in the slightly accrescent saucer-shaped calyx, white, drupaceous, glabrous, the stone inequilaterally ovoid, 10–11 mm long, 6–7 mm broad, ruminate, the endocarp bony, 1-locular.

Distribution. *Cordia protracta* is known only from wet forests at low elevations along the coast of San Blas and Chocó provinces in Colombia.

Cordia protracta is known from only a few localities in Panama. A distinctive species, it is perhaps most closely related to *C. correae* but differs by having falcate, shiny leaves, and white fruits. Further, *C. correae* occurs at high elevations in cloud forests in contrast with the lowland wet forests inhabited by *C. protracta.*

Additional specimens examined. PANAMA. SAN BLAS: vicinity of Puerto Obaldía, *Croat 16873* (MO (2)); Mulatuppu, Río Ibedi, *Duke 8483* (MO); 3–4 hours up Río Mulatupo by foot, *Kirkbride 233, 234* (MO).

Cordia sebestena L., Sp. Pl. 190. 1753. TYPE: without locality or collector's name (holotype, LINN (Savage Catalog number 253.2), not seen; microfiche, MO).

Cordia speciosa Salisb., Prodr. Stirp. Chap. Allerton 111. 1796. TYPE: not seen.

Small tree or shrub to 8 m tall, the twigs glabrescent. Leaves persistent; petioles (1.0–)1.5–3.8(–4.5) cm long, pubescent, the hairs simple, appressed; blades ovate, (7–)9–20(–22) cm long, (4.5–)6–12(–14) cm wide, the apex acute, the base rounded to obtuse, rarely somewhat cordate, often slightly uneven, the margin entire or occasionally slightly undulate, the adaxial surface scabrous, the hairs from a basal cystolith, the abaxial surface nearly glabrous with hairs sparse and restricted to the veins. Inflorescence subterminal, cymose, 6.5–12 cm broad, with 12–45 flowers, the branches strigillose. Flowers on pedicels 4–6 mm long, distylous; calyx tubular-campanulate, 11–24 mm long, ribs absent, glabrous or with an indument of 2 types of hairs, the first type simple and straight, 0.4–0.6 mm long, appressed, white to translucent, the second type simple, curly, 0.2 mm long or shorter, brown, usually 2-lobed but sometimes with up to 5 irregular and uneven lobes; corolla bright reddish orange, funnelform, 30–58 mm long, 5–7-merous, the lobes ovate to very widely ovate, 8–10 mm long; stamens 5–7, the filaments 22–33 mm long, the upper 2–6 mm free, glabrous, the anthers oblong, 2.8–3.8 mm long; ovary conical, 1.5–3 mm long; style 13–35 mm long, the stigma lobes clavate. Fruits completely enclosed in the accrescent calyx and often extending in a thin tip up to 12 mm beyond the fruit, drupaceous, white, the stone ovoid, 2–4 mm long, 1.5–2.3 cm wide, the endocarp bony.

Distribution. *Cordia sebestena* is basically pan-Caribbean in distribution, occurring from southern Florida through the West Indies, and to the Atlantic coast of southern Mexico, Central America, and northern South America. It grows along coastal strands and is particularly common on the offshore islands of Central America. In Panama it appears to be native only in the Comarca de San Blas.

Cordia sebestena is grown ornamentally throughout warm areas of the world for its bright orange-red flowers. It is the only Panamanian species of sect. *Cordia* and is distinctive in its large, funnelform corolla and large, drupaceous fruits completely enclosed by the accrescent calyx. The fruits are edible and are very sweet, although quite mucilaginous.

Additional specimens examined. PANAMA. PANAMÁ: San Francisco de la Caleta (atras del S.A.S.), *Carrasquilla 178* (F, MO) (probably cultivated). SAN BLAS: Isla Soskatupu, *Duke 8963* (MO, US), *15476* (MO); Guadia Tupo, *Dwyer 6864* (MO (3)); 50 mi. W of Ailigandi, on SW shore, *Edwards 1* (F, MO); Soskatupu Island, 0–150 m, *Elias 1698* (MO); small coral island NW of Ailigandi, *Hammel & D'Arcy 5051* (MO); Playón Chico and vicinity, Pinkanti hillside near bay, *Stier 186* (MO); Playón Chico and vicinity, Yantuppu, *Stier 192* (MO).

Cordia spinescens L., Mant. Pl. 2: 206. 1771; I. M. Johnston, J. Arnold Arbor. 30: 103. 1949. TYPE: based on a collection from "*India orientali*" (cf. Johnston, 1949a) (holotype, LINN (Savage Catalog number 253.2), not seen; microfiche, MO).

Varronia ferruginea Lam., Tab. Encyc. 1: 418. 1791; Poir., Encyc. 4: 263. 1797; Desv., J. Bot. (Desvaux) 1: 266, t. 9. 1809; *Cordia ferruginea* (Lam.) Roemer & Schultes, Syst. Veg. 4: 458. 1819. TYPE: based on plants cultivated in Paris (holotype, P-JU, number 6525a, not seen; microfiche, MO).

Cordia riparia Kunth in Humb., Bonpl. & Kunth, Nov. Gen. Sp. 3: 71, t. 207. 1818; I. M. Johnston, J. Arnold Arbor. 30: 103. 1949. TYPE: Colombia: Mompox, Magdalena Valley, no collector named on specimen (holotype, P in herb. Humboldt, not seen; microfiche, MO).

Cordia laxiflora Kunth in Humb., Bonpl. & Kunth, Nov. Gen. Sp. 3: 72. 1818; I. M. Johnston, J. Arnold Arbor. 30: 103. 1949. TYPE: Colombia: between Mompox and Morales, Magdalena Valley, no collector named on specimen (holotype, P in herb. Humboldt, not seen; microfiche, MO).

Cordia schomburgkii DC., Prodr. 9: 490. 1845. TYPE: Guyana. Without definite locality: 1838, *Schomburgk 406* (holotype, G-DC, not seen; microfiche, MO).

Cordia thibaudiana DC., Prodr. 9: 489. 1845. TYPE: without locality or collector (holotype, G-DC, not seen; microfiche, MO).

Cordia pauciflora Rusby, Mem. Torrey Bot. Club 6: 83. 1896. TYPE: Bolivia: near Cochabamba, *Bang 1291* (not seen).

Cordia costaricensis I. M. Johnston, J. Arnold Arbor. 30: 103. 1949. TYPE: Costa Rica. San José: vicinity of El Generál, 1,190 m, Aug. 1936, *A. F. Skutch 2828* (holotype, GH; isotypes, K, MICH, MO, NY, US).

Shrub 1–3(–6) m tall, the branches arching to sprawling, the twigs puberulent to hirsute. Leaves deciduous, on slightly recurved spurs 1.5–3(–4) mm long; petioles (1–)3–11(–15) mm long, puberulent to hirsute; blade ovate to elliptic-ovate, (3–)4–11.5(–14) cm long, (1.4–)2–6.5(–7.8) cm wide, the apex acute to attenuate or slightly acuminate, the base obtuse to rounded, the margin coarsely serrate to minutely denticulate, the adaxial surface scabrous to scabrid, rarely merely papillose, the abaxial surface puberulent to tomentulose, sometimes with most of the hairs restricted to the veins. Inflorescences axillary, spicate, (1.3–)2.5–8.5(–11.5) cm long, 4–7(–9) mm broad, the peduncle adnate to the petiole at the base, (1–)2–4.5(–6.5) cm long, puberulent to hirsute. Flowers sessile, distylous; calyx campanulate, (1.8–)2.3–3.5(–4.2) mm long, ribs absent, strigillose to puberulent and usually with small, globose wax particles, the 5 lobes deltate to shallowly triangular; corolla white, tubular, (3–)3.8–5.4(–6.2) mm long, truncate to frilled at the apex, the tube (1.7–)2–2.7(–3.1) mm long; stamens 5(–6), the filaments (2.7–)3.3–5(–6.2) mm long, the upper (0.5–)1–2(–2.4) mm free, puberulent just beneath the point of insertion, the free portion glabrous, the anthers ellipsoid, 0.6–0.8(–1) mm long; ovary ovoid to broadly ovoid, 0.7–1.3 mm long; disc crateriform to annular (0.2–)0.4–0.6(–1.1) mm tall or enclosing the entire surface of the ovary; style (1.5–)2–4(–4.8) mm long, the stigma lobes clavate. Fruits drupaceous, ½ to nearly completely enclosed in the slightly accrescent calyx, red, 3.7–4.1 mm long, (2–)2.7–3.3 mm broad, the stone ovoid to broadly ovoid, the endocarp bony.

Distribution. *Cordia spinescens* is a very widespread, weedy species that occurs from Central Mexico into South America, although it is apparently absent in the West Indies. It grows from sea level to 2,000 m in elevation in a wide variety of habitats. In Panama it is known from all regions except Los Santos.

Cordia spinescens is extremely variable but is easily recognized by its axillary spicate inflorescences with the base of the peduncle adnate to the petiole of the subtending leaf. This is the most commonly collected species of *Cordia* in Mexico and Central America. *Cordia spinescens* is often found in open disturbed areas and is very common in moist ditches along roadsides. Unlike the other shrubby species of sect. *Varronia* that usually have a rather erect form of growth, *C. spinescens* often has long arching branches.

The species of sect. *Varronia* characterized by spicate inflorescences, three of which occur in Central America, make up the most complex group in the entire genus (discussion under *C. curassavica*). This assemblage is centered in the Andes, and numerous species have been described from this region, although some should certainly be placed in synonymy. As a group, they are phenotypically plastic, and apparently all of the species involved are interfertile. Since most species of sect. *Varronia* with spicate inflorescences are widespread, natural hybridization is common, which has contributed to the confusion surrounding this group. As defined here, *Cordia spinescens* has its closest relatives in South America in *Cordia multispicata* Cham., and perhaps in the West Indies in *Cordia brownei* (Friesen) I. M. Johnston.

There is extreme morphological variability between populations of *Cordia spinescens.* Plants from low to middle elevations have ovate leaves with acute to slightly acuminate apices and elongate spikes in the axils of fully expanded leaves with the peduncle adnate to the petiole. At higher elevations in Panama and Costa Rica, the plants have more attenuate leaves, and the spikes appear well before the leaves are expanded, often giving the appearance of a paniculate rather than spicate inflorescence. These are not true panicles, however, since as flowering proceeds, the leaves expand and the inflorescence structure thus becomes the same as in plants from lower elevations. This variant from the uplands of Panama and Costa Rica was originally described by Johnston (1949a) as *Cordia costaricensis*, and the type (*Skutch 2828*) as well as several collections made at a similar stage of development differ from the more typical lowland plants in having shorter, broader spikes with more crowded flowers, more acuminate calyx lobes, more attenuate leaf apices, more prominently serrate leaf margins, and evenly hirsute or velutinous stems. However, intergradation between these upland populations and typical *C. spinescens* is so extensive that more intermediates are observed throughout their combined range than are individuals exhibiting characters of the extremes. These intermediates do not exhibit any reduction in pollen stainability and there is no evidence of habitat differentiation between them and either of the extremes.

With a species as variable as *Cordia spinescens*, it is not surprising that there has been considerable nomenclatural confusion. The name *Cordia ferruginea* (Lam.) Roemer & Schultes was widely applied by earlier authors, although Johnston (1949a) correctly pointed out that the Linnaean name *C. spinescens* has priority and must be accepted. The types of these two names are clearly conspecific, despite the fact that Linnaeus mistakenly described *C. spinescens* as East Indian; no species of sect. *Varronia* are native in the Old World. This confusion probably resulted from the fact that *C. spinescens* had been cultivated in Europe at least as early as the late eighteenth century, as indicated by Johnston (1949a), suggesting that Linnaeus probably based his description on a cultivated specimen. Lamarck clearly based his description of *Varronia ferruginea* on plants that were cultivated in Paris in 1791.

Additional specimens examined. PANAMA. BOCAS DEL TORO: along railroad track near station at Milla 5, *Croat 16485* (F, MO); Changuinola Valley, *Dunlap 280* (US), *281* (GH); Changuinola Valley, Isla Potrero, *Dunlap 460* (CFMR, F); upper Río Changuinola, few miles upstream from Changuinola, *Dwyer 4385A* (MO); trail leading to ridge above Almirante, *Gentry 2758* (F, MO, NY); Río San Pedro, *Gordon 48* (MO); Chiriquí border along continental divide on carretera del Oleoducto ca. 1 km N of Quebrada Arena, IRHE Fortuna Hydro Electric Project, 1,150 m, *Knapp 5085* (MO); Changuinola to 5 mi. S at junction of ríos Changuinola and Terebe, 100–200 ft., *Lewis et al. 845* (K, MO, UC, US); Almirante, near road to Chiriquí, ca. 200 ft., *McDaniel 5075* (MO); Chiriquí Lagoon, Water Valley, *Wedel 1633* (MO, US), *1672* (MO), *1801* (GH, MO); Chiriquí Lagoon, Old Bank Island, *Wedel 2169* (MO, US); Quebra Nigua, *Wedel 2741* (MO, US); Chiriquí Lagoon, Isla Colón, *Wedel 2839* (MICH, MO, NY, US). CANAL AREA: Barro Colorado Island, *Aviles 103* (MO); *Bangham 495* (F, GH); Escandente, alrededores de la repressa Miraflores, *Correa 1181* (MO); Barro Colorado Island, *Croat 4400* (F, MO, SCZ); Pipeline Road at Río Agua Salud, *Croat 4731* (MO, SCZ (2)); Frijoles, near railroad station, *Croat 6265A* (MO); Barro Colorado Island, *Croat 7470* (F, MO, NY, SCZ); near Frijoles station, *Croat 8922* (MO, NY, SCZ), *8922* (MO, SCZ); Barro Colorado Island, *Croat 11763* (F (2), MO), *12811* (F, MO); Pipeline Road N of Gamboa ca. 24 km beyond gate, less than 300 ft., *Croat 38264* (MO); Barro Colorado Island, *D'Arcy 3983* (MO); Pan-American Highway near La Chorrera, *D'Arcy 9429* (MO); road C-21, *Duke 5791* (MO (2), NY); Albrook, *Dwyer 6714* (MO); Frijoles, *Ebinger 307* (F, MEXU, MO, US); near Farfan beach, *Gentry 1399* (F, MO, NY, SCZ); Pipeline Road, 2–4 mi. N of Gamboa, ca. 100 m, *Gentry 6541* (C, CAS, F, L, MEXU, MO, NY, RSA); Corozal, *Greenman & Greenman 5207* (GH, MO (2)); Gatún Station, *Hayes s.n.* (G, MO), *s.n.* (GH (2), MO, US), *608* (MO, NY (2), US); *Heriberto 49* (NY, US); Barro Colorado Island, *Hladik 65* (MO); Pipeline Road near Río Agua Salud, *Kennedy & Redemsky-Young 1809* (C, F, MO, NY, US); Barro Colorado Island, *Kenoyer 410, 641* (US); Gamboa, *McDaniel 5045* (MO); Curundu, 30–40 m, *Miller 1046* (MO); Gatún, *Ostenfeld 81* (C); near old Fort Lorenzo, mouth of Río Chagres, *Piper 5938, 5967, 5988* (US); vicinity of Ancon, *Piper 6030* (US); between Corozal and Ancon, 10–30 m, *Pittier 2171* (NY, US); grounds of Fort San Lorenzo, *Porter et al. 5006* (MO, SCZ, UC); W slope of Ancon Hill, vicinity of Balboa, 20–75 m, *Seibert 403* (MO, NY, US); Barro Colorado Island, *Shattuck 42* (F, GH, MO), *480* (F, MO (2)), *1073* (F, MO (2)); Balboa, *Standley 25570, 25591* (US); Summit, *Standley 26954* (US); Balboa, *Standley 27008* (US); Hills W of the Canal, near Gatún, *Standley 27183* (US); Gamboa, *Standley 28534* (US); along the old Las Cruces Trail, between Fort Clayton and Corozal, *Standley 29114* (US); vicinity of Summit, *Standley 29998* (US); vicinity of Fort Sherman, *Standley 31060* (US); Obispo, *Standley 31785* (US); Miraflores Locks area, *Tyson 1134* (MO, SCZ); 1 mi. Cordia tacarcunensis James S. Miller, sp. nov. TYPE: Panama. Darién: trail from Pucuro to Cerro Mali, vicinity of Tapaliza River, 100 m, tropical moist forest, 13 Jan. 1975, *Alwyn H. Gentry & Scott Mori 13546* (holotype, MO 2288082). Figure 5.

Arbor vel frutex ad 3 m alta, ramunculo glabro. Folia persistentia, petiolis 6–10 mm longis; laminae anguste ovato-ellipticae, 8.1–14.5 cm longae, 4.5–6.5 cm latae, apice acuminatis, base acutis, superficie papillosa. Inflorescentiae axillares, parvae dichotome cymosae, 4–6 cm latae. Flores unisexuales, plantis dioeciis; calyx campanulatus, 2.7–3 mm longus, 5-lobatus, strigillosus; corolla alba, tubuliformis, 4.8 mm longa, 5-lobata, lobo reflexa, oblonga, 2.2 mm longa; stamina 5, filis villosis, antheris ellipticis. Fructus drupaceus, putamine inaequilateraliter ovoideo, 5 mm longo.

Small tree or shrub 3 m tall, the twigs glabrous. Leaves persistent; petioles 6–10 mm long, canaliculate adaxially, minutely strigillose; blades narrowly elliptic-ovate, 8.1–14.5 cm long, 4.5–6.5 cm wide, the apex acuminate, the base acute and sometimes slightly decurrent, the margin entire, the adaxial surface lacking hairs but densely covered with small scaly papillae, the abaxial surface nearly glabrous, with small scaly papillae and a few widely scattered appressed hairs. Inflorescences axillary, numerous per stem, dichotomous cymes, 4–6 cm broad, the axes densely brown strigillose. Flowers unisexual, the plants dioecious. Female flowers with small, nonfunctional anthers, sessile; calyx campanulate, 2.7–3 mm long, 3–3.5 mm wide at mouth, ribs absent, dark-brown strigillose, the 5 lobes shallowly triangular, 0.5 mm long; corolla white, tubular with reflexed lobes, 4.8 mm long, 5-merous, the lobes oblong, 2.2 mm long, 1 mm wide, the tube 2 mm long; stamens 5, nonfunctional, the filaments 2.8 mm long, the upper 2 mm free, villous toward the middle of the free portion, the anthers ellipsoid, 0.5 mm long; ovary ovoid, 2.3 mm long, 2 mm broad; disc crateriform, 0.4 mm tall, 1.2 mm broad, glabrous; style 2.5 mm long, the stylar branches 1.9 mm long, the stigma lobes fan-shaped. Male flowers unknown. Fruits seated in the slightly accrescent saucer-shaped calyx, drupaceous, glabrous, the stone inequilaterally broadly ovoid, 5 mm long, 5 mm broad, endocarp bony, 1-seeded.

Distribution. *Cordia tacarcunensis* is known only from the type collection made

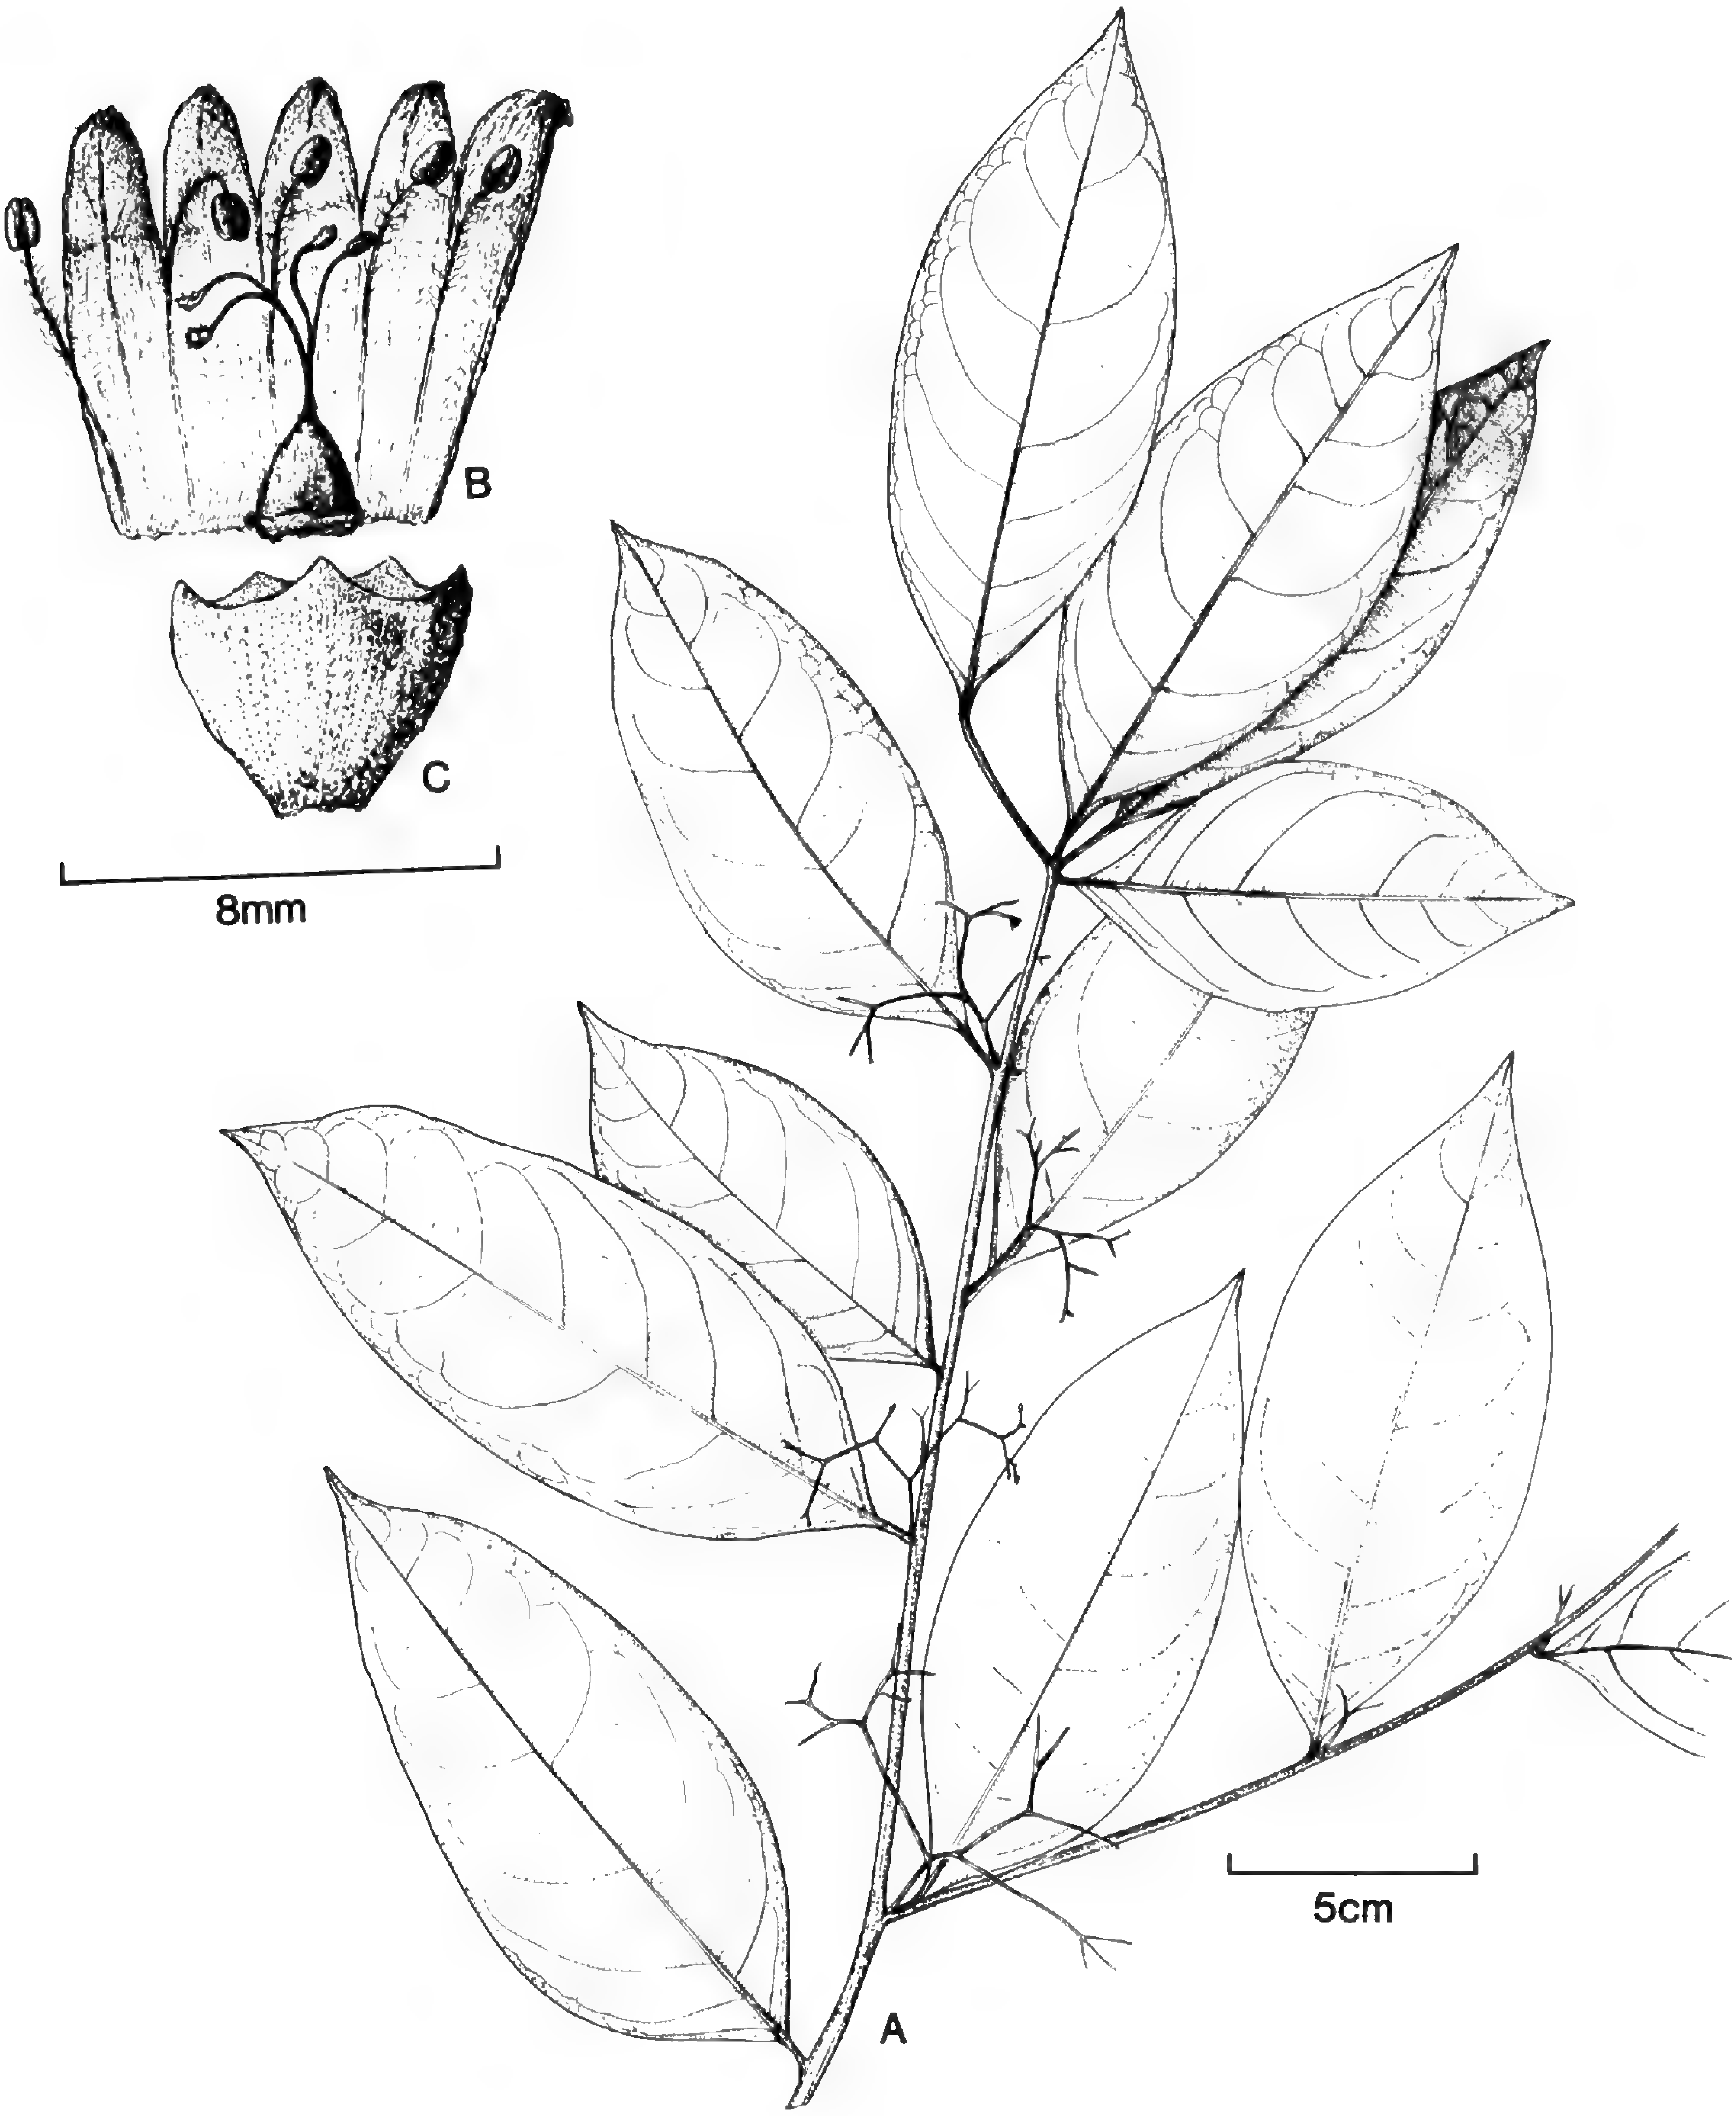

FIGURE 5. Cordia tacarcunensis.—*A. Flowering branch.—B. flower with corolla opened.—C. Calyx. From* Gentry & Mori 13546 *(MO), Darién, Panama.*

near the base of Cerro Tacarcuna on the Colombia–Darién border.

Cordia tacarcunensis is probably most closely related to *C. protracta* and *C. correae,* with which it shares a similar growth habit and a three-parted calyx. It is distinctive, however, in its small, axillary inflorescences and its fan-shaped stigma lobes. In addition to the *C. panamensis* and *C. diversifolia* species groups, *C. tacarcunensis* is the only member of sect. *Myxa* in Central

America known to be dioecious; the breeding systems of its two presumed closest relatives are not known.

Cynoglossum L., Sp. Pl. 134. 1753; Gen. Pl. ed. 5. 65. 1754. TYPE: *Cynoglossum officinale* L., vide Britton & A. Brown, Ill. Fl. N. U.S. ed. 2, 3: 75. 1913.

Perennial (rarely annual or biennial) herbs from a thickened rootstock, usually branched, pubescent or rarely glabrous. Leaves alternate, simple, entire, the basal leaves on distinct petioles, the cauline leaves usually sessile. Inflorescences racemes or panicles, the branches scorpioid, usually ebracteate. Flowers bisexual, usually pedicellate; sepals 5, nearly distinct to the base, accrescent in fruit; corolla blue, purple, or rarely white, salverform to campanulate, 5-lobed, with 5 apparent protuberances in the mouth; stamens 5, the anthers on short filaments or nearly sessile, oblong to ellipsoid; ovary 4-lobed, the style gynobasic, the stigma 1, capitate. Fruits of 4 spreading nutlets, attached apically to the gynobase, the scar restricted to the apical half of the ventral surface, the dorsal surface with short glochidiate spines.

Cynoglossum contains about 80 species found throughout much of the world although generally absent from lowland tropical forest. Many species are cultivated ornamentals and this, combined with the epizoochorously dispersed, glochidiate spiny fruits, has allowed many members of the genus to become naturalized far from their natural ranges.

Cynoglossum amabile Stapf & J. R. Drumm., Kew Bull. 1906: 202. 1906. SYNTYPES: China. Yunnan: Mengtze, *W. Hancock 133* (K, not seen); Szemao, 350 m, *A. Henry 9365* (MO). Sichuan: Tatsienlu, *Soulié 861* (K, not seen); without locality, 2,700–4,050 m, *A. E. Pratt 887* (K, not seen); without locality, *M. Leichtlin s.n.* (K, not seen).

Erect biennial or perennial herb from a thick rootstock, to 0.5(–1) m tall, the stems densely strigose. Basal leaves on petioles to 4.5(–11) cm long, the blade narrowly elliptic, 6–11(–17) cm long, (1–)1.5–2.5(–3) cm wide, the apex acute, the base attenuate to cuneate, the margin entire, the adaxial surface strigillose to strigose, the abaxial surface pilose to pubescent; cauline leaves sessile, lanceolate to narrowly elliptic, 3–6(–8) cm long, 0.7–2 cm wide, the apex acute, the base clasping and usually somewhat lobed, the margin entire, the adaxial surface strigillose to strigose, the abaxial surface pubescent to hirtellous. Inflorescence terminal, a panicle of small cymes, to 16(–30) cm long, the branches cymose, densely strigillose. Flowers bisexual, on pedicels to 5 mm long; sepals 5(–7), lanceolate to lance-ovate, 2–3(–4) mm long, strigose; corolla blue, rotate, 5(–7)-merous, the lobes widely obovate, 2–3(–4) mm long, the tube 1.3–2.5 mm long, with 5 hooded protuberances in the mouth, these alternate with the stamens and often puberulent; stamens 5(–7), the anthers ellipsoid, (0.5–) 0.8–1.3 mm long, nearly sessile or on short filaments to 0.5 mm long, inserted just below the mouth of the corolla tube; ovary 4-lobed, the surface smooth, the disc basal, the style gynobasic, 0.8–2 mm long, the stigma capitate. Fruits of 4 spreading nutlets, 4–6 mm broad, the nutlets ovate, flat to convex on the dorsal surface, with glochidiate spines to 0.5 mm long.

Distribution. *Cynoglossum amabile* is native to China but has become commonly naturalized in the Neotropics, being found in open areas at elevations above 1,500 m in elevation. In Panama, it is known only from Chiriquí; it is undoubtedly also in adjacent parts of Bocas del Toro.

Cynoglossum amabile can be easily distinguished from *Hackelia mexicana* (Schldl. & Cham.) I. M. Johnston, the other common small blue-flowered species of Boraginaceae in Chiriquí, by the shorter spines on its fruits and the cauline leaves usually clasping at the base, rather than cuneate as in *H. mexicana.* The only one of the syntypes that I have seen is the collection made by A. Henry, which is labeled as having pink flowers. As blue flowers are characteristic of the species and pink-flowered forms are unusual, the selection of a lectotype will have to be from one of the remaining specimens.

Additional specimens examined. PANAMA. CHIRIQUÍ: Dist. of Boquete, E of Cerro Punta, area called Bajo Chorro, 2,600 m, *Antonio 1032* (MO); Monte Azul, 1.4 mi. N of Entre Ríos on E slopes of Cerro Punta, 3 mi. by road from town of Cerro Punta, 2,250 m, *Antonio 2723* (MO); Cerro Punta–David, 1,000–2,500 m, *Beliz 218* (MO); Volcán Barú, 3,474 m, *Beliz 355* (MO); Finca Collins, vicinity of Boquete, *Blum & Dwyer 2580* (MO); 5.4 km del Hato de Volcán en el camino a Las Lagunas, *Correa & Lazor 1472* (MO); 2 mi. Ehretia P. Browne, Civ. Nat. Hist. Jamaica 168. 1756. TYPE: *Ehretia tinifolia* L., Syst. Nat., ed. 10. 936. 1759.

Trees or shrubs, pubescent or glabrous. Leaves alternate, petiolate, entire or serrate. Inflorescences terminal, cymose to paniculate. Flowers bisexual; sepals 5, imbricate or open in bud; corolla white, tubular with 5 spreading lobes; stamens 5, usually exserted, the lower portion of the filaments adnate to the corolla tube, the anthers oblong to ellipsoid; ovary ovoid, 2- or 4-locular, the style terminal, bifid, the stigmas 2, clavate or capitate. Fruits drupaceous, ovoid to nearly spherical, the stone separating into 2, 2-seeded or 4, 1-seeded pyrenes.

The pantropical genus *Ehretia* comprises about 50 species with most occurring in Africa and tropical Asia. Only three species are known from the New World, one of which is found in Panama.

Ehretia latifolia DC., Prodr. 9: 503. 1845. TYPE: Herb. Amat. (holotype, G-DC, not seen; microfiche, MO).

Ehretia mexicana S. Watson, Proc. Amer. Acad. Arts 26: 144. 1891. TYPE: Mexico. Jalisco: base of mountains near Lake Chapala, *C. G. Pringle 3085* (lectotype, here designated, GH; isolectotypes, BH, BM, F, GH, MO, NY (2), UC, US (2)).

Ehretia luxiana J. D. Smith, Bot. Gaz. (Crawfordsville) 18: 5. 1893 (corrected reprint). TYPE: Guatemala. Quiche: San Miguel Uspantán, 6,100 ft., Apr. 1892, *Heyde & Lux 3065* (holotype, F 575900; isotypes, MO, NY, US).

Ehretia cordifolia Robinson, Proc. Amer. Acad. Arts 29: 319. 1894. TYPE: Mexico. Jalisco: valley, Zapotlán, 19 May 1893, *C. G. Pringle 4382* (holotype, F 106011; isotypes, A, BM, GH, MO, NY, UC, US (2)).

Ehretia viscosa Fern. in Sarg., Trees & Shrubs 1: 25, pl. 13. 1902. TYPE: Mexico: Morelos, near Cuernavaca, 29 May 1899, *C. G. Pringle 7777* (holotype, F 120287; isotypes, BH, GH, MEXU (2), MO, NY, UC).

Ehretia tehuacana Greenman, Publ. Field Columbian Mus., Bot. Ser. 2: 339. 1912. TYPE: Mexico. Puebla: Las Mohoneras, Tehuacán, 2,200 m, *C. Conzatti 2220* (holotype, F 235156; isotype, GH).

Ehretia austin-smithii Standley, Publ. Field Mus. Nat. Hist., Bot. Ser. 18: 984. 1938. TYPE: Costa Rica. Alajuela: Zarcero, in pasture, 1,850 m, Mar. 1938, *Austin Smith H528* (holotype, F 919653; isotype, MO).

Tree to 10 m tall, the twigs glabrous or nearly so. Leaves persistent; petioles 7–18 mm long, glabrous or nearly so; blades ovate, 4–13 mm long, 2–6.6 cm wide, the apex acute to slightly acuminate, the base obtuse to rounded, the margin serrate, the adaxial surface glabrous to sparsely strigillose, the abaxial surface glabrous. Inflorescence terminal, paniculate, to 8 cm long and 7 cm broad, the peduncle glabrous to sparsely puberulent. Flowers sessile, bisexual; sepals 5, ovate to narrowly triangular, 1.5–2 mm long, ciliate along the margin but otherwise glabrous; corolla white, 5-merous, the lobes ovate, 1.5–2.8 mm long; stamens 5, the filaments 4.5–5 mm long, the upper 3.4–4.4 mm free, glabrous, the anthers ellipsoid, 1–1.5 mm long; ovary broadly ovoid, 1–1.5 mm long, the style bifid, 1.4–3.3 mm long, the stigma lobes truncate. Fruits drupaceous, white, ellipsoid to ovoid, 10–15 mm long.

Distribution. *Ehretia latifolia* is known from Mexico south to Chiriquí Province in Panama, where it is found at 1,000–2,500 m in elevation.

Ehretia latifolia, as here defined, is a widespread, variable species. The numerous synonyms are based on minor variations in leaf shape and indument, characters that vary considerably on an individual tree as well as between individuals of a single population (Miller, unpubl.). As in most species of *Ehretia,* the plants are quite attractive while in flower, but flowering occurs only for a short period.

Additional specimens examined. PANAMA. CHIRIQUÍ: a lo largo del camino que va de Bambito a los llanos de lava, 6,000 ft., *Correa & Lazor 1410* (F, MO); at opening to canyon to Bambito, 5,000 ft., *Tyson 5870* (MO (2)); Río Chiriquí Viejo Valley, near Bambito, *White 220* (F, GH, MO).

Hackelia Opiz in Bercht., Oekon.-techn. Fl. Böhm. 2(2): 146. 1838. TYPE: *Hackelia deflexa* (Wahlenb.) Opiz in Bercht., Oekon-techn. Fl. Böhm. 2, pt. 2, 147. 1839; I. M. Johnston, Contr. Gray Herb. 68: 45. 1923.

Erect, perennial or biennial herbs, pubescent or less commonly glabrous. Leaves alternate, entire, the basal leaves usually long-petiolate, the cauline leaves short-petiolate to sessile. Inflorescence a raceme or panicle, the branches scorpioid, ebracteate or with inconspicuous bracts. Flowers bisexual; sepals 5, free to the base or nearly so, slightly accrescent in fruit; corolla blue, often with a yellow center, or rarely white to pale yellow, salverform, 5-lobed, with 5 well-developed protuberances in the mouth; stamens 5, included in the corolla tube, the anthers elliptic to oblong, on short filaments; ovary 4-lobed, the style gynobasic, the stigma capitate. Fruits of 4 nutlets, the attachment to the pyramidal gynobase medial, the scar conspicuous, the dorsal surface with elongate glochidiate spines, these longer along the margins.

Hackelia is a genus of about 40 species of the New World, Europe, and Asia; it is clearly centered in western North America. Only a single species occurs in Panama.

Hackelia mexicana (Schldl. & Cham.) I. M. Johnston, Contr. Gray Herb. 68: 46. 1923. *Cynoglossum mexicanum* Schldl. & Cham., Linnaea 5: 114. 1830. *Echinospermum mexicanum* (Schldl. & Cham.) Hemsley, Biol. Cent.-Amer., Bot. 2: 377. 1882. *Lappula mexicanum* (Schldl. & Cham.) E. Greene, Pittonia 2: 1882. 1891. TYPE: Mexico. Veracruz: in Monte Macuiltepetl, near Jalapa, *Schiede 208* (not seen).

Lappula costaricensis Brand in Fedde, Repert. Spec. Nov. Regni Veg. 18: 310. 1922. *Hackelia costaricensis* (Brand) I. M. Johnston, Contr. Gray Herb. 68: 46. 1923. TYPE: Costa Rica: San José, *Hoffman 152* (not seen).

Lappula guatemalensis Brand in Fedde, Repert. Spec. Nov. Regni Veg. 18: 311. 1922. *Hackelia guatemalensis* Brand in Engl., Pflanzenr. 4, 252: 120. 1931. SYNTYPES: Guatemala: Quiche, *Heyde & Lux 3043* (not seen). Guatemala: Huehuetenango, *Seler & Seler 3144* (not seen).

Erect perennial herb from a thick rootstock, to 1.5 m tall, the stems pubescent. Basal leaves on petioles 9–17 cm long, lanceolate, 6–15 cm long, 2.5–4.5 cm wide, the apex acuminate to attenuate, the base cuneate to decurrent, the margin entire, cauline leaves lanceolate to elliptic, 8–23 cm long, 2–7.5 cm wide, the apex acuminate, the base cuneate to decurrent, the margin entire, the uppermost usually sessile, those below on petioles to 16 cm long, the adaxial surface strigose, the abaxial surface strigose to sparsely pilose, densely strigose along the main veins. Inflorescences terminal or from the upper leaf axils, a simple or once-branched raceme, 12–25 cm long, the rachis strigose to hirsute. Flowers bisexual, on pedicels to 5 mm long, these elongating to 15 mm in fruit; sepals 5, lanceolate, 1.5–2 mm long, strigose; corolla blue, yellow in the mouth, rotate, 5-merous, the lobes very widely ovate or obovate to widely oblong, 1.5–2.5 mm long, the tube 1.4–2 mm long, with 5 protuberances in the mouth; stamens 5, the anthers ellipsoid, 0.5–0.7 mm long, nearly sessile, inserted in the middle of the corolla tube; ovary 4-lobed, the lobes tuberculate, enclosed at the base by the disc, the style gynobasic, 0.5–0.7 mm long, the stigma capitate. Fruits of 4 nutlets, 2.5–3.2 mm long, densely glochidiate, the spines 1–4 mm long.

Distribution. Hackelia mexicana occurs from Mexico, south through Central America, to Venezuela, Colombia, Ecuador, and Peru, where it can be found in open disturbed areas at 1,200–3,500 m in elevation. In Panama, it is known only from upland Chiriquí, but it is certainly expected in adjacent areas of Bocas del Toro.

Hackelia mexicana is a common weed of upland Chiriquí, where it is highly visible and distinct with its bright blue flowers. In this region *H. mexicana* is most easily confused with *Cynoglossum amabile*, although, as indicated under the latter species, *H. mexicana* differs in having cauline leaves that are not clasping at the base, nutlets with a medial attachment to the gynobase, and much longer glochidiate spines on the nutlets.

Additional specimens examined. PANAMA. CHIRIQUÍ: E of Cerro Punta, area called Bajo Chorro, 2,600 m, *Antonio 1023* (MO); Cerro Punta, 7,000 ft., *Blum et al. 2422* (MO); slopes of Las Cumbres near Cerro Punta, *Croat 13679* (MO); Las Cumbres, hogback ridge N of Quebrada Iglesia, near town of Cerro Punta, *Croat & Porter 16096* (MO); 12 mi. above Boquete on road to Volcán Barú, 2,900–2,950 m, *Croat 34900* (MO); E slope of Volcán de Chiriquí (Barú), above Boquete, *Davidse & D'Arcy 10284* (MO); Potrero Muleto, Volcán de Chiriquí, 10,400 ft., *Davidson 1018* (GH, MO); just below last climb in Alto Respinga, 2,700 m, *D'Arcy 12135* (MO); Alto Respinga and above, 2,800 m, *D'Arcy s.n.* (MO); along Boquete Trail, Cerro Respinga, 2,000–2,500 m, E of town of Cerro Punta, *Gentry 5949* (GH, MO); along Boquete trail, Cerro Respinga, 2,000–2,500 m, E of town of Cerro Punta, *Gentry 6014* (MO); path above Cerro Punta to Boquete, 2,500 m, *Hamilton & Stockwell 3421* (MO); path above Cerro Punta to Boquete, 2,500 m, *Hamilton & Krager 3738* (MO); Bajo Chorro, *Hladik 195* (MO); near Paso de Respingo, in pasture and disturbed oak forest, ca. 2,300 m, *Mori & Kallunki 5737* (MO); around El Potrero camp, 2,800–3,000 m, *Pittier 3106* (GH); vicinity of Cerro Punta, 6,800 ft., *Ridgway & Solis 2394* (MO); ca. 3.7 km E of bridge NE of Cerro Punta on road through Bajo Grande, 2,250–2,400 m, *Stevens 18217* (MO); 3.7 km along road through Bajo Grande from bridge NE of Cerro Punta, 2,250–2,400 m, *Sytsma & Stevens 2117* (MO); along the trail between Cerro Punta and the Quebrada Bajo Grande, 2,000–2,100 m, *Wilbur et al. 11897* (GH); Finca Lerida to Peña Blanca, 1,750–2,000 m, *Woodson & Schery 333* (GH (2), MO); vicinity of Casita Alta, Volcán de Chiriquí, 1,500–2,000 m, *Woodson et al. 890* (GH (2), MO).

Heliotropium L., Sp. Pl. 130. 1753; Gen. Pl. ed. 5, 130. 1754. TYPE: *Heliotropium europeaum* L., Sp. Pl. 130. 1753.

Annual or perennial herbs or rarely low shrubs. Leaves alternate, rarely opposite or whorled. Inflorescences bracteate or ebracteate, helicoid cymes borne singly or in groups of 2–4, or the flowers borne individually along leafy stems. Flowers bisexual; sepals 5, imbricate, free or nearly so to the base, often unequal in size, occasionally accrescent; corolla salverform, funnelform, or tubular, white, or white with a yellow center, or occasionally blue to purple, 5-lobed; stamens 5, inserted in the throat of the corolla tube, the anthers free or apically connate; ovary 4-locular, often 4-lobed, the style terminal or absent, the stigma 1, conical. Fruits dry, breaking into 2 or 4 nutlets at maturity.

Heliotropium comprises about 200 species and is essentially cosmopolitan, with the greatest number of species occurring in dry, tropical regions. Despite the relative abundance of species in most neotropical countries, only four species are known from Panama. These are all widespread, weedy species found throughout the Neotropics, and two have become widespread in the Old World. *Heliotropium arborescens* L., a South American species, is often cultivated for its attractive purple flowers and might be found in gardens in Panama, although no collections exist.

The pantropical genera *Heliotropium* and *Tournefortia* L., and the monotypic Argentine genus *Ixorhea* Fenzl make up the subfamily Heliotropioideae. *Heliotropium* is a morphologically diverse genus, and Johnston (1928) recognized 11 sections in South America, three of which are known from Panama. *Heliotropium* is a genus of herbs with dry fruits, in contrast with the woody habit and fleshy fruits that characterize *Tournefortia*.

KEY TO THE SPECIES OF *HELIOTROPIUM* IN PANAMA

1a. Plants glabrous .... *Heliotropium curassavicum*
1b. Plants with pubescent stems and leaves.
  2a. Inflorescence terminal or internodal, spicate or a helicoid cyme, with numerous flowers.
    3a. Corolla lavender; plants erect; leaves wider than 2 cm .. *Heliotropium indicum*
    3b. Corolla white; plants procumbent; leaves narrower than 2 cm .... *Heliotropium procumbens*
  2b. Inflorescence axillary, 1-flowered .... *Heliotropium lagoense*

Heliotropium curassavicum L., Sp. Pl. 130. 1753. TYPE: Curaçao: *P. Browne s.n.* (holotype, LINN (Savage Catalog number 179.11), not seen; microfiche, MO).

Low herb, often somewhat succulent, glabrous, often glaucous, the stems procumbent to ascending. Leaves lacking a distinct petiole; blades oblanceolate, 10–35 mm long, 1–5(–10) mm wide, the apex acute to rounded, the base cuneate, the margin entire, glabrous and often glaucous on both surfaces. Inflorescence internodal, a once- or twice-branched helicoid cyme, rarely simple, the peduncle 11–20(–32) mm long, the branches (1.8–)3–6(–8) cm long. Flowers bisexual; sepals 5, lanceolate to ovate or oblong, ca. 1.5 mm long, glabrous; corolla white, 2–2.5 mm long, the 5 lobes 1 mm long, the tube 1 mm long, glabrous; stamens 5, the anthers nearly sessile, inserted near the middle of the corolla tube, ellipsoid, 0.5–0.8 mm long; ovary ovoid, the disc well developed, the stigma sessile, broadly conical. Fruits ovoid, 1–2 mm long, glabrous, 4-lobed, separating into 4 nutlets at maturity.

Distribution. Heliotropium curassavicum is usually found growing along the edges of lakes, streams, or tidal flats from sea level to 600 m in elevation. It occurs from the United States through Central America and the West Indies and South America; it has also apparently become introduced and widespread in the Old World (Nowicke & Miller, in press). This species is known in Panama only from the province of Los Santos.

Heliotropium curassavicum is one of the most distinctive species of the genus and is the only member of sect. *Halmyrophila* I. M. Johnston. It is easily recognized by its glabrous, succulent nature. Several varieties of this species have been recognized (Johnston, 1928; Frohlich, 1981); the populations in Panama are all of the typical variety.

Additional specimens examined. PANAMA. LOS SANTOS: Salinas de Chitré, *D'Arcy & Croat 4199* (MO); Monagre Beach, *Dwyer 4177* (MO (2)); Monagre Beach, 5 mi. SE of Chitré, *Tyson et al. 3023* (MO).

Heliotropium indicum L., Sp. Pl. 130. 1753. TYPE: *P. Browne s.n.* (holotype, LINN (Savage Catalog number 179.2), not seen; microfiche, MO).

Annual herb to 50 cm tall, the stems pubescent to pilose, the hairs simple. Leaves on petioles (7–)10–25(–40) mm long, pubescent, often pilose at the base; leaf blade ovate, (2.7–)5–10(–12) cm long, (2–)3–5(–7) cm wide, the apex acute to obtuse, the base obtuse to truncate and usually decurrent along the petiole, the margin unevenly serrate to undulate, the adaxial surface with widely scattered appressed hairs, the abaxial surface nearly glabrous with only a few hairs scattered along the veins, to nearly villous. Inflorescence internodal, an unbranched or very rarely dichotomous helicoid cyme, the peduncle (1–)2–3(–6) cm long, pubescent, the fertile portion (6–)9–16(–20) cm long. Flowers bisexual; sepals 5, lanceolate, 2–3 mm long, pubescent; corolla purple to occasionally white, salverform, 5-merous, the lobes ovate, 1–1.5 mm long, the tube 3–4 mm long, pubescent outside; stamens 5, the anthers sessile or nearly so, inserted just below the middle of the corolla tube, ellipsoid, 0.6–0.8 mm long; ovary globose, 0.5–1 mm long, the disc well-developed, the style 0.5–1 mm long, the stigma capitate. Fruits angular ovoid, with an apical beak, 2–3 mm long, glabrous, the 2 lobes spread apart and ultimately separating into 2 nutlets at maturity.

Distribution. *Heliotropium indicum* is a weed of disturbed habitats from sea level to 1,000 m in elevation nearly throughout the world with the exception of cold regions. In Panama, it is known from all regions except the Comarca de San Blas, but is probably there as well.

Heliotropium indicum is a coarse, annual weed and one of the most commonly encountered species of the genus. Although it is essentially worldwide in distribution, Johnston (1928) suggested that it was probably South American, possibly Brazilian, in origin. Its closest relative is *H. elongatum* Hoffm. ex Roemer & Schultes, a species of southeastern South America, and the two make up sect. *Tiaridium* (Lehm.) Griseb., which is characterized by a weedy, annual habit, salverform corollas, and ribbed, glabrous fruits. *Heliotropium indicum* is easily recognized by its purple (rarely white) corollas and strongly angular fruits with prolonged apices.

Additional specimens examined. PANAMA. BOCAS DEL TORO: Bocas del Toro, *Carleton 195* (GH); Old Bank Island, *Wedel 1986* (GH, MO). CANAL AREA: Pipeline Road to 18 km N of Gamboa, *D'Arcy 10618* (MO); flooded pasture bordering Chagres River, about 2 mi. N of Gamboa, *Lazor 3498* (MO); Barro Colorado Island, *Starry 249* (MO). VERAGUAS: 1.3 km E of the intersection of the Panamerican Highway and road P38 to Atlaya, *Folsom 2932* (MO); 2 mi. S of Canazas, *Tyson 3725* (MO).

Heliotropium lagoense (Warm.) Gürke in Engl. & Prantl, Nat. Pflanzenfam. 4 Abt. 3a, 97. 1893. *Schleidenia lagoensis* Warm., Vidensk. Meddel. Dansk Naturhist. Forren. Kjobenhavn 1867: 15. 1868. TYPE: Brazil. Minas Gerais: Lagoa Santa, 1863–1866, *Warming 21971* (C, holotype, not seen; photo, MO).

Procumbent herb, the stems with a few scattered, appressed hairs. Leaves on short petioles to 1.5 mm long; blade narrowly elliptic to oblanceolate, 3–6 mm long, 1.2 mm wide, the apex acute, the base acute, the margin entire, the adaxial surface glabrous, the abaxial surface glabrous or with a few scattered, appressed hairs. Flowers borne individually in the leaf axils, on pedicels 2–4(–6) mm long; sepals 5, ovoid, ca. 2 mm long, glabrous; corolla pale blue to white and yellow in the throat, the 5 lobes widely ovate, ca. 1 mm long, the tube ca. 2 mm long, glabrous; stamens 5, the anthers ovoid, ca. 0.4 mm long, sessile, inserted near the middle of the corolla tube; ovary ovoid, ca. 0.5 mm long, the disc scarcely evident, the stigma sessile, capitate. Fruits ovoid, 1.2 mm long, glabrous, 4-lobed, separating into 4 nutlets at maturity.

Distribution. *Heliotropium lagoense* occurs from Mexico through South America and the West Indies, and is found at elevations below 200 m (rarely to above 1,000 m) usually in open savannas. In Panama, it is known from a single collection from the province of Coclé.

Heliotropium sect. *Orthostachys* R. Br. is the largest section of the genus and certainly the most complex taxonomically. It is found throughout tropical regions of the world and is particularly well represented in the Neotropics, where Johnston (1928) suggested that approximately 50 species occur. *Heliotropium lagoense* and *H. procumbens* are the only members of the section known to occur in Panama. *Heliotropium lagoense* is a member of subsect. *Axillaria* and is easily recognized by its diminutive habit of growth and axillary flowers that are not aggregated into the helicoid cymes that characterize all of the other Panamanian species.

Additional specimens examined. PANAMA. COCLÉ: mountains beyond Pintada, 400–600 m, *Hunter & Allen 525* (MO).

Heliotropium procumbens Miller, Gard. Dict. ed. 8, no. 10. 1768; I. M. Johnston, Contr. Gray Herb. 81: 52. 1928. TYPE: Colombia. Bolívar: Cartagena, *Houston s.n.* (holotype, BM, not seen).

Heliotropium americanum Miller, Gard. Dict. ed. 8, no. 10. 1768. TYPE: Mexico. Veracruz: *Houston s.n.* (holotype, BM, not seen).

Heliotropium inundatum Sw., Prodr. 40. 1788. TYPE: Jamaica (not seen).

Heliotropium decumbens Lehm., Nov. Actorum Acad. Caes. Leop. Carol. German. Nat. Cur. 9: 128. 1818. TYPE: Venezuela. Sucre: Cumaná, *Humboldt 57* (holotype, P, not seen; microfiche, MO).

Heliotropium simplex Meyen, Reise 1: 436. 1834. TYPE: Chile. Tacna: Arica, *Meyen s.n.* (holotype, B, not seen).

Heliotropium inundatum var. *cubense* DC., Prodr. 9: 540. 1845. TYPE: Cuba. La Habana: near Havana, 1829, *Ramón de la Sagre 239* (holotype, G-DC, not seen; microfiche, MO).

Heliotropium bridgesii Rusby, Mem. Torrey Bot. Club 4: 224. 1895. TYPE: Bolivia. Cochabamba: Cochabamba, *M. Bang 950* (holotype, NY; microfiche, MO; isotype, US).

Heliotropium inundatum var. *chacoense* R. E. Fries, Ark. Bot. 6(11): 22. 1906. TYPE: Bolivia. Tarija: along Río Pilcomayo near Ft. Crevaux, *Fries 1614* (isotype, US).

Herb to 30 cm tall, the stems procumbent to ascending, strigose to pubescent. Leaves on petioles (3–)5–10(–15) mm long, strigose to pubescent; leaf blade elliptic to narrowly elliptic, 11–20(–35) mm long, 6–11(–17) mm wide, the apex acute to rounded, the base acute to cuneate, the margin entire, the adaxial surface strigose, the abaxial surface strigose to sericeous. Inflorescence internodal or terminal, a once- or twice-branched helicoid cyme, the peduncle (3–)8–20(–26) mm long, strigose to sericeous, the fertile portion 20–45(–75) mm long. Flowers bisexual; sepals 5, lanceolate, 1–1.2 mm long, one often exceeding the others in length, strigose; corolla white, the 5 lobes lanceolate to lance-ovate, 0.5–0.6 mm long, the tube 0.9–1.2 mm long, villous in mouth, strigose to strigillose outside; stamens 5, the anthers ellipsoid but acuminate at the apex, 0.2–0.3 mm long, sessile or nearly so, inserted from near the base to just beneath the middle of the corolla tube; ovary globose, 0.2–0.3 mm long, the disc scarcely evident, the stigma sessile, capitate. Fruits globose, ca. 1 mm long, strigillose, faintly 4-lobed, separating into 4 nutlets at maturity.

Distribution. *Heliotropium procumbens* is widespread from the southern United States south throughout all of the Neotropics, at elevations of 0–1,500 m in a wide variety of habitats. In Panama, it is known from the provinces of Coclé, Herrera, Los Santos, and Panamá.

A common weed, *Heliotropium procumbens* is extremely variable in shape, size, and indument of its leaves. Its wide geographic distribution and morphological variability have spawned considerable taxonomic problems, and numerous segregates have been proposed. Despite this, the species has been interpreted broadly by most recent authors.

Additional specimens examined. PANAMA. COCLÉ: 20 mi. S of Nata, *D'Arcy & Croat 4120* (MO); Río Coclé, W of Penonomé, *Folsom 2920* (MO). HERRERA: alrededores de Ocú, *Diaz 13A* (GH, MO). LOS SANTOS: Río Tonosí, vicinity of Tonosí, *Lewis et al. 1575* (MO). PANAMÁ: area around Madden Dam, 50–80 m, *Huft 1775* (MO); near Tapia River, Juan Diaz region, *Maxon & Harvey 6750* (GH); roadside between Chepo and Río Bayano, *Porter 5170* (MO); Macapale Island in Madden Lake, *Tyson 5501* (MO); weedy roadsides within 1 mi. of Chepo, *Wilbur & Luteyn 11799* (GH, MO).

Moritzia DC. in Meisner, Pl. Vasc. Gen. 1: 280; 2: 188. 1840. TYPE: *Moritzia ciliata* (Cham.) DC. in Meisner, Pl. Vasc. Gen. 2: 188. 1840.

Erect perennial herbs. Basal leaves often forming a spreading, open rosette, the cauline leaves alternate and usually considerably smaller than the basal ones. Inflorescence terminal, ebracteate, a sparsely branched cyme of spikes or racemes. Flowers bisexual; calyx tubular to narrowly campanulate; corolla tubular with spreading lobes, 5-merous, the lobes ovate to deltate, the tube with protuberances or tufts of hairs in the mouth; stamens 5, on short filaments, the anthers oblong; inserted above the middle of the corolla tube; ovary 4-lobed, the style gynobasic, the stigma obscurely bilobed. Nutlets solitary by abortion, erect, smooth to muricate but lacking spines.

Moritzia is an essentially South American genus of five species, only one of which, *M. lindenii*, extends into Central America. It is closely related to *Thaumatocaryon* (Johnston, 1924, 1927), from which it differs in having all of the leaves alternate and in lacking protuberances in the mouth of the corolla tube.

Moritzia lindenii (A. DC.) Gürke ex Benth. in Engl. & Prantl, Nat. Pflanzenfam. 4(3): 121. 1894. *Meratia lindenii* A. DC. in DC., Prodr. 10: 104. 1846. TYPE: Venezuela. Distrito Federal: Caracas, *Linden 944* (not seen).

Erect perennial herb to 50 cm tall, the stems strigose. Basal leaves sessile or on broad petioles to 5 cm long, narrowly elliptic to lanceolate or oblanceolate, 8–16 cm long, 1–3.5 cm wide, the apex acute, the base attenuate, the margin entire, the adaxial surface strigose, the abaxial surface strigose, the cauline leaves sessile, lanceolate to lance-ovate, 2.5–7 cm long, 0.4–1.4 cm wide, the apex attenuate to acuminate, the base acute, the margin entire, strigose on both surfaces. Inflorescences terminal, cymose, 3–10 cm long, the branches strigose. Flowers bisexual; calyx cylindrical, the 5 lobes lanceolate, 1.5–2.2 mm long, strigose; corolla blue, tubular with spreading lobes, 5-merous, the lobes widely ovate to depressed ovate, 0.9–1.3 mm long, the tube 2–2.4 mm long, pubescent in the mouth, strigillose outside; stamens 5, the anthers ellipsoid, 0.6–1 mm long, sessile, inserted just below the mouth of the corolla tube; ovary 4-lobed, the style gynobasic, 0.9–1.1 mm long, the stigma capitate. Nutlet ovoid, 2–2.5 mm long, muricate.

Distribution. *Moritzia lindenii* ranges from Venezuela, Colombia, and Ecuador north to Panama and adjacent Costa Rica. It occurs above 3,000 m in elevation. In Panama, it is known only from the province of Bocas del Toro but may be in upland Chiriquí as well.

Moritzia lindenii has been collected only once in Panama, although several collections are known from adjacent areas of Costa Rica. It is expected at high elevations in the same general region as *Cynoglossum* and *Hackelia*, the other two blue-flowered, herbaceous Boraginaceae known from Panama. It differs from members of these genera by lacking spines on its nutlets, only one of which develops to maturity, in contrast with the glochidiate spines on the four nutlets of *Cynoglossum* and *Hackelia*.

Additional specimens examined. PANAMA. BOCAS DEL TORO: Cerro Fabrega and vicinity near Costa Rican frontier, south of summit, 3,150–3,335 m, *Weston 10162* (MO).

Tournefortia L., Sp. Pl. 140. 1753. TYPE: *Tournefortia hirsutissima* L., Sp. Pl. 140. 1753; I. M. Johnston, Contr. Gray Herb. 92: 66. 1930.

Small trees, shrubs, or woody vines. Leaves alternate or rarely opposite, petiolate or rarely sessile, entire. Inflorescence terminal or internodal, dense to lax, a sparsely to profusely branched cyme. Flowers bisexual; sepals 5, one often exceeding the others in length, persistent; corolla white to green or yellow-green, tubular, with 5 spreading lobes; stamens 5, the anthers usually sessile or nearly so, borne within the corolla tube; ovary ovoid to globose, 4-locular, the style terminal or absent, the stigma conical. Fruit drupaceous, often white at maturity, later drying and separating into 2 or 4 bony nutlets containing 1 or 2 seeds.

Tournefortia includes about 150 species and has representatives in most warm areas of the world, although most species occur in the Neotropics. *Mallatonia* (Griseb.) Britton, *Argusia* Amman, and *Messerschmidia* L. ex Hebenstreit have been treated as distinct by several authors, but Nowicke & Skvarla (1974) showed that pollen morphology does not support their continued separation. The three species that have been placed in these segregate genera differ from other members of *Tournefortia* in being strand plants with a pronounced corky exocarp and a similar sericeous indument.

Species of *Tournefortia* vary in habit. Most Panamanian species are lianas, sprawling shrubs, or sparsely branched erect shrubs, only a few becoming small trees. There often appears to be considerable variation in habit within a single species.

KEY TO THE SPECIES OF *TOURNEFORTIA* IN PANAMA

1a. Plants vining; fruits distinctly 4-lobed; the anthers apically connate (sect. *Cyphocyema* I. M. Johnston).
2a. Leaves densely white puberulent to tomentose below; corolla tube 2–2.3 mm long .... *T. volubilis*
2b. Leaves evenly short-strigillose below; corolla tube 3.3–5 mm long .... *T. maculata*
1b. Plants various in habit; fruit not deeply 4-lobed; the anthers free (sect. *Tournefortia*).
3a. Leaves opposite.
4a. Stems densely puberulent .... *T. ramonensis*
4b. Stems densely and unevenly pubescent to hirsute .... *T. johnstonii*
3b. Leaves alternate.
5a. Corolla tube 10–13 mm long .... *T. angustiflora*
5b. Corolla tube up to 10 mm long.
6a. Stems shaggy-villose, the hairs 3–4 mm long; sepals 5.5–7.5 mm long .... *T. cuspidata*
6b. Stems glabrous or with hairs less than 1.5 mm long; sepals less than 5 mm long.
7a. Corolla lobes 3–4.5 mm long.
8a. Corolla tube white with green stripes, 3.5–5 mm long; sepals 1.7–3.2 mm long; anthers bilobed, pendent in the mouth of the corolla tube .... *T. multiflora*
8b. Corolla green to yellow-green, the tube 7–10 mm long; sepals 3.5–5 mm long; anthers lanceolate, sessile and inserted below the mouth of the corolla tube .... *T. urceolata*
7b. Corolla lobes 1–3 mm long.
9a. Sepals up to 2 mm long.
10a. Corolla tube 5.5–6.5 mm long, the lobes 2.3–3 mm long; tertiary veins obscure .... *T. bicolor*
10b. Corolla 3.5–4 mm long, the lobes 1.5–2 mm long; tertiary veins evident .... *T. glabra*
9b. Sepals longer than 2 mm.
11a. Corolla tube 9–9.5 mm long; tertiary veins obscure .... *T. tacarcunensis*
11b. Corolla tube 3–6 mm long; tertiary veins evident.
12a. Sepals 4.3–4.5 mm long .... *T. brenesii*
12b. Sepals 2.5–4 mm long.
13a. Stems strigose to hirsute; leaves strigose; corolla lobes 1–1.6 mm long .... *T. hirsutissima*
13b. Stems glabrous or sparsely strigillose; leaves essentially glabrous; corolla lobes 2–2.5 mm long .... *T. longispica*

Tournefortia angustiflora Ruíz Lopez & Pavón, Fl. Peruv. 2: 25, pl. 151. 1799. TYPE: Peru. Huánuco: Chicoplaya and Pueblo Nuevo, *Hipólito Ruíz & José Pavón s.n.* (not seen).

Scandent shrub to 1 m tall, occasionally a liana or tree to 5 m tall, the twigs glabrous to puberulent. Leaves alternate; petioles 5–12(–16) mm long, sparsely strigillose to puberulent; blade lance-ovate to lanceolate, 6–

15(–17) cm long, 2–6(–8) cm wide, the apex acuminate to attenuate, the base acute to cuneate, the margin entire, the adaxial surface sparsely strigillose to nearly glabrous, the abaxial surface with short, appressed hairs along the veins. Inflorescence terminal or internodal, a sparsely branched cyme, the peduncle (1–)2–4(–8) cm long, strigillose or puberulent to nearly glabrous, the fertile branches recurved, 2–9(–14) cm long. Flowers sessile, borne 2–4 mm apart; sepals 5, triangular, 1.2–1.6 mm long, sparsely strigillose; corolla white, 5-merous, the lobes ovate, 2–2.6 mm long, the tube 10–13 mm long, strigillose outside, puberulent on the inner surface of the lobes; stamens 5, the anthers lanceoloid, 2.5–3 mm long, sessile, inserted in the lower half of the corolla tube; ovary globose, ca. 1 mm long, the style to 0.8 mm long or lacking, the stigma conical. Fruits white, ovoid, often slightly inequilateral, 3–5 mm long, glabrous.

Distribution. Tournefortia angustiflora is wide-ranging and common in wet forests from Mexico south through northwestern South America to Peru, from sea level to 600 m in elevation. It is known from most provinces in Panama and is probably in all of them.

Tournefortia angustiflora is distinctive within the genus in having narrow, tubular corollas more than 1 cm long and somewhat asymmetrical fruits. It is vegetatively similar to *T. bicolor*, but the two are quite different when fertile.

Additional specimens examined. PANAMA. BOCAS DEL TORO: Daytonia Farm, region of Almirante, *Cooper 166* (GH); 10–15 mi. inland from mouth of Changuinola River, *Lewis et al. 876* (GH, MO); Chiriquí Lagoon, Water Valley, *Wedel 1600, 1785* (GH, MO), *1802* (MO), *1832* (GH, MO); Chiriquí Lagoon, Old Bank Island, *Wedel 1880, 2004* (GH, MO); Chiriquí Lagoon, Isla Colón, *Wedel 2867, 2960* (GH, MO). COCLÉ: El Valle de Antón, 600 m, *Allen 2059* (GH, MO); summit of Cerro Pilón, above El Valle de Antón, 2,700 ft., *Dwyer et al. 4501* (MO); 46 km N from Penonomé on road to Coclesito, 100 ft., *Hammel 1695* (MO); hills NE of El Valle de Antón, 2,000 ft., *Lewis et al. 1799* (MO); Boca del Toabre at confluence of Río Toabre and Río Coclé del Norte, *Lewis et al. 5508* (MO). COLÓN: near Nuevo Tonosí 2 mi. from Portobelo on road to Nombre de Dios, 100 m, *Croat 33523* (MO); along Río Guanche about 1–2 km from Portobelo Highway toward Cerro Bruja, 0–50 m, *Huft & Knapp 1783* (MO); along dirt trail, 4 km NW of Salamanca, 13 km NE of Buenos Aires, 340–410 m, *Nee 9063* (MO). DARIÉN: Río Tuqueza below Quebrada Venado, *Bristan 1076* (GH); El Real, Quebrada Trapiche, *Duke & Bristan 315* (MO); vicinity of Santa Fe, *Duke 9496* (MO); Cocalito, *Dwyer 4465* (MO (2)). HERRERA: roadside between El Potrero and Las Minas, *Croat 9655* (MO); 12 mi. S of Ocú on Las Minas road, *Graham 235* (GH); Punta Mala, *Tyson 2714* (MO); 10 mi. S of Ocú, *Tyson et al. 2863* (MO). PANAMÁ: Panamerican Highway 22 km E of Bayano Bridge, near bridge over stream, less than 200 m, *Folsom 1396* (MO); Sabanas near Chepo, *Hunter & Allen 94* (MO); Alahajuela Chagres Valley, 30–100 m, *Pittier 2371* (GH). SAN BLAS: mainland opposite Ailigandi, from mouth of Ailigandi River to 2.5 mi. inland, *Lewis et al. 167* (MO).

Tournefortia bicolor Sw., Prodr. 40. 1788. TYPE: Jamaica (not seen).

Tournefortia laevigata Lam., Encycl. 1: 416. 1791. TYPE: Guadeloupe, *Badier s.n.* (not seen).

Tournefortia nitida Kunth in Humb., Bonpl. & Kunth, Nov. Gen. Sp. 3: 84. 1819. TYPE: Colombia. Bolívar: near Cartagena (not seen).

Tournefortia bicolor Sw. var. *calycosa* J. D. Smith, Bot. Gaz. (Crawfordsville) 14: 27. 1889. TYPE: Guatemala. Alta Verapaz: Pansamalá, 3,800 ft., *H. von Tuerckheim 980* (holotype, US 944708).

Woody vine, shrub, or small tree to 3(–7) m tall, the twigs glabrous or sparsely short-strigillose. Leaves alternate; petioles (0.8–)1–2 cm long, glabrous or very sparsely short-strigillose; leaf blade elliptic or ovate to narrowly elliptic or lance-ovate, (8–)11–14(–19) cm long, (3.5–)5–8 cm wide, the apex acuminate to acute, the base obtuse to rounded or less commonly acute, the margin entire, the adaxial and abaxial surfaces glabrous or with a few widely scattered, appressed hairs, the tertiary veins obscure. Inflorescence terminal, a dense cyme, the peduncle to 3 mm long, the branches glabrous to sparsely strigillose, the fertile branches 2–5 cm long. Flowers sessile, crowded, usually borne less than 2 mm apart; sepals 5, lanceolate, 1.5–2 mm long, sparsely to evenly strigillose; corolla white, sometimes with a greenish tint, 5-merous, the lobes ovate and often apiculate, 2.3–3 mm long, the tube 5.5–6.5 mm long, strigillose outside; stamens 5, the anthers lanceoloid, 1.3–2 mm long, sessile, inserted below the middle of the corolla tube; ovary globose, 0.4–0.6 mm long, the stigma sessile, conical. Fruits ovoid, white, 3–5 mm long, glabrous.

Distribution. *Tournefortia bicolor* is common in wet forest from sea level to 1,800 m throughout the Neotropics, ranging from Mexico through Central America and the West Indies to northern and western South America. In Panama, it is known from all provinces except Herrera.

Tournefortia bicolor is closely related to *T. hirsutissima* (Johnston, 1935) but has generally been considered to be distinct (Nowicke, 1969; Gibson, 1970). Nash & Moreno (1981), however, treated *T. bicolor* as a form of *T. hirsutissima.* Both species are widespread in the Neotropics, and although *T. bicolor* generally occurs in wetter habitats, the two can be found together at numerous localities such as along the shore of Barro Colorado Island (Croat, 1978). *Tournefortia bicolor* differs from *T. hirsutissima* in being essentially glabrous and in having sepals 1.5–2 mm long, a corolla 5.5–6.4 mm long, and corolla lobes 2.3–3 mm long; *T. hirsutissima* is generally pubescent, the sepals are 2.5–4 mm long, and the corollas are 3.5–5.3 mm long with lobes 1–1.6 mm long. Morphological and ecological data strongly support recognition of *T. bicolor.*

Additional specimens examined. PANAMA. BOCAS DEL TORO: Río San Pedro, *Gordon 78C* (MO); along runway at Bocas, *Lazor et al. 2347* (MO); Chiriquí Lagoon, Water Valley, *Wedel 986, 1838* (GH, MO); Chiriquí Lagoon, Old Bank Island, *Wedel 1952, 1992, 2090* (GH, MO); Chiriquí Lagoon, Fish Creek Hills, *Wedel 2427* (GH, MO); Chiriquí Lagoon, Cocoa Cay, *Wedel 2877* (GH, MO). VERAGUAS: along last major stream between Santa Fe and Escuela Agricola Alto Piedras, 420 m, *Croat & Folsom 33832* (MO); Río Santa María near bridge below Santa Fe, 300–400 m, *Knapp & Kress 4326* (MO); 2 mi. W of Santa Fe, 400–800 m, *Liesner 838* (GH, MO (2)).

Tournefortia brenesii Standley, Publ. Field Mus. Nat. Hist., Bot. Ser. 18: 989. 1938. TYPE: Costa Rica. Alajuela: El Silencio (Los Angeles) de San Ramón, Feb. 1933, *Brenes 17103* (holotype, F 859855).

Shrub to 3 m tall, the branches brown-strigose to pubescent, later glabrous. Leaves alternate but often densely clustered near the ends of branches; petioles 3–10(–27) mm long, glabrous to brown pubescent; leaf blades lanceolate, 9.5–17(–19) cm long, (2–)2.5–5.5(–6.3) cm wide, the apex acuminate to attenuate, the base acute, the margin entire to unevenly undulate or dentate, the adaxial surface glabrous, the abaxial surface glabrous except for scattered short appressed hairs along the secondary veins, the tertiary and quarternary veins clearly visible. Inflorescence terminal or subterminal, cymose, branching dichotomously 2–4 times, the peduncle to 11 cm long, brown puberulent to strigillose. Flowers on short pedicels to 5 mm long, borne (2–)4–10 mm apart; sepals 5, ovate to lanceolate, 4.3–4.5 mm long, ca. 1.7 mm wide, glabrous to sparsely strigillose; corolla white, tubular with spreading ovate to lanceolate lobes, these acute at the apex, 2.6–2.7 mm long, the tube 4.8–5 mm long, strigillose outside; stamens 5, the anthers oblong to lanceoloid, sessile or nearly so, inserted in the middle of the corolla tube; ovary globose, ca. 1 mm long, the disc crateriform, the style ca. 1 mm long, the stigma pyramidal. Fruit ovoid, 6–8 mm long, 5–6 mm wide, white at maturity, often capped by the persistent stigma.

Distribution. *Tournefortia brenesii* is restricted to cloud forests from 800–1,350 m in elevation in Panama and Costa Rica. In Panama it is known only from the province of Veraguas.

Tournefortia brenesii is distinct in its compact habit of growth, with the leaves clustered densely near the branch tips, and broad, accrescent sepals.

Additional specimens examined. PANAMA. VERAGUAS: vicinity of Escuela Agricultura Alto Piedra near Santa Fe, along trail to top of Cerro Tute, 3,500 ft., *Antonio 4957* (MO); Cerro Tute, ridge up from former Escuela Agricola, Santa Fe, 1,000–1,300 m, *Hamilton & Dressler 3080* (MO); ridge of Cordillera de Tute, trail to Cerro Tute, above Escuela Agricola Alto de Piedra, just W of Santa Fe, 800–1,350 m, *Knapp & Dressler 5403* (MO); Cerro Tute, ca. 10 mi. NW of Santa Fe, on ridgetop in cloud forest, above 1,000 m, *Mori 6760* (MO).

Tournefortia cuspidata Kunth in Humb., Bonpl. & Kunth, Nov. Gen. Sp. 3: 83.

1818. TYPE: Ecuador. Guayas: Guayaquil, *Humboldt & Bonpland s.n.* (holotype, P, not seen).

Tournefortia obscura A. DC. in DC., Prodr. 9: 517. 1845. TYPE: Guyana: *Schomburgk 571* (holotype, G-DC, not seen; microfiche, MO).

Scandent woody vine or sprawling shrub to 2 m tall, the twigs villose with hairs to 4 mm long. Leaves alternate; petioles 3–8 mm long, stout, shaggy-villose; blade lance-ovate, elliptic, ovate, or rarely obovate, 8–13(–19) cm long, 3–6(–9) cm wide, the apex acuminate, the base acute to obtuse, the margin entire, the adaxial surface strigose, the abaxial surface strigose to nearly villous, especially along the veins. Inflorescence terminal, a few- to much-branched, dense cyme, the sterile portions of branches shaggy villous. Flowers sessile, very closely spaced; sepals lanceolate, 5.5–7.5 mm long, strigose to hirsute; corolla white to green, 5-merous, the lobes ovate, 1–1.8 mm long, the tube 6.5–8 mm long, strigose to sericeous on the outside; stamens 5, the anthers lanceoloid, 1.3–1.5 mm long, sessile, inserted beneath the middle of the corolla tube; ovary globose to ovoid, ca. 1 mm long, the style 0.4–0.5 mm long, the stigma conical. Fruits ovoid, 3–4.5 mm long, white at maturity, breaking into (2–)4 nutlets at maturity, glabrous.

Distribution. *Tournefortia cuspidata* is common in disturbed areas of moist to wet forests at elevations below 400 m from Mexico to South America, and it occurs on Trinidad and Tobago. In Panama it is known from Bocas del Toro, Canal Area, Coclé, Colón, Darién, Panamá, and San Blas.

Tournefortia cuspidata is a distinctive species readily recognized by its shaggy, villous twigs with the hairs up to 4 mm long and sepals greater than 5 mm long. This is one of the most commonly collected species in southern Central America and northern South America. It is perhaps most closely related to *T. hirsutissima* but differs in its much longer hairs and sepals. Although the long hairs on the stems are usually diagnostic, these are greatly reduced in plants from adjacent Chocó, Colombia.

Additional specimens examined. PANAMA. BOCAS DEL TORO: along railroad tracks near station at Milla 5, *Croat & Porter 16493* (MO); Changuinola to 5 mi. S at junction of ríos Changuinola and Terebe, 100–200 ft., *Lewis et al. 951* (GH, MO); Almirante, near Dos Milla, *McDaniel 5138* (MO); Chiriquí Lagoon, Water Valley, *Wedel 770* (GH, MO), *1282* (MO), *1674* (GH, MO); Chiriquí Lagoon, Old Bank Island, *Wedel 1959* (GH, MO); Chiriquí Lagoon, Little Bocas, *Wedel 2510* (MO), *2559* (GH, MO); Chiriquí Lagoon, Isla Colón, *Wedel 2961* (GH). SAN BLAS: El Llano–Carti Road, 350 m, *de Nevers & Herrera 4222* (MO); trail from Puerto Obaldía to La Bonga, tributary of the Río Armila, ca. 2 hours walk from Puerto Obaldía, 0–50 m, *Knapp & Mallet 4679* (MO); along newly cut road from El Llano to Carti-Tupile, continental divide to 1 mi. from divide, 300–500 m, *Liesner 1297* (GH, MO).

Tournefortia glabra L., Sp. Pl. 141. 1753. TYPE: without locality or collector (holotype, LINN (Savage Catalog number 193.5), not seen; microfiche, MO).

Small tree or shrub to 5(–10) m tall, the twigs glabrous to sparsely strigillose. Leaves alternate; petioles 1–4(–5) cm long, sparsely strigillose to nearly glabrous; leaf blade narrowly elliptic to lance-obovate, (8–)12–18 (–25) cm long, (2.5–)5–8(–12) cm wide, the apex acuminate, the base attenuate and usually strongly decurrent, the margin entire, the adaxial surface sparsely strigillose to nearly glabrous, the abaxial surface with a few hairs scattered along the veins, the tertiary veins evident. Inflorescence internodal or terminal, a loosely branched cyme, the peduncle 3–8 (–14) cm long, sparsely strigillose to nearly glabrous, the branches 3–8(–10) cm long. Flowers sessile, borne (1–)2–3(–4) mm apart; sepals lanceolate, 1–1.2 mm long, sparsely strigillose; corolla white or greenish white, 5-merous, the lobes lanceolate, 1.5–2 mm long, the tube 3.5–4 mm long, strigillose outside; stamens 5, the anthers ellipsoid, 0.6–1 mm long, sessile or nearly so, inserted above the middle of the corolla tube; ovary ovoid, 0.7–1.5 mm long, the disc crateriform to scarcely evident, the style 1–1.2 mm long, the stigma capitate. Fruits white at maturity, very broadly ovoid, 3–4 mm long, glabrous.

Distribution. Tournefortia glabra occurs in diverse moist to wet habitats from sea level to 2,700 m in elevation. It is found from Mexico through Central and South America and in the West Indies. In Panama, it is known from Bocas del Toro, Chiriquí, Coclé, Colón, Panamá, San Blas, and Veraguas.

Tournefortia glabra is one of the few small understory trees in the genus found in Central America. This species is vegetatively quite similar to *T. acutiflora* Martens & Galeotti of northern Central America and southern Mexico, but differs in having calyx lobes shorter than 1.5 mm long.

Additional specimens examined. PANAMA. BOCAS DEL TORO: region of Almirante, Daytonia farm, *Cooper 376* (GH, MO); along road to Chiriquí Grande, 450 m, *McPherson 7391* (MO); Chiriquí Lagoon, Water Valley, *Wedel 1573, 1746* (GH, MO). COLÓN: ridge top leading N from Río Escandaloso towards Cerro Bruja, 600 ft., *Hammel 2708* (MO). DARIÉN: between Quebrada Venado and Peje swamp on the headwaters of Río Tuquesa, *Bristan 1006* (MO); Río Ucurganti, *Bristan 1139* (MO); trail SE of Manene to Río Cuasi, *Hartman 12197* (MO); premontane rainforest 0–2 mi. E of Tres Bocas along the shortest headwater of Río Cuasi, *Kirkbride & Duke 1144* (MO (2)); Río Tuquesa, at middle Tuquesa Mining Company camp called Charco Peje, 250 m, *Mori 7002, 7093* (MO); Paya, Río Paya, *Stern et al. 396* (GH, MO). PANAMÁ: Cerro Campana, 600 m, *Antonio 1730* (MO); trail up to Campana Ridge, *Correa & Dressler 377* (MO (2)); forest near dam site south of Canita, *Croat 14531* (MO); cloud forest on Cerro Campana near FSU building, *Croat 14809* (MO); Cerro Campana, 800 m, *D'Arcy 11141* (MO); Cerro Campana, 2,500 ft., *D'Arcy & Hamilton 14931* (MO); Río Bayano, near crossing of Pan-Am Highway, above confluence with Río Chepo, *Duke 3974* (MO (2)), *3998* (MO); Piria–Canasas Trail near Piria, 100 m, *Duke 14330* (MO); area around Torti Arriba, *Folsom 5129* (MO); near top of Cerro Campana, above FSU cabin, *Gentry 5770* (MO); 3.8 mi. E of Río Ipeti, S along river and into lower slopes of Serranía de Maje, 50–200 m, *Huft & Jacobs 2002* (MO); near Cerro Campana, on trail radiating from end of road which passes Campana water tank, *Kirkbride & Hayden 312* (MO); forest edges along Río Pirati, about ½ hour walk from Pan-American Highway, foothills of the Serranía de Maje, 50–100 m, *Knapp & Mallet 5167* (MO); Cerro Campana, trails just inside entrance to Parque Nacional, 850 m, *Miller & Miller 995* (MO); Parque Nacional Cerro Campana, 2 km N of highway 707, 850 m, *Stein & Hamilton 1140* (MO); base of Serranía de Canazas, ca. 15 km SW of Canaza near Río Torti, 150 m, *Stein 1387* (MO); steep slopes S of Canita, 200 m, *Webster et al. 16885* (MO); lower slopes and trail to Cerro Campana, *Witherspoon 8400* (MO). SAN BLAS: El Llano–Carti Road, km 16.7, trail W to Río Carti Grande, 250–350 m, *de Nevers & Herrera 4177* (MO); along the headwaters of Río Mulatupo, *Elias 1751* (MO). VERAGUAS: El Cuchillo, near Cerro Tute, up from Santa Fe, 1,300 m, *Hamilton et al. 1240* (MO).

Tournefortia hirsutissima L., Sp. Pl. 140. 1753. *Messerschmidtia hirsutissima* (L.) Roemer & Schultes, Syst. Veg. 4: 451. 1819. TYPE: without locality or collector (holotype, LINN (Savage Catalog number 193.1), not seen; microfiche, MO).

Tournefortia schomburgkii DC., Prodr. 9: 517. 1845. TYPE: Guyana: 1837, *Schomburgk 70* (holotype, G-DC, not seen; microfiche, MO; isotype, K).

Woody vine, sprawling shrub, or small tree, the twigs strigose to hirsute. Leaves alternate; petioles (3–)8–15(–20) mm long, strigose to hirsute; leaf blade lance-ovate to narrowly elliptic, (7–)11–18(–20) cm long, (2.5–)3.5–6(–8) cm wide, the apex acuminate to acute, the base acute to obtuse, the margin entire, the adaxial surface strigose, the abaxial surface strigose to pubescent, the tertiary veins evident. Inflorescence terminal or rarely internodal or axillary, a much-branched, dense cyme, the peduncle (1–)2–4(–5) cm long, strigose to hirsute, the fertile branches 1.5–4(–6) cm long. Flowers sessile, borne 1–2 (–3) mm apart; sepals lanceolate, 2.5–4 mm long, strigillose; corolla white, 5-merous, the lobes ovate, 1–1.6 mm long, the tube 3.5–5.3 mm long, strigillose outside; stamens 5, the anthers lanceoloid, 1.1–1.3 mm long, sessile, inserted beneath the middle of the corolla tube; ovary globose, 0.8–1 mm long, the disc scarcely evident, the stigma nearly sessile, capitate. Fruits white, ovoid, 3–4 mm long, strigillose.

Distribution. *Tournefortia hirsutissima* is found in diverse habitats from sea level to 2,000 m in elevation, and is ubiquitous throughout the Neotropics. In Panama, it is known from the Canal Area, Chiriquí, Darién, Panamá, and San Blas.

Tournefortia hirsutissima is one of the most commonly collected members of the genus and appears to be most closely related to *T. bicolor* (discussion under that species). The two can be distinguished most easily by the usually strigose upper leaf surface in *T. hirsutissima,* while it is glabrous or nearly so in *T. bicolor.* One collection from Darién (*Stern 501*) is unique in having a white abaxial leaf surface, but it otherwise fits well within *T. hirsutissima,* agreeing in all other aspects.

Additional specimens examined. PANAMA. CANAL AREA: forest reserve, near crossing of Cruces trail and Madden Dam road, *Bartlett & Lasser 16348* (GH, MO); Juan Mina, *Bartlett & Lasser 16529* (GH, MO); Barro Colorado Island, *Croat 4797, 6246, 10750A, 11718* (MO); roadside W of Gatún Locks, *Croat 12432* (MO); vicinity of Fort San Lorenzo, *Croat 12521* (MO); Barro Colorado Island, *Croat 15054* (MO); along road between Gatún Locks and Ft. Sherman, *Croat 15380* (MO); hill above Thatcher-Ferry Bridge, *Croat 17014* (MO); Fort Sherman, *Dwyer & Robyns 172* (MO); *Dwyer 6685* (MO); Madden Dam, Boy Scout Camp Road, *Dwyer & Elias 7513* (MO); Gatún Station, *Hayes 61* (GH); vicinity of Río Chagres Bridge, road leading to abandoned weather post, ca. 2 km by road SE of Gamboa along highway to Balboa, *Lasseigne 4271* (MO); west side of Ferry Thatcher Bridge, along mangrove margin, *Lazor 2881* (MO); Pipeline Road, *Meijer 160* (MO); Pipeline Road, 10–15 mi. from Gamboa, 100 m, *Miller 1027* (MO); along road from Fort Sherman to Fort San Lorenzo, *Porter et al. 4984* (MO); vicinity of Madden Dam, near Río Chagres, 50–75 m, *Seibert 560* (MO); Barro Colorado Island, *Shattuck 970* (MO (3)); *Starry 238* (MO); Fort Sherman near mouth of Chagres River, *Tyson 1535* (MO); Old Fort San Lorenzo, *Tyson 1571, 1572* (MO); *Tyson & Blum 3698* (GH, MO); Barro Colorado Island, *Wilson 44* (MO). CHIRIQUÍ: Llanos on slopes of Volcán de Chiriquí Viejo and along Río Chiriquí Viejo, 1,200 m, *Allen 968* (MO); Boquete, lumber road into the hills east of the Río Caldera, 4,500–6,500 ft., *Allen 4654* (GH, MO); Burica Peninsula, Quebrada Manzanillo, 9 km SSW of Puerto Armuelles, *Busey 746* (MO); 1 mi. W of airport at Puerto Armuelles, *Croat 21905* (MO); Puerto Limónes, along coast near the beach, *Croat 22119* (MO); Burica Peninsula, Distrito Guanabano, disturbed areas along Quebrada Quanabano, 0–100 m, *Croat 22534* (MO); San Bartolo Arriba W of Puerto Armuelles, *Croat 26700* (MO); Las Lagunas area W of Hato del Volcán, 1,400 m, *Hamilton & Stockwell 3562* (MO); Burica Peninsula, 2.5 km W of Puerto Armuelles, 80 m, *Liesner 16* (MO); Burica Peninsula, Quebrada Merica, 4 mi. S of Puerto Armuelles, 0–100 m, *Liesner 384* (MO); along road 3–5 mi. NW of El Hato del Volcán towards Costa Rica across the Río Chiriquí Viejo, 3,000–4,000 ft., *Luteyn 859* (MO); valley of the upper Río Gariche, 1,050–1,100 m, *Seibert 357* (GH, MO). COLÓN: 4 mi. W of Portobelo, near sea level, *Antonio 1764* (MO); Portobelo, *Billberg 269* (GH); Isla Grande, *D'Arcy 4033B* (MO); Portobelo, *Dwyer 5146* (GH); La Guayra, E of Portobelo, *Knapp & Mallet 5725* (MO). DARIÉN: headwaters of Río Chico, 500–750 ft., *Allen 4638* (GH); vicinity of Caña, 1,750 ft., *Stern et al. 501* (GH). SAN BLAS: through cultivation on mainland in front of Ustupo, *D'Arcy 9507* (MO).

Tournefortia johnstonii Standley, Publ. Field Mus. Nat. Hist., Bot. Ser. 18: 991. 1938. TYPE: Costa Rica. Heredia: Cerro de las Caricias, north of San Isidro, 2,000–2,400 m, *P. C. Standley & J. Valerio 52087* (holotype, US 1306982).

Shrub to 3 m tall, or rarely a small tree to 6 m tall, the twigs velutinous. Leaves opposite, the lateral buds usually with small expanding leaves with appearance of stipules; petioles 9–30(–40) mm long, velutinous; leaf blade lanceolate to ovate, (7.8–)10–18(–23) cm long, (3–)4–8(–10) cm wide, the apex acuminate, the base cuneate to acute, the margin entire to unevenly undulate, the adaxial surface velutinous, the abaxial surface velutinous, the secondary veins 10–12, the tertiary and quaternary veins clearly evident. Inflorescence terminal, a once- or rarely twice-branched cyme, the branches (2.5–)4–15 cm long, the peduncle (3–)5–12 cm long, velutinous. Flowers bisexual, sessile, borne 1–5 (–7) mm apart; sepals 5, lanceolate, 6–10.5 mm long, strigillose to strigose; corolla tubular with spreading lobes, white to green, 5-merous, the lobes lance-ovate to ovate, the apex acuminate, 2.6–5 mm long, the tube 8–10 mm long, strigillose, at least near the apex; stamens 5, the anthers lanceoloid, 1.5–2 mm long, sessile, inserted just below the mouth of the corolla tube; ovary ovoid, 0.8–1 mm long, the disc scarcely evident, the style 3–3.5 mm long, the stigma conical. Fruits white, ovoid, 4.5–7 mm long, separating into 2–4 nutlets at maturity.

Distribution. Tournefortia johnstonii occurs only in Panama and Costa Rica in cloud forests at elevations of 1,000–3,000 m. In Panama it is known only from the provinces of Chiriquí and Veraguas.

Tournefortia johnstonii is very similar in general aspect to *T. ramonensis* but differs in being a smaller plant with longer, coarser indument on the twigs. Also, the lower leaf surfaces of *T. johnstonii* are usually darker in color after drying.

Additional specimens examined. PANAMA. CHIRIQUÍ: Cerro Colorado, near continental divide, 1,500 m, *Antonio 1459* (MO); along road between Cerro Punta and Las Nubes, 1,800–2,100 m, *Croat 26391* (MO); Las Nubes, 2,000 m, *Croat 26456* (MO); E of Boquete along steep, forested slopes and in wooded pastures on Cerro Azul near Quebrada Jaramillo, 1,620–1,700 m, *Croat 26867* (MO); Alto Respinga and above, 2,800 m, *D'Arcy 9991* (MO); mountain directly S of Cerro Respinga, *D'Arcy 10811* (MO); E slope of Volcán de Chiriquí (Baru), above Boquete, along road in oak forest, 2,600 m, *Davidse & D'Arcy 10264* (MO); Volcán de Chiriquí, 9,000 ft., *Davidson 976* (GH, MO); along Boquete trail, Cerro Respinga, 2,000–2,500 m, *Gentry 5978, 6013* (MO); path above Cerro Punta to Boquete, 2,500 m, *Hamilton & Stockwell 3417* (MO); *Hamilton & Krager 3741* (MO); 7 km NW of Cerro Punta, 7,200 ft., *Hammel 1472* (MO); Cerro Hornito, 5,600 ft., *Hammel 3043* (MO); Quebrada Alemán, 8 mi. VERAGUAS: Cerro Tute, E slopes, 1 km beyond Escuela Agricola Alto Piedra above Santa Fe, 1,200–1,450 m, *Sytsma & Anderson 4593* (MO).

Tournefortia longispica James S. Miller, sp. nov. TYPE: Panama. Bocas del Toro: road from Fortuna Dam to Chiriquí Grande, 3.1 mi. N of continental divide, 700 m, disturbed primary forest, *G. McPherson 6778* (holotype, MO 3386969). Figure 6.

Suffrutex ad 2 m altus, ramulis glabris. Folia alterna; petioli (1.5–)2.5–4(–6.5) cm longi; lamina elliptica ad oblonga, (14–)17–25 cm longa, (5.5–)6.5–9(–10.5) cm lata, apice acuminata, basi acuta ad attenuata, glabra. Inflorescentia terminalis, cyma ramorum duorum, ad 30 cm longorum post anthesin composita, pedunculo 10–22 cm longo, glabro vel fere glabro. Flores sessiles, 1–5 mm distantibus; sepala lanceolata, 2.5–3 mm longa; corolla alba ad pallido-viridis, tubularis, lobis patulis, ovatis ad late ovatis, 2–2.5 mm longis, tubo extus strigilloso; antheris 1.5–2 mm longis, sessilibus, ad medium tubi insertis; stylus 0.6–1 mm longus, stigmate conoidi. Fructus globosi ad valde lato-ovoidei, 6–9 mm longi, 9–12 mm lati, glabri, laeves.

Shrub to 2 m tall, the twigs glabrous. Leaves alternate; the petioles (1.5–)2.5–4(–6.5) cm long, glabrous or nearly so; leaf blade elliptic to oblong, (14–)17–25 cm long, (5.5–)6.5–9(–10.5) cm wide, the apex acuminate, the base acute to attenuate, the margin entire, the adaxial surface glabrous, the abaxial surface glabrous but with very small appressed hairs along the major veins, the secondary veins 8–11, the tertiary veins evident, the quaternary veins often obscure. Inflorescence terminal or subterminal, usually a twice-branched cyme, the branches elongate, to 30 cm long at fruiting, the peduncle 10–22 cm long, glabrous to shortly brown puberulent or strigillose. Flowers sessile, bisexual, borne 1–5 mm apart; sepals 5, lanceolate, 2.5–3 mm long, sparsely to evenly strigillose; corolla tubular with spreading lobes, white to pale green, 5-merous, the lobes ovate to widely ovate, 2–2.5 mm long, the tube 4–5.5 mm long, strigillose outside; stamens 5, the anthers lanceoloid, 1.5–2 mm long, sessile, inserted in the middle of the corolla tube; ovary ovoid, 0.8–1 mm long, the disc crateriform or barely evident, the style 0.6–1 mm long, the stigma conical. Fruits white, globose to very broadly ovoid, 6–9 mm long, 9–12 mm broad, glabrous, smooth.

Distribution. Tournefortia longispica is known only from Panama from the provinces of Bocas del Toro, Chiriquí, Coclé, and Veraguas, where it occurs in cloud forests at elevations of 600–1,500 m.

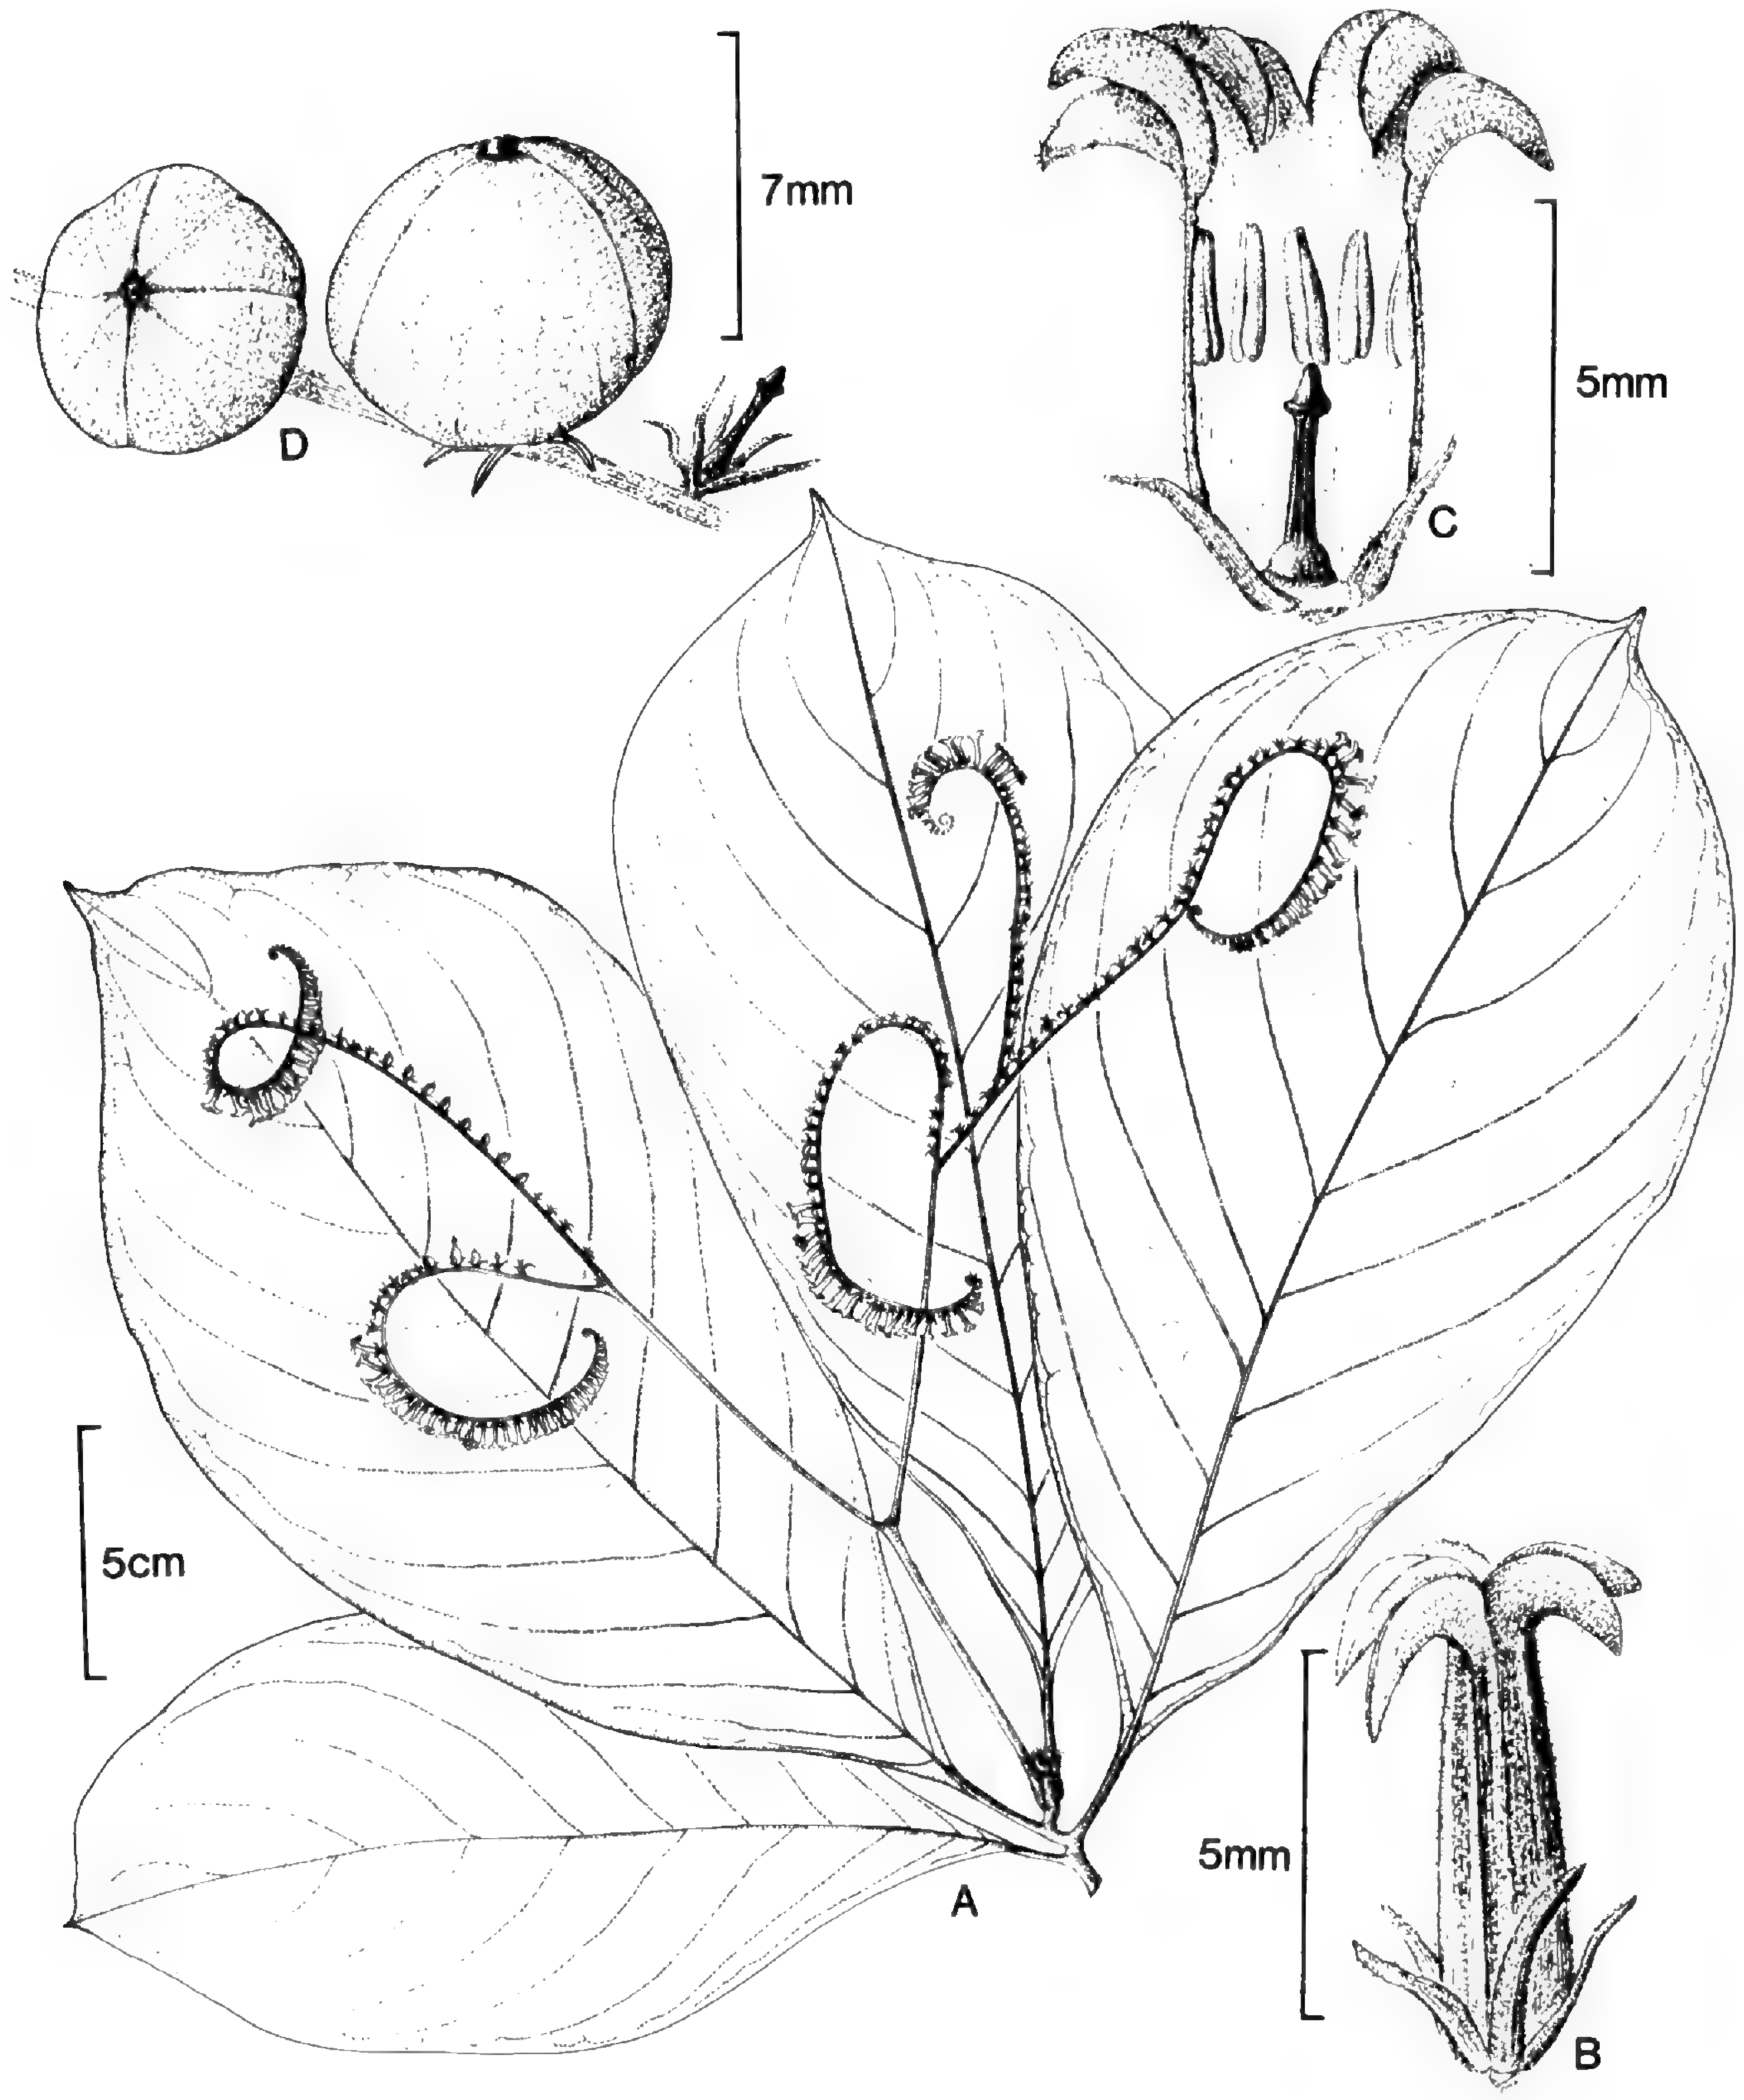

FIGURE 6. Tournefortia longispica.—*A. Flowering branch.—B. Flower.—C. Flower with corolla opened.—D. Fruits. A–C from* McPherson 6778 *(MO), Bocas del Toro, Panama; D from* McPherson 7247 *(MO), Bocas del Toro, Panama.*

Tournefortia longispica is distinct within the genus in having an elongate, dichotomously branched inflorescence and large, nearly glabrous leaves. It has no known close relatives in Panama but could be confused with *T. glabra*, which differs in having a much-branched inflorescence. Several of the collections have large, swollen fruits apparently parasitized by insects, a common condition in the genus.

Additional specimens examined. PANAMA. BOCAS DEL TORO: E slope of La Zorra to divide, *Kirkbride & Duke 824* (MO); in forest along trail down hill from Finca Serrano, 4,600 ft., *Hammel 6166* (MO); along trail on divide separating Chiriquí and Bocas del Toro, 1,150 m, *McPherson 7247* (MO). CHIRIQUÍ: Fortuna Dam area to N of reservoir near Quebrada Bonito, 1,100 m, *Churchill 5811* (MO); W side of Río Hornito, 1,100–1,300 m, *D'Arcy 16009* (MO). COCLÉ: El Copé on Pacific side ½ hour walk from sawmill, *Antonio 2109* (MO); Cerro Pilón, El Valle, 3,000 ft., *Duke & Lallathin 14962* (MO); Cerro Pilón, 2,900 ft., *Dwyer & Lallathin 8687* (MO); El Valle, *Folsom 2658* (MO); New Works at Rivera sawmill, Alto Calvario, 600–800 m, *Folsom 3164* (MO); Cerro Pilón, 900–1,173 m, *Liesner 786* (MO). VERAGUAS: Ridge of Cordillera de Tute, trail to Cerro Tute, above Escuela Agricola Alto de Piedra, just W of Santa Fe, 800–1,350 m, *Knapp & Dressler 5425* (MO).

Tournefortia maculata Jacq., Enum. Syst. Pl. 14. 1760; Select. Stirp. Amer. Hist. 47. 1763. TYPE: Colombia, Bolívar: Cartagena (not seen).

Woody climbing vine, the twigs sparsely strigillose, later glabrous. Leaves alternate; petioles (3–)5–12 mm long, sparsely short-strigillose; leaf blade (3–)5–9 cm long, (1.5–) 2.5–4 cm wide, the apex acuminate to attenuate, the base acute to obtuse and often slightly decurrent, the margin entire, the adaxial surface very sparsely short-strigillose, the abaxial surface evenly short-strigillose. Inflorescence usually terminal, a loose, much-branched cyme, the branches to 5 cm long, the peduncles 18–24 mm long, puberulent to strigillose. Flowers sessile, borne 1–10 mm apart, bisexual; sepals lanceolate to triangular, 0.8–2 mm long, strigillose; corolla pale yellow-green, 5-merous, the lobes filiform, 1.5–3 mm long, the tube 3.3–5 mm long, densely strigillose; stamens 5, the anthers lanceoloid, 0.8–1 mm long, connate apically, nearly sessile, inserted in the mouth of the corolla tube; ovary ovoid, 0.8–1 mm long, the disc crateriform to scarcely evident, the style 0.8–4 mm long, the stigma capitate. Fruits 4-lobed, 2.5–4 mm long, glabrous, white with black markings.

Distribution. *Tournefortia maculata* ranges from Mexico to South America and the West Indies and is found in a wide variety of habitats from sea level to 1,500 m in elevation. In Panama it is known from most provinces and probably occurs in all of them.

Tournefortia maculata is distinctive, with its four-lobed fruits and glabrous leaves. The only other Central American *Tournefortia* with four-lobed fruit is *T. volubilis*, which differs in having sericeous leaves. These two belong to sect. *Cyphocyema* I. M. Johnston, a complex group of species centered in South America and characterized by four-lobed fruits and apically connate anthers.

Additional specimens examined. PANAMA. CANAL AREA: Río Abajo, *Bartlett & Lasser 16398* (GH, MO); low woods E of Bella Vista, a suburb of Panama City, *Maxon & Valentine 6942* (GH); Fort San Lorenzo, Fort Sherman Military Reservation, *Maxon & Valentine 7011* (GH); vicinity of Salamanca Hydrographic Station, Río Pequeni, 80 m, *Woodson et al. 1630* (GH, MO). CHIRIQUÍ: Boquete, 4,000 ft., *Davidson 853* (MO); Bajo Mona, mouth of Quebrada Chiquara, along Río Caldera, 1,500–2,000 m, *Woodson 1007* (GH). SAN BLAS: to Udirbi, El Llano–Carti Road, 200–350 m, *D'Arcy et al. 16037* (MO). VERAGUAS: along road between Santa Fe and Escuela Agricola Alto Piedra, 600–800 m, *Croat 26007* (GH, MO); Río de Jesus, *Dwyer 339* (MO); Isla de Coiba (Penal Colony), *Dwyer 2330* (MO); 5 mi. E of Santiago, *Tyson et al. 4284* (MO).

Tournefortia multiflora James S. Miller, sp. nov. TYPE: Panama. Veraguas: NW of Santa Fe, 8.8 km from Escuela Agricola Alto de Piedra, on road to Calovebora, elev. 1,900 ft., *S. Mori 6659* (holotype, MO 3386967). Figure 7.

Frutex vel arbor parva ad 5 m alta, ramulis glabris. Folia alterna sed saepe prope apices caulis conferta, paene sessilia vel in petiolis ad 2(–7) cm longis, suffultis; lamina elliptica, 16–50 cm longa, 8–18 cm lata, apice obtuso ad rotundato et saepe abrupta brevi-acuminato, base attenuata quasi glabra. Inflorescentia terminalis, paniculata,

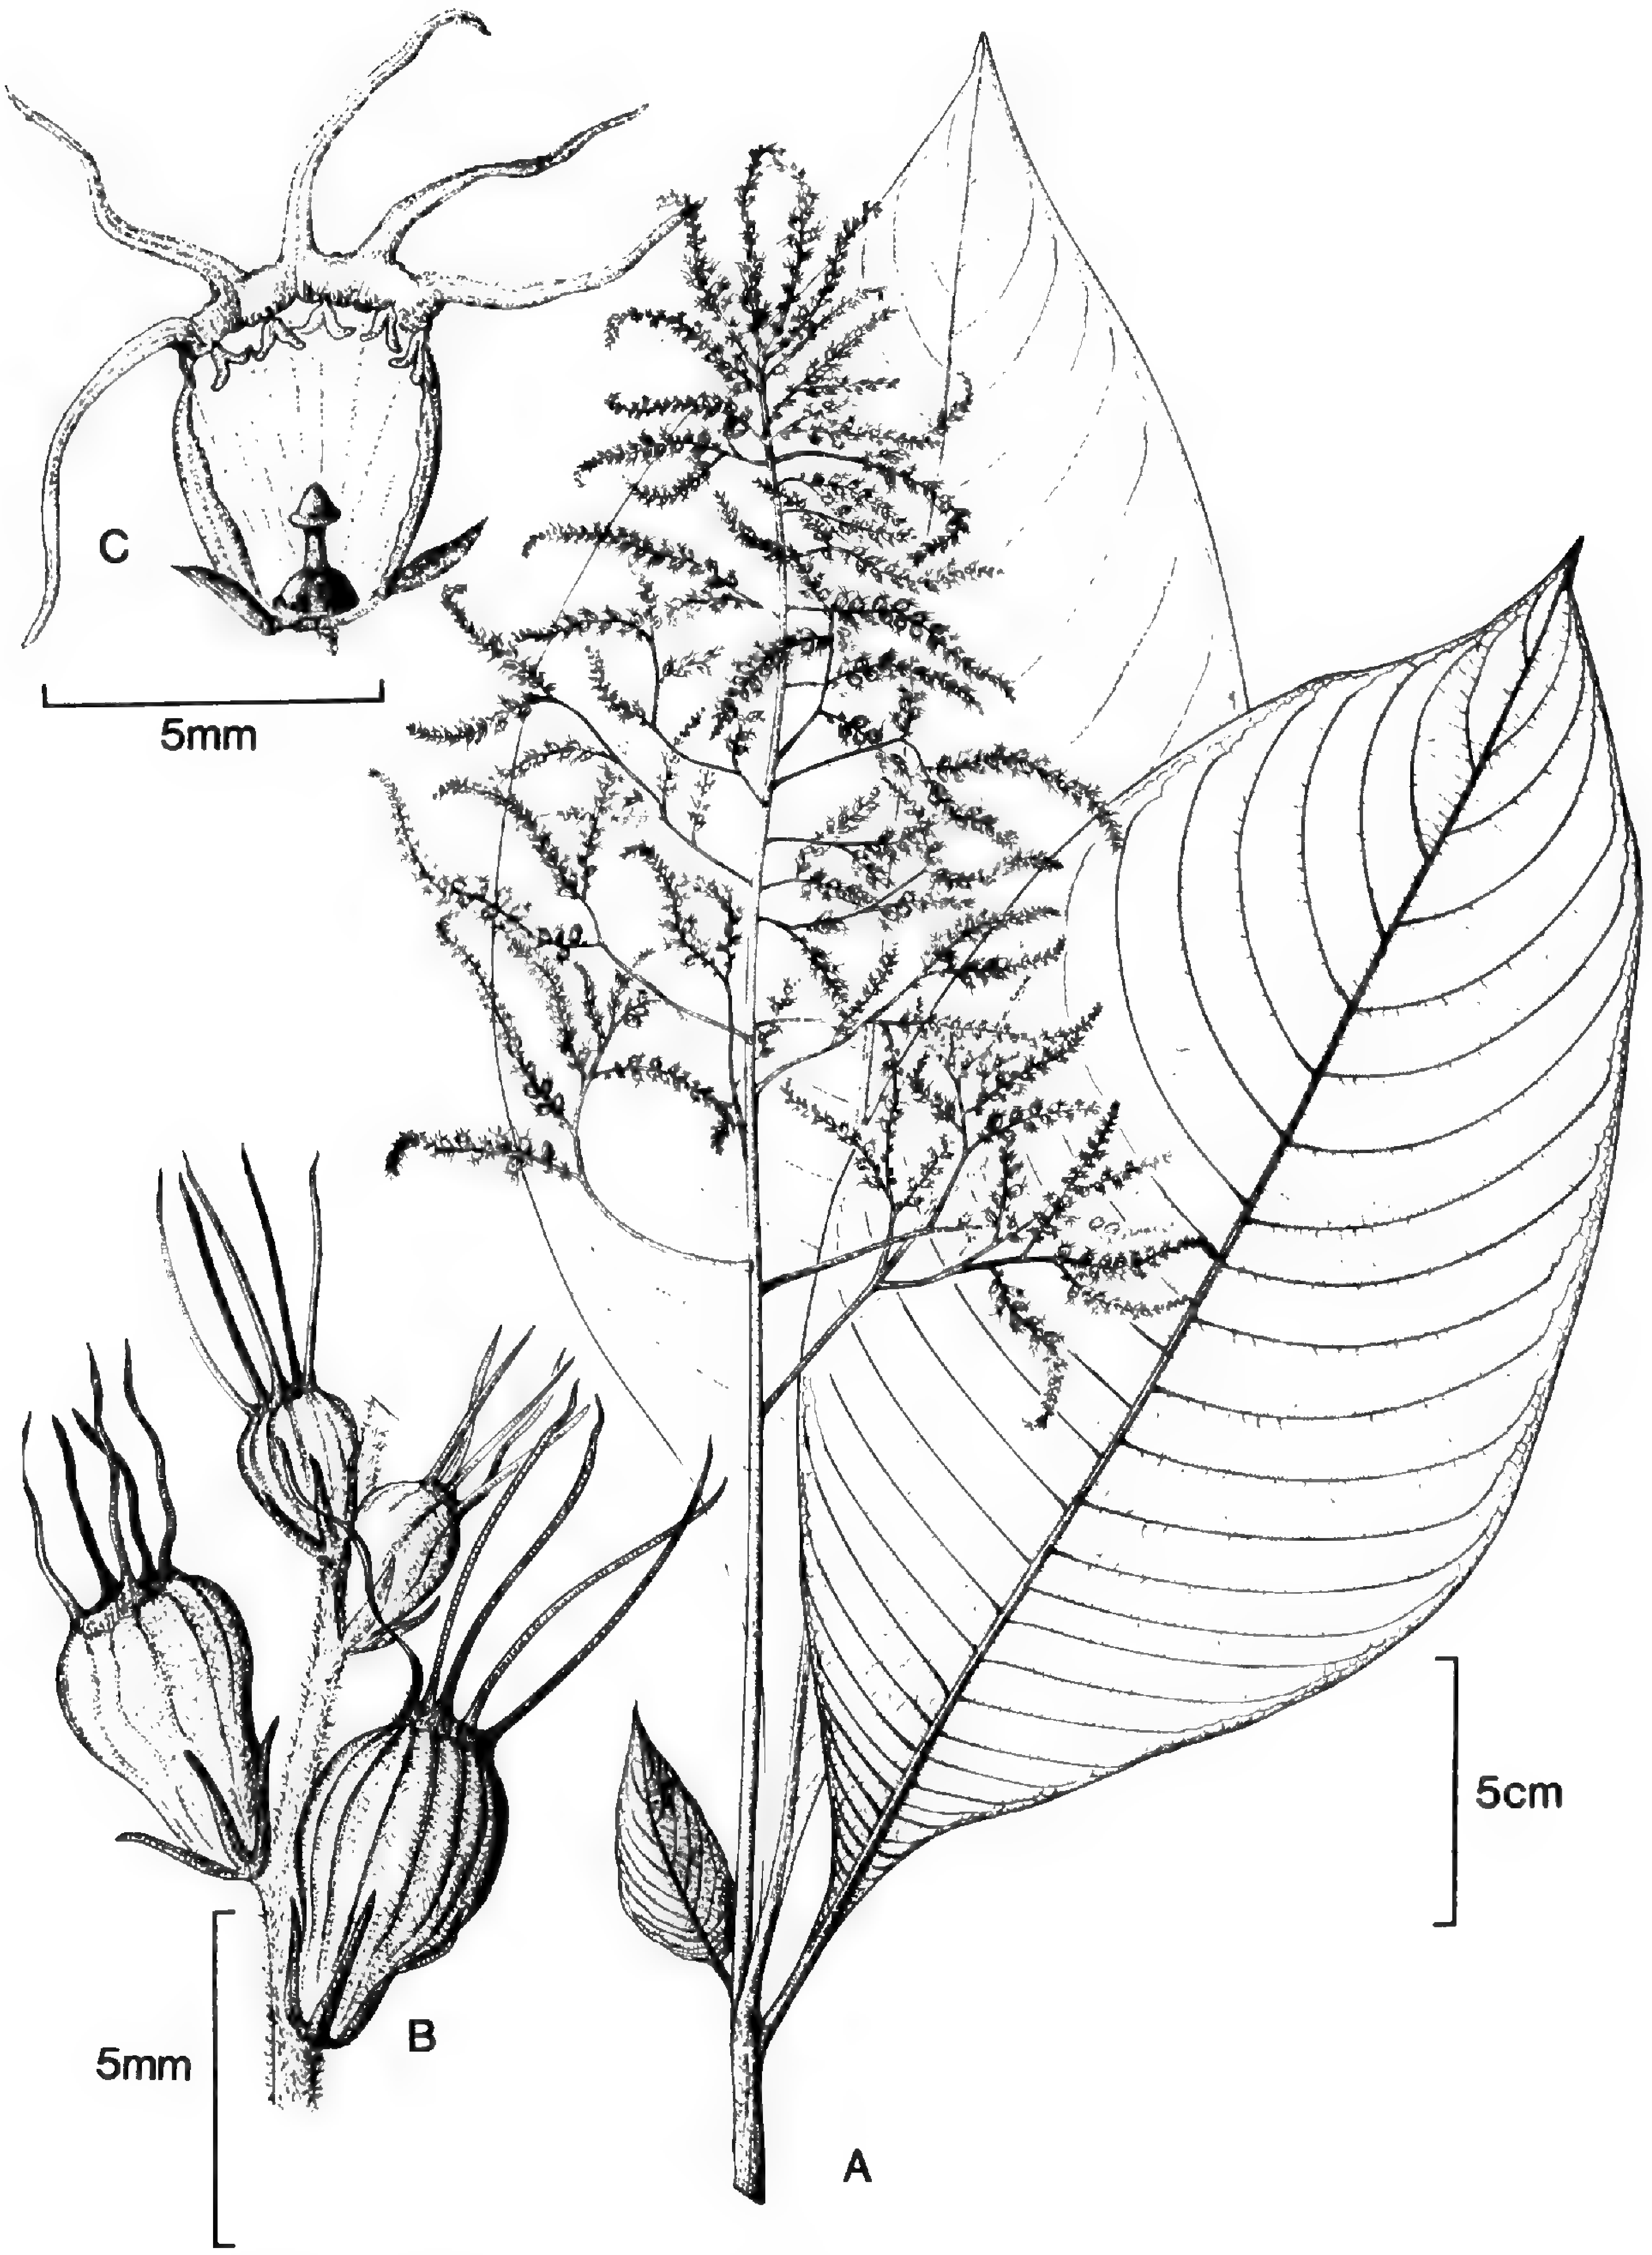

FIGURE 7. Tournefortia multiflora.—*A. Flowering branch.—B. Flowers.—C. Flower with corolla opened showing pendent anthers. From* Mori 6659 *(MO), Veraguas, Panama.*

20–40 cm longa, 16–30 cm lata, pedunculo 10–19 cm longo, fusco-puberulo. Flores sessiles, seorsum 2–5 mm dispositi; sepala 5, lanceolata, 1.7–3.2 mm longa; corolla viridi-alba, striis atroviridibus ornata, urceolata lobis patulis, pentameris, lobis linearibus, 3–4.5 mm longis, tubo 3.5–5 mm longo, extus puberulo; stamina 5, antheris conspicua bilobatis et in ore corollae tube pendentibus, 0.5–0.8 mm longis; stylus 0.5–1.6 mm longus, stigmate conoidi, puberulo. Fructus albi, ovoidei, 4.5–5.5 mm longi, 3–4 mm lati, glabro.

Shrub or small tree to 5 m tall, the twigs glabrous. Leaves alternate but often crowded near the stem apices, nearly sessile or on petioles to 2(–7) cm long; blade elliptic, 16–

50 cm long, 8–18 cm wide, the apex obtuse to rounded and often abruptly short-acuminate, the base attenuate, the margin entire, the adaxial surface essentially glabrous with widely scattered, short, appressed hairs, the abaxial surface glabrous, strigillose along the midrib and the 15–22 arcuate secondary veins, the tertiary and quaternary veins clearly evident. Inflorescence terminal, paniculate, 20–40 cm long, 16–30 cm broad, the peduncle 10–19 cm long, the peduncle and branches brown-puberulent. Flowers sessile, borne 2–5 mm apart; sepals lanceolate, 1.7–3.2 mm long, puberulent or strigillose to glabrous; corolla urceolate with spreading lobes, greenish white with darker green stripes, the lobes linear, 3–4.5 mm long, the tube 3.5–5 mm long, puberulent outside; stamens 5, the anthers distinctly bilobed and pendent in the mouth of the corolla tube, 0.5–0.8 mm long; ovary globose, 0.5–0.9 mm long, the disc crateriform, the style 0.5–1.6 mm long, the stigma conical, puberulent. Fruits ovoid, white, 4.5–5.5 mm long, 3–4 mm broad, glabrous.

Distribution. *Tournefortia multiflora* is known only from Panama, where it occurs in wet forest in the provinces of Veraguas and Colón from 400–900 m in elevation.

Tournefortia multiflora is distinctive with its large leaves to 50 cm long and unique in the genus in its large, many-flowered inflorescence, unusual striped flowers with linear corolla lobes, pendent anthers, and puberulent stigma. Despite these distinctions, it does have a gynoecium with a conical stigma and the two-lobed fruits that characterize the genus. It also has pollen grains that are similar to the majority of other species of *Tournefortia* (Nowicke & Miller, unpubl.). Johnston (1954) noted that pollen morphology seems to be a valuable generic character in the Boraginaceae, and, although unique in some characters, *T. multiflora* clearly falls within the morphological and palynological boundaries of the genus.

Additional specimens examined. PANAMA. COLÓN: Santa Rita Ridge trail, beyond end of Santa Rita Ridge Road (Panamanian Highway (R20D)), 17–35 km from Boyd–Roosevelt Highway, 400–800 m, *Mori & Crosby 6413* (MO). VERAGUAS: along Río Primero Braso, *Croat 25976* (MO); N of Santa Fe, 6.5 km from Escuela Agricola Alto de Piedra, *Mori & Kallunki 3067* (MO).

Tournefortia ramonensis Standley, Publ. Field Mus. Nat. Hist., Bot. Ser. 18: 992. 1938. TYPE: Costa Rica. Alajuela: Los Angeles de San Ramón, Apr. 1928, *Brenes 6118* (holotype, F 851176; isotype, NY).

Shrub to 3 m tall, the twigs densely puberulent. Leaves opposite; petioles 13–28 mm long, densely puberulent; leaf blades widely ovate to lance-ovate, 8.9–15 cm long, 3.5–9 cm wide, the apex acuminate, the base acute and decurrent, the margin entire to unevenly dentate, the adaxial surface sparsely strigillose, the abaxial surface sparsely pubescent, lighter in color than above, the tertiary and quaternary veins clearly visible. Inflorescence terminal or axillary, a once- or twice-branched cyme, the branches 3–7.5 mm long, the peduncle 6–9 cm long, brown puberulent. Flowers sessile, borne 2–4 mm apart, bisexual; sepals lanceolate, ca. 6 mm long, strigillose; corolla tubular with spreading lobes, greenish white, the lobes ovate, 2 mm long, the tube 9.5 mm long, puberulent outside; ovary ovoid, 1 mm long, the disc crateriform, the style 4 mm long, the stigma pyramidal. Fruits broadly ovoid, white, 4–5 mm long, 3–4.5 mm broad, glabrous, the style often persisting.

Distribution. *Tournefortia ramonensis* is known only from high elevations in cloud forests in Costa Rica and the provinces of Bocas del Toro and Chiriquí in Panama.

Tournefortia ramonensis is distinctive in being one of only two Panamanian members of the genus with opposite leaves. The other, *T. johnstonii*, is a low shrub rather than a tree and has coarse velutinous twigs compared with the puberulent twigs of *T. ramonensis*.

Additional specimens examined. PANAMA. BOCAS DEL TORO: Robalo Trail, northern slopes of Cerro Horqueta, 6,000–7,000 ft., *Allen 4919* (GH, MO). CHIRIQUÍ: vicinity of Bajo Chorro, 1,900 m, *Woodson & Schery 609* (GH (2), MO).

Tournefortia tacarcunensis A. Gentry & Nowicke, Ann. Missouri Bot. Gard. 64: 134. 1977. TYPE: Panama. Darién: Cerro Tacarcuna, west ridge, trail from summit camp to waterfall east of camp, 1,550–1,700 m, *A. H. Gentry & S. Mori 14114* (holotype, MO 2280271).

Low subshrub to 0.5 m tall, the twigs glabrous or nearly so. Leaves alternate; petioles 2–3 mm long, glabrous or nearly so; leaf blade elliptic to elliptic-ovate, 8.3–23 cm long, 3.2–8 cm wide, the apex acuminate, the base cuneate, the margin entire to unevenly undulate, the adaxial surface glabrous, the abaxial surface glabrous, much lighter than above, tertiary and quaternary veins obscure. Inflorescence terminal, a once- or twice-branched dichotomous cyme, the peduncle 2–6 cm long, brown-strigillose. Flowers borne 2–3 mm apart, bisexual; sepals lanceolate, 3.5–4.5 mm long, sparsely brown-puberulent; corolla tubular, white or greenish white, the lobes spreading, very widely ovate, rounded at the apex, 2–2.2 mm long, the tube 9–9.5 mm long; stamens 5, the anthers ovoid to lanceoloid, 1.3–1.5 mm long, sessile, inserted just below the mouth of the corolla tube; ovary globose to ovoid, 1–1.7 mm long, the disc scarcely evident, the style 6–7 mm long, the stigma conical. Fruits broadly ovoid, white, 4–6 mm long, 4–5.5 mm broad, glabrous.

Distribution. *Tournefortia tacarcunensis* is known only from Darién in Panama and Valle in Colombia in cloud forests of the Serranía del Darién above 1,500 m in elevation.

Tournefortia tacarcunensis is poorly understood, being known from only the type and a collection from adjacent Colombia, both from Cerro Tacarcuna. While it appears to be endemic in this region, this is one of the most poorly known areas of both Panama and Colombia.

Tournefortia urceolata James S. Miller, sp. nov. TYPE: Panama. Bocas del Toro: along continental divide from road branching N off main Fortuna–Chiriquí Grande Highway near continental divide, 1.1 mi. from main highway, ca. 1,200 m, *T. B. Croat & M. H. Grayum 60301* (holotype, MO 3386968). Figure 8.

Frutex ad 2 m altus, ramulis glabris vel fere glabris. Folia alterna, petiolis 8–32 mm longis; lamina lanceolata vel angusto-elliptica ad elliptica, (10.7–)13.5–31(–38) cm longa, (3.2–)4–14(–17.5) cm lata, apice acuminata, basi attenuata, glabris vel fere glabra. Inflorescentia terminalis, pyramidalis cymis parvis praedita, 13–28 cm longa, pedunculo (5–)9–21 cm longo. Flores sessiles vel in pedunculis brevibus ad 1 mm longis, seorsum 1–3 mm dispositis; sepala lanceolata, 3.5–5 mm longa; corolla viridis ad viridi-flava, tubularis ad urceolata lobis patulis, lanceolatis, 3–4 mm longis; antheris 1–2 mm longis, sessilibus, infra faucem fere ad medium corollae tubi insertis; stylus 1.7–2.5 mm longus, stigmate spinulo ad puberulo. Fructus late ovoidei, albi, 4–6 mm longi, 4–6 mm lati, glabri.

Shrub to 2 m tall, the twigs glabrous to brown puberulent. Leaves alternate; petioles 8–32 mm long, glabrous to brown-puberulent, the blade lanceolate or narrowly elliptic to elliptic, (10.7–)13.5–31(–38) cm long, (3.2–)4–14(–17.5) cm wide, the apex acuminate, the base attenuate, the margin entire, the adaxial surface glabrous, the abaxial surface essentially glabrous, strigillose along the major veins and papillose between them, the secondary veins 9–15, the tertiary and quaternary veins clearly evident. Inflorescence terminal, pyramidal, a panicle of small cymes, 13–28 cm long, the peduncle (5–)9–21 cm long, brown strigillose to puberulent. Flowers sessile or on short petioles to 1 mm long, borne 1–3 mm apart; sepals 5, lanceolate, 3.5–5 mm long, sparsely to evenly strigillose; corolla green to greenish yellow, tubular to urceolate with spreading lobes, 5-merous, the lobes lanceolate, 3–4 mm long, the tube 7–10 mm long, strigillose outside; stamens 5, the anthers lanceoloid, 1–2 mm long, sessile, inserted from just below the mouth to just above the middle of the corolla tube; ovary ovoid, 0.5–0.8 mm long, the disc scarcely evident to crateriform, the style 1.7–2.5 mm long, the stigma conical, spinulose to puberulent. Fruits broadly ovoid, white, 4–6 mm long, 4–6 mm broad, glabrous.

Distribution. *Tournefortia urceolata* is

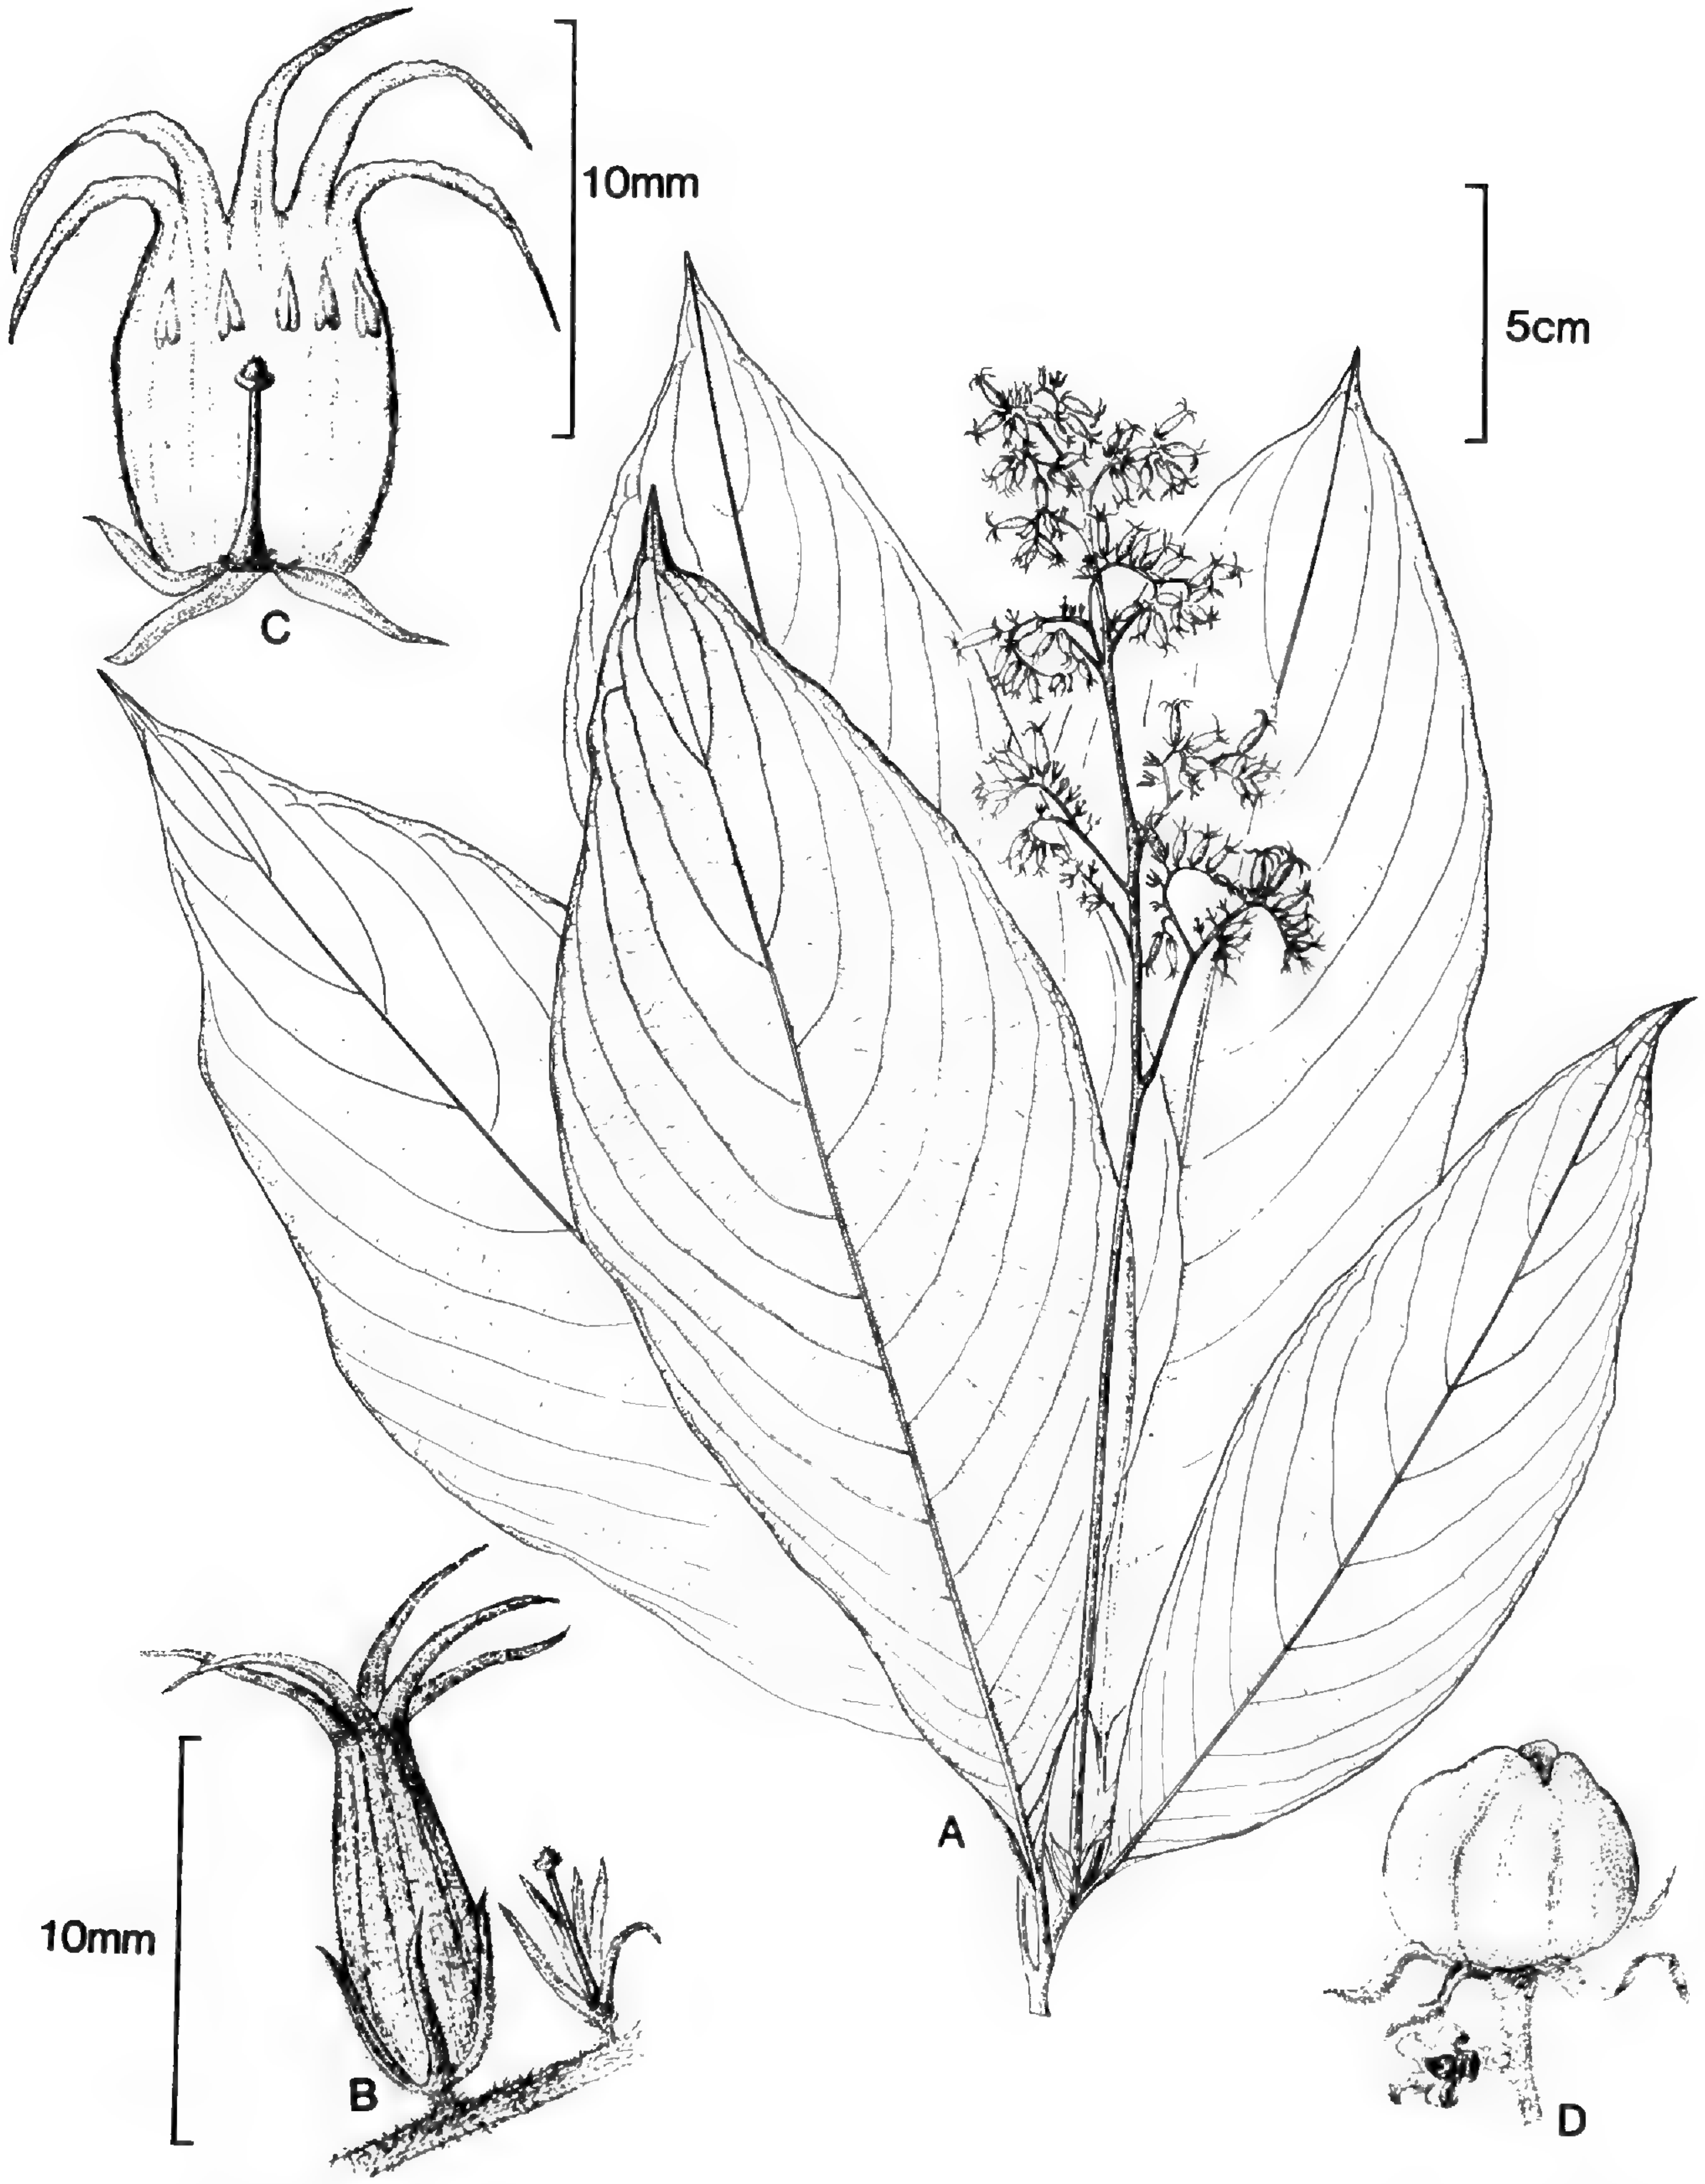

FIGURE 8. Tournefortia urceolata.—*A. Flowering branch.—B. Flower.—C. Flower with corolla opened.—D. Fruit. A–C from* Croat & Grayum 60301 *(MO), Bocas del Toro, Panama; D from* Croat 37301 *(MO)*.

known only from Panamá in Chiriquí, Colón, and San Blas, where it occurs in cloud forests at elevations of 400–2,300 m.

Tournefortia urceolata is distinct in its large glabrous leaves with relatively obscure venation and urceolate corollas. Vegetatively it somewhat resembles *T. glabra* but can be distinguished by its less prominent tertiary veins, sepals longer than 3 mm, and corolla longer than 7 mm.

Additional specimens examined. PANAMA. CHIRIQUÍ: Fortuna Dam area, on Kaolin hill, just N of reservoir, 1,100–1,400 m, *D'Arcy et al. 15919* (MO); forested slopes below divide ridge near Cerro Pate Macho, 6,200 ft., *Hammel 5817* (MO); Palo Alto, 4.5 mi. NE of Boquete, forest along western branch of headwaters of Río Palo Alto, 6,300 ft., *Hammel 7414* (MO); S slopes of Cerro Pate Macho, along Río Palo Alto, 1,300–1,800 m, *Knapp et al. 2077* (MO); ca. 0.5 km E of Cerro Pate Macho, headwaters of Río Palo Alto, 1,800–2,100 m, *Knapp et al. 2121* (MO); SE slopes and summit of Cerro Pate Macho, trail from Río Palo Alto, 4 km NE of Boquete, 1,700–2,100 m, *Sytsma et al. 4845* (MO). COLÓN: on Santa Rita Ridge Road, 17–35 km from Boyd-Roosevelt Highway, 400–800 m, *Mori & Crosby 6413* (MO). SAN BLAS: Cerro Brewster, headwaters of Río Cangandí, 2,300 ft., *De Nevers et al. 5500* (MO).

Tournefortia volubilis L., Sp. Pl. 140. 1753. TYPE: without locality or collector (holotype, LINN (Savage Catalog number 193.3), not seen; microfiche, MO).

Tournefortia floribunda Kunth in Humb., Bonpl. & Kunth, Nov. Gen. Sp. 3: 79. 1818. TYPE: Venezuela. Sucre: prope Cumaná (holotype, B-WILLD, not seen; microfiche, MO).

Tournefortia velutina Kunth in Humb., Bonpl. & Kunth, Nov. Gen. Sp. 3: 79, t. 201. 1818. TYPE: Mexico. Guerrero: Acapulco, *collector unknown 3863* (holotype, P, not seen; microfiche, MO).

Tournefortia potosina Standley, Contr. U. S. Natl. Herb. 23: 1230. 1924. TYPE: Mexico, San Luis Potosí: Tamasopo Canyon, 750 m, *C. G. Pringle 3518* (holotype, US 316801; isotype, CAS).

Woody vine or occasionally a small shrub, the twigs densely puberulent. Leaves alternate; petioles 4–8(–12) mm long, densely puberulent; leaf blade lanceolate to lance-ovate, (2.7–)5–7(–10.4) cm long, (1–)2–3.5(–5) cm wide, the apex acuminate, the base obtuse to rounded, the margin entire, the adaxial surface strigillose, the abaxial surface densely puberulent to nearly tomentose. Inflorescence terminal or internodal, a loosely branched cyme, the peduncle 3–16 mm long, the fertile branches 3–5(–10) cm long. Flowers sessile, borne 1–5 mm apart; sepals linear-lanceolate, 1.2–1.8 mm long, densely strigillose; corolla dull yellow or white to pale green, the lobes linear-lanceolate, ca. 1.5 mm long, the tube 2–2.3 mm long, densely strigillose outside; stamens 5, the anthers ovoid, 0.5–0.7 mm long, connate apically, sessile, inserted near mouth of corolla tube; ovary ovoid, 0.6–0.8 mm long, the stigma conical, exceeding the calyx lobes, elongate. Fruits distinctly 4-lobed, 2–3 mm long, glabrous, white with dark brown to black spots at the apex.

Distribution. *Tournefortia volubilis* is widely distributed in dry, disturbed areas from sea level to 600 m in elevation from Mexico throughout Central America to Panama, and is found in the West Indies. In Panama it is known only from the provinces of Los Santos and Panamá.

Tournefortia volubilis is a member of the complex sect. *Cyphocyema* I. M. Johnston, a group centered in South America. It differs from the only other Central American species of the section, *T. maculata,* in having pubescent leaves (discussion under *T. maculata*).

Additional specimens examined. PANAMA. LOS SANTOS: Monagre Beach, *Dwyer 4182* (MO (2)). PANAMÁ: Coronado Beach, 6 mi. E of San Carlos, *Croat 14261* (MO); near Playa Río Mar, 10–100 ft., *Duke 11761* (MO).

THE GENUS *XYRIS* (XYRIDACEAE) IN VENEZUELA AND CONTIGUOUS NORTHERN SOUTH AMERICA[1]

Robert Kral[2]

ABSTRACT

This work is a taxonomic treatment of those species of Xyris *(Xyridaceae) now known to occur in Venezuela and contiguous northern South America, including parts of Brazilian Amazonia. A general discussion of the morphology of* Xyris *is given, particularly as to the construction of the inflorescence and flower. Problems with the previously accepted sections of* Xyris *are stated; it appears that the major distinguishing feature for these sections (placentation type) breaks down when Guayanan material is studied. The taxonomy is done for 87 species (14 newly described), including 4 subspecies (one newly described) and 7 varieties. Synonymy and full descriptions are presented, along with diagnostic keys. Nearly all taxa are illustrated with full plates.*

The first comprehensive treatment of *Xyris* of the Guayana Highland was authored by Dr. Bassett Maguire of the New York Botanical Garden and Dr. Lyman B. Smith of the Smithsonian Institution (Botany of the Guyana Highland V, *Memoirs of the New York Botanical Garden* 10: 8–72. 1963). That excellent work has provided a basis for this supplemental study, which includes new information on species already described and descriptions of several new *Xyris*. Also, the coverage is extended to include Andean species from western Venezuela and Colombia as well as those from the Guayanas to the east and the contiguous territories of Brazil. Useful sourceworks for this have been: J. M. Idrobo, "Xyridaceas de Colombia," *Caldasia* VI(29): 185–245. 1954; J. Lanjouw, Xyridaceae *in Flora of Suriname* I(1): 225–244. 1966; L. B. Smith & R. J. Downs, Xyridaceae *in Flora Brasilica* IX(11): 1–211 + index. 1968; L. B. Smith & R. J. Downs, "Las especies Peruanas de la Familia Xyridaceae," *Publicaciones del Museo de Historia Natural "Javier Prado," Serie B. Botanica* (15)1–13, + figs. 1963.

As was stated by Maguire & Smith (l.c.), Brazilia, to the south of the Amazon, and Guayana, to the north, comprise the two largest centers for *Xyris* in the world; each major area has large numbers of endemics, with new ones being discovered on any major expedition into these regions. The authors continue:

> It is suggested that *Xyris* in South America, with its present bicentric distribution, may have occupied at one time an essentially identical and continuous area, and that in subsequent history, by the intervention of the Amazon Basin, the original area became divided, and that since then a parallel evolution has proceeded without appreciable interchange.

---

[1] *Many hundreds of specimens have been examined in the preparation of the work and I acknowledge the assistance of curators and staffs of F, GH, K, L, MO, NY, P, U, and US who kindly made loans and facilities available. I could not have done the work were it not for Dr. Lyman B. Smith, who provided me the opportunity to undertake the project in the first place, who reviewed descriptions of most of the new species, and who is therefore coauthor of them; Dr. Otto Huber, ecologist and authority on the botany of tropical American savanna, who has provided specimens for study, who led me to a grand, albeit short, trip into the Yapacana savannas, and who has provided friendly criticisms along the way; and Dr. Julian A. Steyermark, whose experience with and knowledge of Venezuelan botany is unsurpassed, and who has made specimens and information available. To all of the above I am deeply grateful. Special thanks are due to Dr. George Rogers, Editor, and to Ms. Janice Wilson, Editorial Assistant, for their patient, thorough, and tactful processing of my work. Their constructive editing has much enhanced the study, and is therefore very gratefully acknowledged.*

ANN. MISSOURI BOT. GARD. 75: 522–722. 1988.

My observations in no way conflict with the above. I can only add that, since the addition of the monotypic *Aratitiyopea* by Steyermark (*Ann. Missouri Bot. Gard.* 71: 298–300. 1984), there are now five genera known for the Xyridaceae, all occurring in, if not solely confined to, the Venezuelan Guayana, with the greatest diversity being in the high sandstone tepuis of the region. *Xyris* is by far the largest of the five. At the rate new species are now being found it will probably well exceed 300 species worldwide. Prior workers have organized these into three subgenera, namely *Pomatoxyris* Endl. with ca. 20 species, Australian, distinguished by axile placentation; *Xyris* (*Euxyris* Endl.) with ca. 100 species, pantropic and North American, distinguished by marginal or parietal placentation; and *Nematopus* Seub., with probably more than 200 species, mainly South American and distinguished by basal or free-central placentation. In dissecting ovularies of Guayanan xyrids preparatory to describing them, I discovered that many of these species, placed by prior workers in *Nematopus*, actually have axile placentation or are transitional from axile, this evidenced by the presence of complete or partial septa in the ovary and fruit. Out of slightly more than 80 taxa studied, 33 show evidence of some septation; some show completely axile placentation.

I suggest that sectionalization of *Xyris* based on mode of placentation perhaps does not reflect the real situation and that there appear to be no other solid characters by which to place species within sections or subgenera consistently. Certainly the sections are arbitrary. Alternatives would be to put the more than 30 Guayanan species with partial or complete septation into *Pomatoxyris*, a perhaps more realistic alternative, even though it eliminates the geographic integrity of that section. Another would be to dispense with *Pomatoxyris*, since subgenus *Xyris*, even as represented in the southeastern United States, may show transition from axile to parietal placentation (*X. elliottii* Chapman, *X. baldwiniana* Schultes, *X. brevifolia* Michaux); therefore, the limits of section *Xyris* could be amplified to accommodate the situation. A third alternative, namely to eliminate the sections altogether, would in my view be best, in that mode of placentation has been nearly the entire basis.

In any event, it would appear that in regard to a phylogeny the Guayana Highland show the greatest diversity in xyrids, with placentation in all genera except *Xyris* wholly axile. It seems that distichous-leaved xyrids with axile placentation have evolved from polystichous-leaved ancestors with axile placentation, at least if Abolbodaceae are to be considered as part of Xyridaceae, a generally accepted classification based on the sound anatomical analyses of Carlquist and others. That being so, *Xyris* may have had its origin in the Guayana Highland.

No further introduction is needed here save to relate what appears to be the basic morphology in *Xyris*.

Species of *Xyris* are mostly high hydroperiod, rosulate plants of acid boggy sites, their alternate, equitant, distichous, lineal leaves approximate and arising from contracted or elongated stems or from scaly rhizomes; some rise from bulbous axillary offshoots; the roots are simple and fibrous (Fig. I).

Leaves are highly variable in structure but are similar to those of *Iris*. The leaf base is open-sheathing, the sheath edges broad and thin, often scarious or hyaline, and entire or variously ciliate; the sheath base is frequently abruptly orbicular-dilated, this most obvious in species with bulbous bases. Above the clasping sheath base, the sides narrow abruptly or gradually to the blade, there converging and merging with it as the ventral margins close. At this point there may be a simple transition to the inner margin of the blade (most species), or the transition may be abrupt, with a ligule of various proportion being produced (Fig. IIb, c). Often in ligulate species the inner edge of the leaf blade may show a strong sulcus or groove for some distance above this junction (Fig. IIc). The leaf blade then shows a convergence of leaf sheath edges to form either a set of ventral edges (as in sulcate-bladed

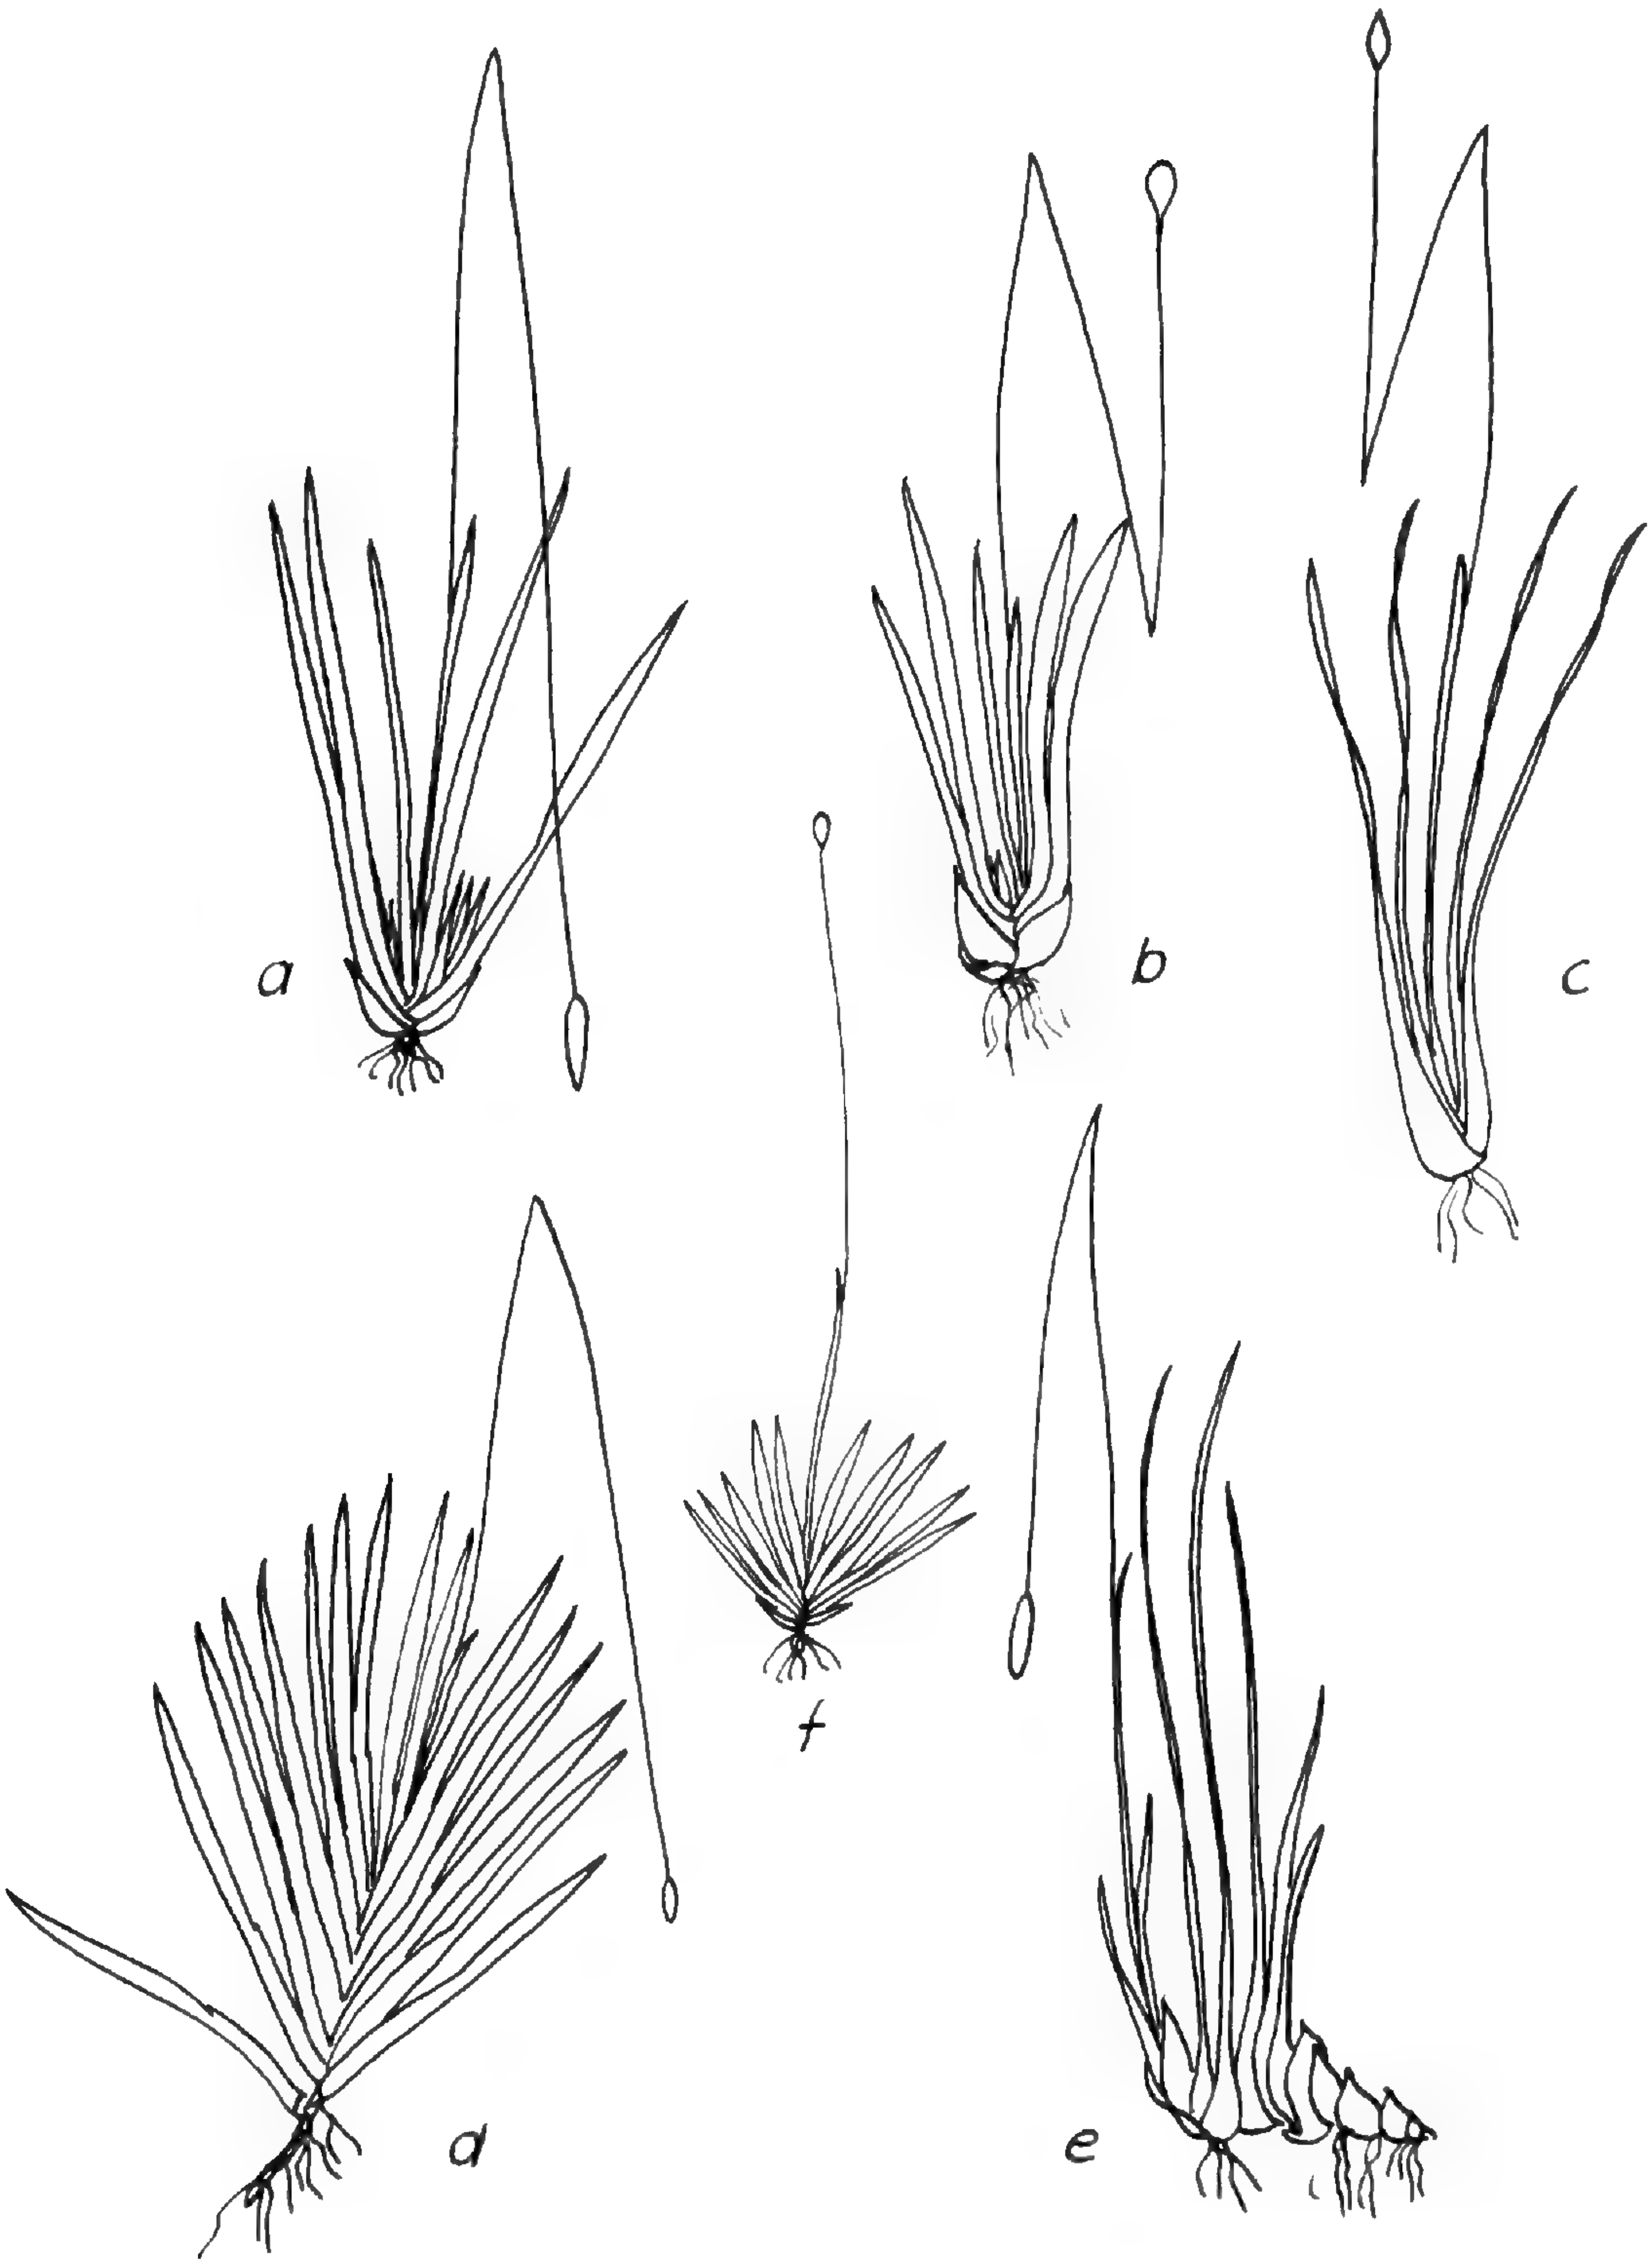

FIGURE I. *Sketches of some common habits in* Xyris.—*a. Base soft, leaves flattened, sheaths keeled.*—*b. Base bulbous, sheaths fleshy-based, blades curvate, flattened.*—*c. Base elongate-bulbous, sheaths firm, blades flexuous and twisted.*—*d. Plant caulescent and rhizomatous, leafy shoots frondlike.*—*e. Plant stout-rhizomatous.*—*f. Annual, leaves spreading flabellately; scape sheaths longer than principal leaves.*

species), or the ventral edges have joined into a single, compound-traced, ventral edge (Fig. IIa). Much *Xyris* taxonomy centers around the characters of the leaf sheath and blade, which tend to be more consistent than most, outside of flower and fruit features. For example, *Xyris* leaf blades may be terete or angulate or flattened; their tips may be extremely varied, with everything from emarginate to conic-subulate, even setiform; their edges and borders are incrassate to thin and variously pubescent or totally smooth; the

ventral sulcus.—d. Sector of leaf blade, this subterete and bicostate.—e. Thin, involute, multicostate blade.—f. Sector of flattened, ciliate leaf blade.—g. Sector of flattened, scabrid leaf blade.—h. Sector of flattened leaf blade with incrassate edges.—i. Sector of terete leaf blade.—j. Acute, incrassate-edged leaf apex.—k. Acute, ciliate leaf apex.—l. Acuminate, incrassate-edged, incurved leaf apex.—m. Acuminate, spinulose-tipped leaf apex.—n. Asymmetrically spinulose-tipped, acute leaf apex.—o. Trigonous-acute leaf apex.—p. Leaf apex narrowly and bluntly conic, trichomiferous.—q. Ovoid spike with spirally imbricate bracts (commonest type with little bract gradation); scape subterete, bicostate.—r. Broadly ovoid spike, sterile bracts involucrate, scape ancipital.—s. Spike biflorous, decussate, scape flattened, incrassate-bordered, twisted.—t. Spike biflorous, decussate, lowest bracts exceeding spike, incurvate.—u. Spike ellipsoid, bracts decussate, 5-ranked, little graded.—v. Spike ovoid, bracts spirally imbricate, lowest pair of bracts distinctly longer than the fertile bracts.—w. Spike obovoid, sterile bracts many, grading gradually into the fertile bracts.

surfaces are variously pigmented, smooth to variously rugose, with raised or sunken or flush stomates, or even quite pubescent (Fig. IId–p). Most of such external characters have long been noted in the literature, particularly by G. O. A. Malme, A. Nilsson, M. Seubert, and others in the late 19th and early 20th centuries.

Xyris plants have scapes arising in axillary fashion enfolded in closed-based, distally open and bladed scape sheaths. The scapes are also quite diverse, usually terete and solid basally and variously multicostate. Distally they vary the most, from terete and ecostate to multicostate, variously flattened, even ancipital; they range from smooth to variously scabrid or ciliate, particularly on the costae (Fig. IIq–w).

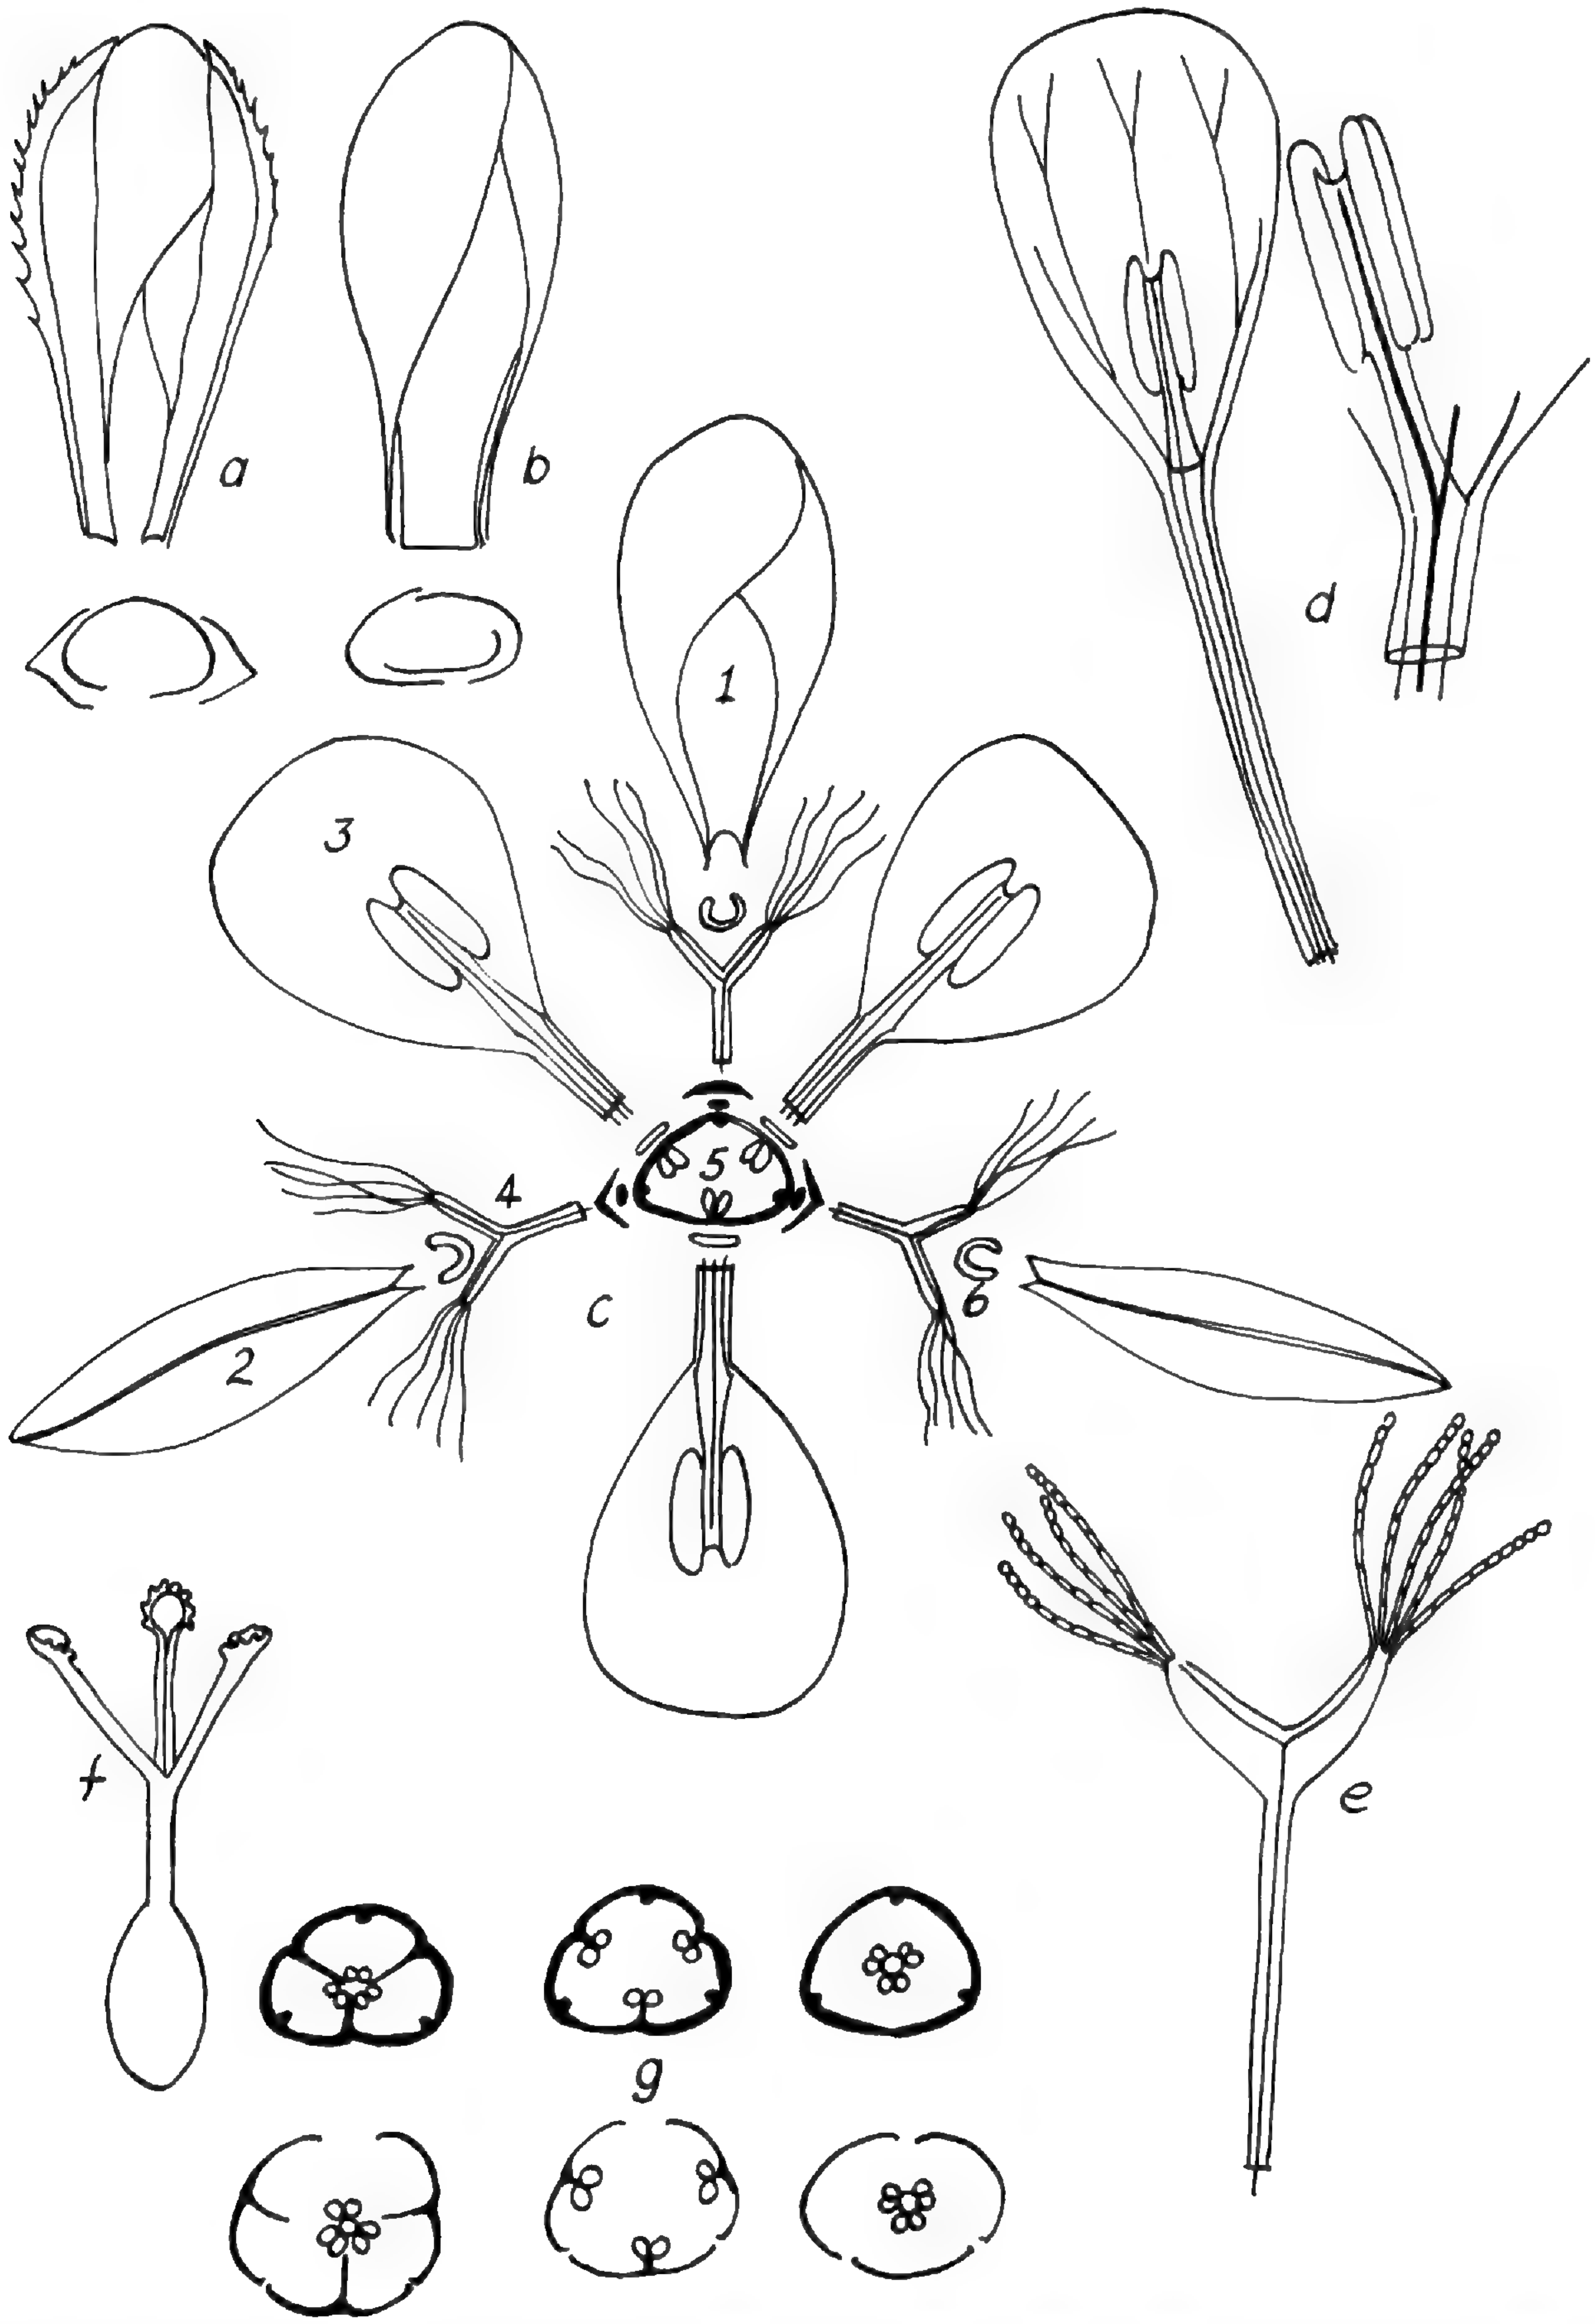
Usually the scape terminates in a single spike (most exceptions being either the Guayanan *X. bicephala* Gleason or anomalous examples). The spike is mostly conelike with either spirally or decussately imbricate bracts. Subsections have been developed on the character of the bracts. One direction of evolution has been toward species with the lower bracts elongate, even leaflike (*X. cipoensis, X. hystrix, X. involucrata, X. uleana*, etc.) with the fertile bracts much shorter and abruptly reduced. Another is toward sterile bracts few at the spike base, somewhat larger than the fertile bracts and transitional to them. A third trend has been for sterile bracts to be many, the lowermost very small, gradually passing into the larger fertile ones. The commonest condition is for there to be a few sterile bracts somewhat smaller than the spirally imbricate fertile ones. Significant also is a bract zone that may run the length of the midbract or be variously apical, the dorsal area. Doubtlessly homologous to the leaf blade in *Xyris*, this is frequently photosynthetic and is mostly distinctly different from the usually chaffy bract matrix. As mentioned above, some bracts in *Xyris* are elongated and may have blades, and when this is so, such are mostly extensions of dorsal area tissue, or at least of midrib tissue (Fig. IVa–h). Bracts on yet other species may lack a dorsal area, and a few species may be versatile in this character. Some examples of *X. tenella* Kunth have bracts with and others without dorsal areas on the same plant, or may have them on the sterile bracts but lack them on the fertile ones. Backs of bracts also vary considerably, from rounded-convex and ecostate (carinate) to strongly folded, navicular, or costate, while the usually thin edges vary from strongly bordered and variously ciliate, lacerate, or fimbriate to entire.

In the axils of the fertile bracts the flowers are solitary, the axis of the indeterminate inflorescence being contracted and headlike or conelike, or quite elongate (as in *X. stenostachya* Steyerm., the most extreme). These flowers are conspicuous at anthesis, usually but a few hours for a single bloom, a given spike producing usually only one or two flowers simultaneously (in the species with contracted spikes several flowers may be open at once, e.g., *X. involucrata* Nees).

A dissection of the flower bud just prior to its expansion is the best approach to understanding the *Xyris* flower (Fig. IIIa–f). The usual *Xyris* bud is narrowly obovoid and planoconvex. There are three sepals. The lateral sepals are boatlike, their keels directed outward, their concave sides clasping the edges of the compressed corolla bud as well as the edges of the inner (dorsal) sepal, which forms a cap over the corolla with its two edges overlapping on the ventral side. The lateral sepals (Fig. IVl, m) are the bonanza for xyridologists in that they vary little from biotype to biotype in a species. In most cases they are free; in fewer instances they are connate;

→

FIGURE III. *Flower and fruit structure.—a. Ventral and cross-sectional view of sepals in bud, lateral sepals enfolding inner (dorsal) thin sepal.—b. Ventral and cross-sectional view of petals in bud, lateral petals enfolding ventral petal.—c. "Exploded"* Xyris *flower. 1. disarticulated dorsal sepal; 2. lateral sepals; 3. petal blades (claws foreshortened) with adnate stamens; 4. staminodia, claws foreshortened, showing flattened, bifurcate*



blades and terminal tufts of trichomes; 5. cross section of flower toward base as parts are oriented in bud, placentation parietal; 6. stylar apex, showing horseshoelike stigma pattern at about level of staminode tip.—d. At left petal blade, claw, adnate stamen (note 3 traces in claw); at right an upper sector of petal claw, oblique view showing branching of median claw trace: one branch into filament base, the other forward into mid-base of petal blade.—e. Staminode showing yokelike blade, bifurcated trace, and moniliform staminodial beard hairs.—f. Gynoecium, showing style base, tubular style branches, and stigmas.—g. Placentation types. Left rank: above—axile placentation in ovary; below—cross section of dehiscing fruit showing septa pulling away from axis. Middle rank: above—parietal placentation in ovary; below—cross section of dehiscing fruit. Right rank: above—central placentation in ovary; below—cross section of dehiscing fruit, valves lacking septa.

very infrequently they may be free toward a spike base, increasingly connate toward that spike apex (e.g., the *X. thysanolepis* complex). The sides of a lateral sepal are mostly very thin; in some cases they are equal or approximately so, and the sepal is equilateral; in fewer instances they are inequilateral (Fig. IVi, j). In all cases the sepal has a midrib (costa or carinal keel) that usually conforms with the angle of the sepal fold; in some cases this keel is thick and firm, made up of many strands of cells oriented longitudinally and breaking outward. The crest of such keels may range from entire to variously scabrid or ciliate (Fig. IVl). In other cases the keel may be produced into a sheet of cells one layer thick, its border made up of simple or compound strands of cells, these forming a lacerate or fimbriate outline (Fig. IVm). The best stage for seeing these characters comes after mature fruit has just formed and the sepals are hardened to produce a typical border.

At anthesis the outer (dorsal) sepal abscisses, falling away calyptralike as the corolla expands (Fig. IIIa). In the bud, the anterior (inner) petal is enfolded by the right (observing the bud from the adaxial side) edge of the left lateral petal and is enfolded by the left edge of the other lateral petal, the right edge of which overlaps the right side of the ventral (inner) petal (Fig. IIIb). All petals are roughly equal in size and usually separate to the base. Each has a long claw and a broad, usually yellow (in Africa there are blue-flowered species) spreading blade, this of a distinctive outline and apical border. There are three functional stamens adnate along the length of the claw. What appear to be three traces run the length of the claw, but the median trace is compound, branching at the blade base, the adaxial branch departing into the divergent filament base and going up into the anther connective (Fig. IIId), the dorsal branch supplying the middle of the petal blade.

Xyris anthers are mostly tetrasporangiate and bilocular, variously separated by a flattened connective, usually bifid distally, and sagittate proximally; their dehiscence is longitudinal, either lateral or extrorse. Alternating with the petal claws and slightly inside them is a whorl of three staminodes in most *Xyris* flowers (in a few these are reduced to nubs of tissue at the floral base or are totally absent, e.g., *X. savanensis* Miq.). The staminode is usually made up of an elongate slender claw about as long as the petal claw, and a yokelike flattened blade wherein the single trace bifurcates, tailing out toward the spreading staminodial branch tip, where there are usually borders of slender, moniliform hairs. The character of the cells making up the beard hairs deserves more attention than it has gotten heretofore and may well be reliable to determine complexes of species (Fig. IIIc-4, e). The ovary is superior, the style tubular, branching midway into three subequal branches whose involute edges are pollen receptive distally. Placentation varies; in most *Nematopus* it is either plainly basal with a brush of long funiculi or free-central with shorter, ascending funiculi. In other *Xyris* the placentation is plainly parietal or appears marginal. But in a significant number of Guayanan species it may be axile and the ovary distinctly trilocular, or it may be axile toward the base and parietal upward in the ovary, or the septa may pull away so that the axis is left with the ovules (Fig. IIIg).

The fruit is usually thin-valved, though there are some definite exceptions in which the walls are hard. Dehiscence is loculicidal along the dorsal side of the carpel.

The seeds may be few or very numerous, diverse in shape and size, 0.3–5 mm long. The outer integument is usually raised into a variously longitudinally ribbed, sometimes also cross-lined surface which is specific in character; distally it may form an empty ribbed beak or it may separate into a crown of narrow scales (e.g., *X. teinosperma* Idrobo & Smith). The contents of the seed are a starchy and proteinaceous, translucent or farinose endosperm and a small basal–lateral embryo.

The type for the genus is *Xyris indica* L. This was based by Linnaeus on an east Indian element and a North American element. J. E. Smith (*Rees' Cycl.* 39. 1818) designated

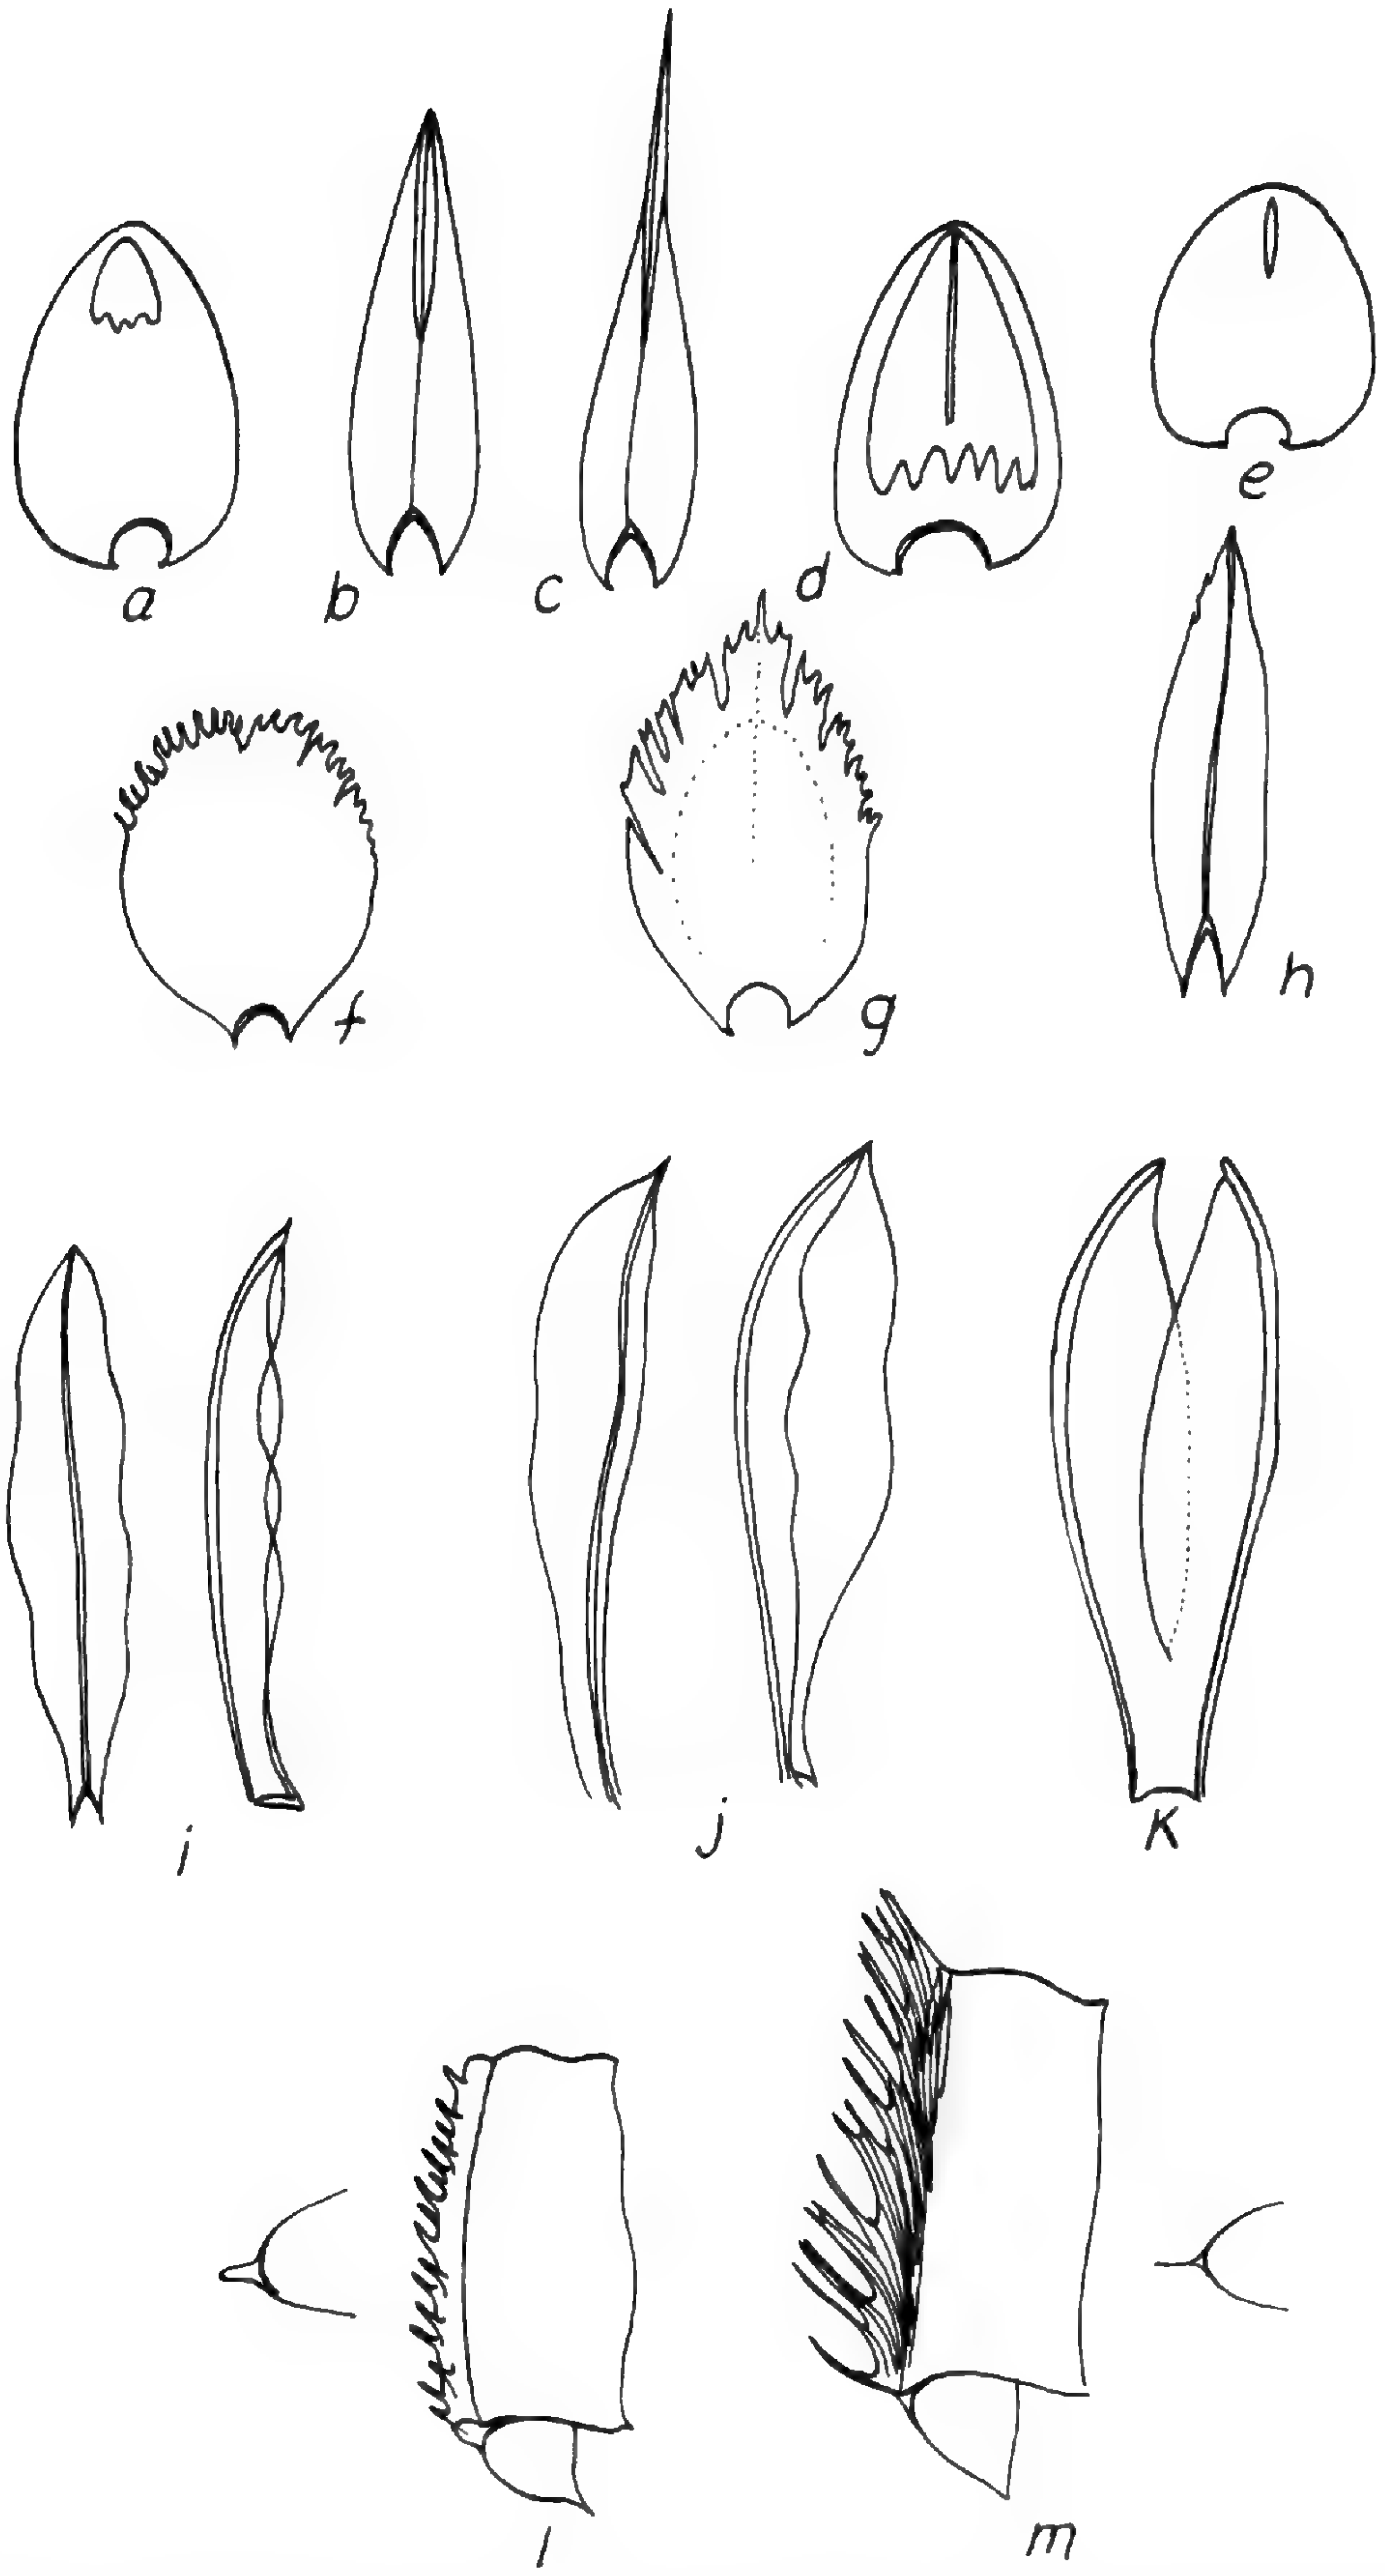


FIGURE IV. *Bract and lateral sepal types.—a. Ovate bract with ovate, subapical dorsal area.—b. Lanciform bract, keeled, with elliptic-linear dorsal area.—c. Lanciform bract, keeled, bladed, the blade comprising a cusp and dorsal area.—d. Ovate bract, mostly dorsal area, the convex bract medially-apically carinate.—e. Broadly ovate bract with narrow, subapical dorsal area.—f. Broadly obovate bract, border thin, lacerate; dorsal area lacking.—g. Broadly elliptic bract, border thin, laciniate, friable; dorsal area lacking.—h. Lanceolate bract, keeled; dorsal area lacking.—i. Dorsal and lateral views of lateral sepal, this oblong-elliptic, equilateral, slightly curvate, with narrow, thick, entire keel.—j. Dorsal and lateral views of lateral sepal, this oblanceolate, inequilateral, with narrow, thick, entire keel.—k. Connate lateral sepals.—l. Midsector of lateral sepal showing thickened, scabro-ciliate keel.—m. Midsector of lateral sepal showing thin (made up of a single layer of cells), ciliate-fimbriate keel.*

the Indian element as *X. indica* while using the North American element for *X. torta* Smith.

In the key below, the characters are based on principal leaves from healthy plants, spikes at seeding time, lateral sepals at seeding time, and on mature fruit and seed. Any attempt to determine sterile or depauperate material, or specimens with immature flowers, fruit, or seed is virtually impossible in a group of this sort.

The key below applies primarily to the *Xyris* of Venezuela, Colombia, and the Guianas. Some taxa discovered in contiguous Brazil, if in habitat likely to be found in Venezuela and the Guianas, are likewise included.

The key applies to healthy material with normally developed, seeding spikes. Principal, not juvenile, leaves are to be used. Overlaps in variation—particularly in trichome characters, lateral sepal and dorsal area color or accrescence, and plant pigmentation—often have necessitated the same species coming out in two or more leads.

KEY TO *XYRIS* OF GUAYANA AND AMAZONIAN NORTHERN SOUTH AMERICA

I. Placentation evidently marginal or parietal, the capsule valves on dehiscence retaining placentae and seeds .... Section *Xyris* (conventional)

II. Placentation free-central or basal or apparently axile, capsule valves on dehiscence with or without septa, but not retaining seeds .... other *Xyris*

I. Section *Xyris* (conventional).

1a. Keel of lateral sepals at least in part lacerate or irregular.

2a. Seeds fully 1 mm long; dorsal area venose and/or midnerve conspicuous; scapes terete distally with (usually) 3 or more strong costae, occasionally multistriate; leaf sheath sometimes long-ciliate.

3a. Principal foliage leaves longer than scape sheaths; spike bracts when dry inrolling and excurving, all with tips lacking tufts of long trichomes .... 1. *X. fallax*

3b. Principal foliage leaves poorly developed, exceeded by scape sheaths; spike bracts when dry not excurving, the lower ones with apical tufts of slender trichomes .... 6. *X. brachyfolia*

2b. Seeds 0.4–0.8(–0.9) mm long; dorsal area not venose or costate as in above; scapes seldom more than bicostate; leaf sheath never ciliate.

4a. Plant base strongly tinged with red or purple; scapes ecostate distally or with costae smooth; seeds fusiform or narrowly ellipsoid, mostly opaque, dark-ribbed, farinous, 0.7–0.9 mm long; plants perennial .... 2. *X. laxifolia*

4b. Plant base greenish, stramineous, dull brown or tan; scapes always with 1–2 (rarely a few more) costae, these usually papillose or scaberulous; seeds ovoid or broadly ellipsoid, amber, translucent, 0.4–0.7 mm long; plants annual .... 3. *X. jupicai*

1b. Keel of lateral sepals either ciliate or entire.

5a. Lateral sepals with keel ciliate; bracts dark dull brown, at maturity strongly spreading, the dorsal area unkeeled, paler but indistinct .... 4. *X. navicularis*

5b. Lateral sepals with keel eciliate, entire; bracts pale greenish tan, lustrous, the indistinct dorsal areas strongly keeled .... 5. *X. anceps*

II. Other *Xyris*.

1a. Margins of leaf sheaths entire.

2a. Plants mostly densely cespitose, evidently perennial; leaf sheaths hard, lustrous, castaneous to reddish brown, usually in strong contrast to leaf blades both in color and texture.

3a. Leaf blades not flattened or 2-edged, for most of their length either terete or very thickened and deeply ribbed and sulcate; ligules prominent, abruptly narrowed to blades.

4a. Dorsal area distinguishable.

5a. Plant bases nearly black .... 7. *X. neblinae*

5b. Plant bases deep brown, pale brown, or reddish brown.

6a. Mature spikes mostly over 1.5 cm long, fusiform or distinctly broadest above middle; leaf blades at least 1 mm thick .... 8. *X. juncifolia*

6b. Mature spikes mostly under 1.5 cm long, ovoid to cylindrical or subglobose; leaf blades less than 1 mm thick.

7a. Bract edges densely pale-villose; plants lacking stout, scaly rhizomes .... 9. *X. lanulobractea*

7b. Bract edges not densely pale-villose; plants with short, stout, ascending, scaly rhizomes .... 10. *X. terrestris*

4b. Dorsal area imperceptible.

8a. Leaf blades and upper sheaths coarsely ribbed and sulcate; sheath bases brown (bases of blades and apices of sheaths mostly rose-purple) .... 11. *X. scabridula*

8b. Leaf blades not deeply ribbed and sulcate; sheath bases (usually tips also) nearly black .... 12. *X. atriceps*

3b. Leaf blades flattened, for most of their length 2-edged, the edges either thickened or sharp; ligules evident or not.

9a. Dorsal area evident.

10a. Scapes strongly flattened, at least 2–2.5 mm broad distally, ancipital.

11a. Several bracts leaflike, forming an involucre .... 13. *X. involucrata*

11b. No bracts leaflike.

12a. Scapes bispicate; seeds under 2 mm long .... 15. *X. bicephala*

12b. Scapes unispicate; seeds over 2 mm long .... 16. *X. teinosperma*

10b. Scapes distally round or if strongly flattened distally not as wide as 2 mm there, not ancipital.

13a. Lowermost sterile bracts distinctly shorter than the fertile ones and grading gradually into them.

14a. Leaf blade edge cartilaginous-thickened, entire or ciliolate; bract borders pale villosulous (low-elevation savanna) .... 17. *X. lomatophylla*

14b. Leaf blade edge not cartilaginous-bordered, smooth; bract borders not pale villosulous, sometimes sparsely short-brown ciliolate .... 18. *X. contracta*

13b. Lowermost sterile bracts as long as or longer than the fertile ones.

15a. Lateral sepals connate, crested with a red villous keel apex; plants glaucous; dorsal area of lowest 1–2 bracts often excurrent as a green blade .... 19. *X. seubertii*

15b. Lateral sepals free, not crested as above; plants not glaucous; dorsal areas bladeless.

16a. Dorsal area large, triangular, punctate, occupying most of bract above middle; low-elevation savanna or granite outcrops, T. F. Amazonas, Venezuela.

17a. Bract borders reddish, long-ciliate; keel of lateral sepals and leaf blade edges ciliate; seeds 1.3–1.4 mm long .... 20. *X. huberi*

17b. Bract borders not reddish, eciliate; keel of lateral sepals sparsely scabrid and leaf blade edges scabrociliate only toward base; seeds ca. 0.5 mm long .... 21. *X. graniticola*

16b. Dorsal area narrower, less conspicuous, not evidently punctate; high savanna of tepuis .... 22. *X. frondosa*

9b. Dorsal area not evident.

18a. Longest leaves rarely with sheaths over ½ as long as blades, mostly ⅓ as long or shorter.

19a. Leaf blades under 3 mm wide.

20a. Keel of lateral sepals toward apex red villous-ciliate; edges of young bracts toward apex red villose .... 23. *X. chimantae*

20b. Keel of lateral sepals ciliate or lacerate but not as above; bract tips entire or brown ciliolate.

21a. Tips of leaf blades strongly callused, thick, blunt; leaf blades coarsely few-ribbed; high tepuis of Amazonas.

22a. Foliage smooth; leaf sheath apex tan to stramineous, lustrous; sheath edge forming a strong, broad ligule apically; keel of lateral sepals narrow, entire or subentire .... 24. *X. stenophylloides*

22b. Foliage harsh, particularly leaf blades toward base; leaf sheath apex and blade bases strongly tinged with red or rose; sheath tending gradually to merge with blade base .... 11. *X. scabridula*

21b. Tips of leaf blades acute or acuminate, sometimes spinulose; leaf blades not coarsely ribbed; high elevations.

23a. Flowers/spike 5–14; lateral sepals inequilateral, the keel long-ciliate above middle .... 25. *X. columbiana*

23b. Flowers/spike 4 or fewer; lateral sepals subequilateral, the keel either not evident or entire, papillate, or distantly scabrociliate.

24a. Lateral sepals ca. 5 mm long; bracts ovate to orbicular, ecarinate, nearly black; seeds ca. 1 mm long .... 26. *X. subulata* (complex)

24b. Lateral sepals ca. 7–8 mm long; bracts narrower, carinate, brown; seeds ca. 2 mm long .... 27. *X. valdeapiculata*

19b. Leaf blades mostly over 3 mm wide.

25a. Scapes ancipital (flattened and sharp-edged) distally, mostly 2.5 mm or more wide (variously scabrid, ciliate, or smooth).
    26a. Spikes obovoid or hemispheric, ca. as broad as long or broader; scape edges scabrid; bracts dark lustrous brown (Duida tepui and adjacent highlands) .... 28. *X. tatei*
    26b. Spikes ovoid-cylindric, distinctly longer than wide; scape edges smooth to pale ascending-ciliate; bracts dull, dark greenish black .... 29. *X. melanovaginata*
25b. Scapes not sharp-edged distally, mostly less than 2.5 mm wide.
    27a. Leaf blades with a rusty border, ciliate (often with reddish vein intervals) .... 30. *X. culmenicola*
    27b. Leaf blades without a rusty border, eciliate .... 31. *X. lugubris*

18b. Longest leaves commonly with sheaths over ½ as long as blades, frequently ⅔ as long or longer.
    28a. Basal bracts forming a leafy involucre longer than the spike .... 14. *X. pallidula*
    28b. Basal bracts not forming a leafy involucre.
        29a. Bracts toward apex with a scarious, lacerate, pale or reddish border; bases of leaf sheaths abruptly orbicular-dilated.
            30a. Scarious bract borders pale to deep red or red-brown; seeds ca. 1 mm long .... 32. *X. thysanolepis* (complex)
            30b. Scarious bract borders almost always pale, off-white; seeds 0.5–0.7 mm long.
                31a. Apices of most bracts acute and distinctly folded; stem bases cloaked with very numerous, closely overlapping leaf sheath bases, these a lustrous brown; endemic to summit elevations, Roraima and adjacent tepuis .... 33. *X. concinna*
                31b. Apices of most bracts broader, often broadly rounded; stem bases usually not as elongate, not as above; widely distributed from medium to high elevations .... 34. *X. hymenachne*
        29b. Bracts not bordered as above; bases of leaf sheaths not abruptly orbicular-dilated.
            32a. Scapes ancipital and strongly ciliate distally.
                33a. Scapes bispicate .... 15. *X. bicephala*
                33b. Scapes unispicate.
                    34a. Hairs of leaf and scape edges rusty, forming a dense border; apices of leaves erect; seeds ca. 1.5 mm long.
                        35a. Main stems rebranching, the branches elongate, forming frondlike plates of leaves; tips of leaves narrowly acute; spikes ellipsoid or obovoid .... 38. *X. ptariana* (extreme)
                        35b. Main stems not rebranching; tips of leaves rounded; spikes hemispheric or subglobose .... 35. *X. decussata*
                    34b. Hairs of leaf and scape pale, usually white or blonde; apices of leaves various; seeds various.
                        36a. Seeds at least 2 mm long; spikes hemispheric or subglobose; bracts very lustrous with subcucullate tips; tips of most leaves incurved-blunt .... 36. *X. albescens*
                        36b. Seeds ca. 1.5 mm long; spikes obovoid or oblong; bracts dull, sooty brown, with flat tips; tips of most leaves erect and acute .... 37. *X. fuliginea*
            32b. Scapes ancipital or not, never ciliate, at most scabridulous along edges; stems forming frondlike plates of leaves (like giant *Fissidens*).
                37a. Spikes 1.5 cm long or shorter, ovoid or broadly obovoid; lateral sepals under 1 cm long, strongly curved, blunt.
                    38a. Ligular apex often excurved; scapes strongly flattened distally, mostly 2.5 mm broad or wider; leaf blades commonly over 4 mm wide .... 38. *X. ptariana*
                    38b. Ligular apex commonly erect or ascending; scapes narrower, usually 2 mm broad or narrower distally; leaf blades usually under 4 mm wide .... 39. *X. witsenioides*
                37b. Spikes mostly 2–2.5 cm long, ellipsoid-cylindric or narrowly obovoid; lateral sepals over 1 cm long, narrowly acute .... 40. *X. xiphophylla*

2b. Plants either aquatic perennials or short-lived perennials or annuals of low- or moderate-elevation savanna, mostly low of habit and slender-scaped, and with small or narrow spikes; leaf sheaths mostly softer, paler, their bases not in sharp contrast to blades in color and texture.

39a. Scapes ancipital, edges at least in combination broader than the scape body; dorsal area and midrib of at least one of the lowest sterile bracts excurrent as a strong cusp or blade (body of lower bracts with a strong keel).

40a. Basal bracts foliaceous, slightly to much longer than the fertile bracts, sharply alate-keeled, spreading or ascending and often forming an involucre; sepals acute .... 41. *X. spruceana*

40b. Basal bracts tending to be incurved, cucullate, the lowest slightly to much longer than the fertile bracts, thus spikes not as noticeably involucrate and spreading-foliaceous; sepals obtuse .... 42. *X. uleana* (complex)

39b. Scapes flattened or terete, but not winged as above; lowest bracts shorter in relation to fertile bracts.

41a. Florets 4 or fewer.

42a. Lateral sepals connate.

43a. Fertile florets 1 per spike.

44a. Leaf blades with edges cartilaginous-thickened; scapes flattened distally with costae making edges .... 44. *X. esmeraldae*

44b. Leaf blades filiform, the edges not noticeably cartilaginous-thickened; scapes filiform-terete, ecostate .... 45. *X. subuniflora*

43b. Fertile florets more than 1 per spike .... 46. *X. connosepala*

42b. Lateral sepals free.

45a. Leaf blades strongly flattened, with narrow, pale, incrassate borders .... 47. *X. guianensis*

45b. Leaf blades terete or somewhat flattened, without pale, incrassate borders.

46a. Leaf sheath apically with a broad ligule, this narrowing abruptly to a terete blade; spikes frequently proliferous; aquatic or emergent plants with foliage often maroon and soft .... 48. *X. spathacea*

46b. Leaf sheath with borders narrowing more gradually to a more flattened, often strongly ribbed blade; spikes not proliferous.

47a. Mature scapes equalled or exceeded by larger leaves; bracts at maturity strongly excurved, thus spikes broadly turbinate .... 49. *X. cyperoides*

47b. Mature scapes definitely longer than leaves; bracts and spikes not as above.

48a. Seeds ca. 1 mm long, including an apical pale coma of short squamellae; scapes and leaf blades rugose or rugulose .... 58. *X. mima*

48b. Seeds 0.4–0.7 mm long, lacking apical squamellae; scapes and leaf blades smooth or nearly so.

49a. Lateral sepals narrow, acute, entire; bract tips acute, with narrow dorsal areas .... 50. *X. toronoana*

49b. Lateral sepals broad, ciliate or ciliolate; bract tips broader, with broader dorsal areas (see no. 47).

41b. Florets 4–many.

50a. Leaf blades filiform and flaccid; sheath bases broadly scarious-bordered, the scarious borders distally producing a strong ligule much broader than the leaf blade base; rhizomatous soft aquatics or marsh emergents.

51a. Leaf blade terete; scapes arising from long, stout, scaly rhizomes; seeds ca. 0.5 mm long .... 51. *X. aquatica*

51b. Leaf blade flattened, strongly nerved; scapes arising from slender rhizomes; seeds ca. 1 mm long .... 52. *X. apureana*

50b. Leaf blades wider and/or firmer; sheath at apex not as above; erhizomatous plants of drier sites.

52a. Spike elongate, more than 4 times as long as wide.

53a. Bracts distichous, spikes flattened .... 53. *X. stenostachya*

53b. Bracts polystichous, spikes terete.

54a. Leaf blades at least toward base with thickened, lustrous cartilaginous margins; leaf sheath keels distally with cartilaginous dark costa.

55a. Spikes sharply acute, fusiform or ellipsoid; seeds 1.2–1.7 mm long .... 54. *X. stenocephala*

55b. Spikes blunt, the mature ones cylindric; seeds 0.6–0.7 mm long .... 55. *X. cylindrostachya*

54b. Leaf blades lacking thickened, lustrous, cartilaginous margins; leaf sheath keels lacking cartilaginous dark costa.

56a. Spike lanceoloid to fusiform, acuminate; fertile bracts at apex with lanceolate dorsal area forming a sharp subapical keel; leaf blades terete most of their length above base .... 56. *X. brachysepala*

56b. Spike ovoid to ellipsoid, lanceoloid, or cylindric, blunt or acute; fertile bracts with broad dorsal areas not forming a sharp subapical keel; leaf blades usually terete only at or toward tips (if at all) .... 57. *X. paraensis* (complex)

52b. Spikes of a broader, shorter outline.

57a. Lateral sepals subequilateral or slightly inequilateral.

58a. Scapes scabrid, tuberculate-rugose, strongly bicostate distally; seeds apically with coma of pale, narrow scales .... 58. *X. mima*

58b. Scapes smooth or at most papillate, usually ecostate or at most striate; seeds without coma.

59a. Spikes broadest at or above middle; leaf blades with strong red border; lateral sepals strongly curved, the keel evenly ciliate .... 59. *X. rubrolimbata*

59b. Spikes ovoid, acute; leaf blades lacking strong red border; lateral sepals not strongly curved, the narrow keel entire or subentire .... 60. *X. cuatrecasana*

57b. Lateral sepals either connate or very inequilateral.

60a. The lateral sepals connate; fertile bracts pectinate-bordered .... 61. *X. pectinata*

60b. The lateral sepals free; fertile bracts not pectinate-bordered.

61a. Staminodia lacking beard; foliage prevalently (one var. excepted) papillose or rugulose, the leaf blades strongly nerved; dorsal areas of fertile bracts mostly narrowly elliptic or linear; seed tips truncate, with a central low apiculus .... 62. *X. savanensis*

61b. Staminodia bearded; foliage prevalently smooth, the leaf blades either less strongly nerved or smooth; dorsal areas of fertile bracts broader or more raised; seed tips not truncate.

62a. Backs of bracts strongly papillose-tuberculate; bract edges at least apically villous or pilose-ciliate.

63a. Lowest pair of bracts incurved-cucullate at tips not much if at all exceeding spike .... 42. *X. uleana* (complex)

63b. Lowest pair of bracts with spreading, trigonous-subulate tips many times longer than spike .... 43. *X. calderonii*

62b. Backs and edges of bracts smooth and entire.

64a. Leaf blades with cartilaginous-thickened borders; seeds 1.2–1.7 mm long .... 54. *X. stenocephala*

64b. Leaf blades without cartilaginous-thickened borders; seeds less than 1 mm long .... 57. *X. paraensis* (complex)

1b. Margins of leaf sheaths at some or all levels variously ciliate with various sorts of hairs.

65a. Dorsal area evident on some or all spike bracts.

66a. Leaves at junction of sheath and blade definitely flattened.

67a. Scapes either strongly flattened distally or with 2 costae making 2 strong edges.

68a. Leaf blade edges and/or scape edges usually with long, straight cilia, rarely smooth, if so then thickened.

69a. Spikes broad; dorsal area broadly triangular, occupying most of upper part of bract; scapes mostly 2 mm wide or more .... 63. *X. surinamensis*

69b. Spikes narrow; dorsal area narrower; scape narrower .... 64. *X. pratensis*

68b. Leaf blade and scape edges scabrociliate with shorter, stiffer hairs .... 65. *X. bicostata*

67b. Scapes distally terete or at least thickened in cross section, 0–many-costate, costae in bicostate types not ciliate or scabrociliate, not making 2 strong edges.

70a. Scapes smooth, without strong costae or merely fluted

71a. Flowers usually more than 4.

72a. Bracts, or some of them, with long hairs on margins or backs or on both.

73a. Bracts rounded, edges villous-ciliate ... 66. *X. globosa*

73b. Bracts acute, some bract backs with white hairs ... 67. *X. arachnoidea*

72b. Bracts without pubescent margins or backs.

74a. Matrix of bracts (at level of dorsal areas) pale brown or pale red-brown, thin, lacerate or entire.

75a. Leaf sheath bases abruptly dilated; plant base thus bulbous.

76a. Fertile bracts apically carinate, acute; leaf blades coarsely few-nerved ... 69. *X. araracuare*

76b. Fertile bracts more rounded, less carinate at apex; leaf blades more flattened, less coarsely nerved ... 70. *X. lacerata*

75b. Leaf sheath bases not abruptly dilated; plant base not bulbous (spike oblate, often proliferous) ... 71. *X. oblata*

74b. Matrix of bracts dark brown, spikes dark; scapes usually lustrous, deep brown or olivaceous or reddish (leaf tip excentrically spinulose) ... 81. *X. setigera* (complex)

71b. Flowers almost always 4 or fewer (spikes mostly narrow; dorsal area narrow, often streaklike, absent on some bracts).

77a. Sheath cilia long and spreading but firm; seeds ovoid, ca. 0.5 mm long; leaf blades linear ... 72. *X. tenella* (complex)

77b. Sheath cilia arachnoid; seeds ellipsoid or cylindric, ca. 1 mm long; leaf blades filiform ... 73. *X. byssacea*

70b. Scapes with strong costae.

78a. Scapes sharply 3-or-more-costate; plant base sub-bulbous; spike broadly ovoid or ellipsoid ... 68. *X. malmeana*

78b. Scapes with costae fewer if multicostate; papillate-scabrid plant base not bulbous (the plants annual and low); spike ellipsoid to lanceoloid ... 72. *X. tenella* (complex)

66b. Leaves at junction of sheath and blade definitely not flattened, at most elliptic in cross section, mostly terete or oval, often with a ventral sulcus.

79a. Spikes few-flowered and narrow (narrowly oblong to linear-lanceoloid).

80a. One pair of lower (sterile) bracts longer than the rest and connivent over spike top ... 74. *X. cryptantha*

80b. Lower bracts not as above, the lowest pair slightly to considerably shorter than the spike ... 75. *X. oxylepis*

79b. Spikes several–many-flowered and broader.

81a. Bract tips narrowly or bluntly acute.

82a. Outer bracts densely hirsute-tomentose or hirsute-ciliate with white hairs; bract tips straight, erect or ascending, bract matrix dark-castaneous ... 76. *X. wurdackii*

82b. Outer bracts not hirsute-tomentose or hirsute-ciliate, mostly smooth; bract tips becoming excurved, bract matrix brown ... 77. *X. frequens*

81b. Bract tips broadly angled to rounded.

83a. Dorsal area broad, comprising most of the bract above middle; leaves strongly angulately ribbed; mostly plants of low-altitude savanna ... 78. *X. subglabrata*

83b. Dorsal area narrower; leaves not strongly ribbed; mostly plants of medium- to high-altitude tepuis.

84a. Scapes smooth, usually lustrous, at most punctate.

85a. Bracts dark brown or dark red-brown, dorsal areas pale and inconspicuous ... 81. *X. setigera* (complex)

85b. Bracts pale brown with darker dorsal areas ... 79. *X. lithophila*

84b. Scapes papillate or tuberculate, usually rugulose or rugose, at least above middle ... 80. *X. carinata*

65b. Dorsal area not evident.

86a. Leaves distinctly compressed at junction of sheath and blade, with the ventral edges about as narrow as the dorsal edge.

87a. Scapes terete distally, ecostate, smooth and also punctate; leaf apex usually excentrically spinulose-tipped.

88a. Leaves 0.5–3 mm wide; lateral sepals 5–6 mm long; seeds 0.5–0.6 mm long ... 81. *X. setigera* (complex)

88b. Leaves 2–3 mm wide; lateral sepals 6.5–7 mm long; seeds 0.9–1 mm long ... 82. *X. riparia*

87b. Scapes terete or somewhat flattened distally, there costate, usually tuberculate-scabrid, ciliate, papillose and/or rugulose at least on the costae; leaf apex not excentrically spinulose-subulate.

89a. Bracts with scarious and lacerate borders different abruptly in texture and color from main bract body.
  90a. Borders of bracts red or red-brown.
    91a. Spikes ellipsoid to broad-cylindric; foliage above dilated base yellow-green, scabrid-papillose-rugulose; scapes ancipital distally .... 83. *X. roraimae*
    91b. Spikes broadly obovoid or turbinate to subglobose; foliage except for leaf edges and costae not yellow-green, smooth; scapes not ancipital .... 32. *X. thysanolepis* (complex)
  90b. Borders of bracts pale.
    92a. Apices of bracts, particularly basal and inner ones, acute, folded; spikes ovoid .... 33. *X. concinna*
    92b. Apices of bracts mostly obtuse, not folded; spikes broadly ellipsoid, obovoid, or subglobose .... 34. *X. hymenachne*
89b. Bracts very dark, usually deep olive-brown, the borders entire and not much contrasting in color.
  93a. Surfaces of leaves and scapes completely rugulose-papillose-tuberculate.
    94a. Lateral sepals all free; capsule valves with strong septa .... 84. *X. schneeana*
    94b. Lateral sepals connate; capsule valves lacking septa .... 85. *X. consolida*
  93b. Surfaces of leaves and scapes smooth or at most papillate only toward leaf sheath base, but edges of leaf blades and of ancipital scape white-ciliolate; lateral sepals free, capsule valves with septa .... 86. *X. kukenaniana*
86b. Leaves definitely thickened at junction of sheath and blade, not 2-edged.
  95a. Tips of leaf blades blunt; scapes rugose-tuberculate or rugulose-papillate .... 87. *X. delicatula*
  95b. Tips of leaf blades subulate-spinulose; scapes totally smooth, or smooth and puncticulate .... 81. *X. setigera* (complex)

1. Xyris fallax Malme, Bih. Svensk. Vet.-Akad. Handl. 22, Afd. 3, no. 2: 12, pl. 1, f. 5. 1896. TYPE: Brazil. Mato Grosso: Sta. Anna da Chapada, *G. Malme 1432* (lectotype, S). Figure 1.

X. erythema Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 12, fig. 1A–F. 1963. TYPE: Guyana: infrequent in wet places, scrub and low forest (8–10 m) on shoulder of east flank above Thompson Camp, 1,418–1,525 m, 10 Aug. 1960, Upper Mazaruni River Basin, Mt. Ayanganna, British Guiana, *S. S. & C. L. Tillett & R. Boyan 45074* (holotype, N; isotype, US).

Low and slender to robust, solitary or cespitose, glabrous or papillose-rugulose perennial to 1 m high, the stems contracted, sometimes perennating by stout (–4 mm thick) horizontal rhizome. Leaves erect to spreading flabellately, (5–)10–30(–40) cm long, often suffused with maroon pigment; sheaths ½ to under ¼ as long as blades, soft, pale lustrous brown, the dilated base entire, multicostate, gradually narrowing and carinate upward, the carina often papillose or ciliate-scabrid, the margins frequently sparsely to densely spreading-pilose-ciliate, gradually narrowing to blade or there producing a broadly triangular, incurved ligule to 2 mm long; blades ensiform-linear, 1–5(–7) mm wide, much flattened, sometimes slightly twisted, the apex narrowly incurved-acute, the margins thin or (usually) lustrous-incrassate, often papillate or minutely scabrociliate, more often smooth. Scape sheaths shorter than main foliage leaves, loosely tubular, multicostate, deep reddish brown proximally, distally opening and broadening, apically with short, erect blades. Scapes straight or somewhat flexuous, twisted, terete and multicostate distally, 1–2 mm thick, the costae smooth or papillate. Spikes lance-cylindric to broadly ellipsoid or ovoid, mostly 1–2 cm long, acute, the base short-attenuate, multiflorous; sterile bracts several, the lowest much smaller than the fertile bracts, narrowly triangular-ovate, carinate, grading gradually upward into the fertile bracts, these mostly broadly ovate or obovate, 5–7 mm long, subentire, apically narrowly rounded, the back with distinct elliptic dorsal areas, convex and ecarinate, the dorsal area bisected by a narrow, low but distinct midnerve. Lateral sepals

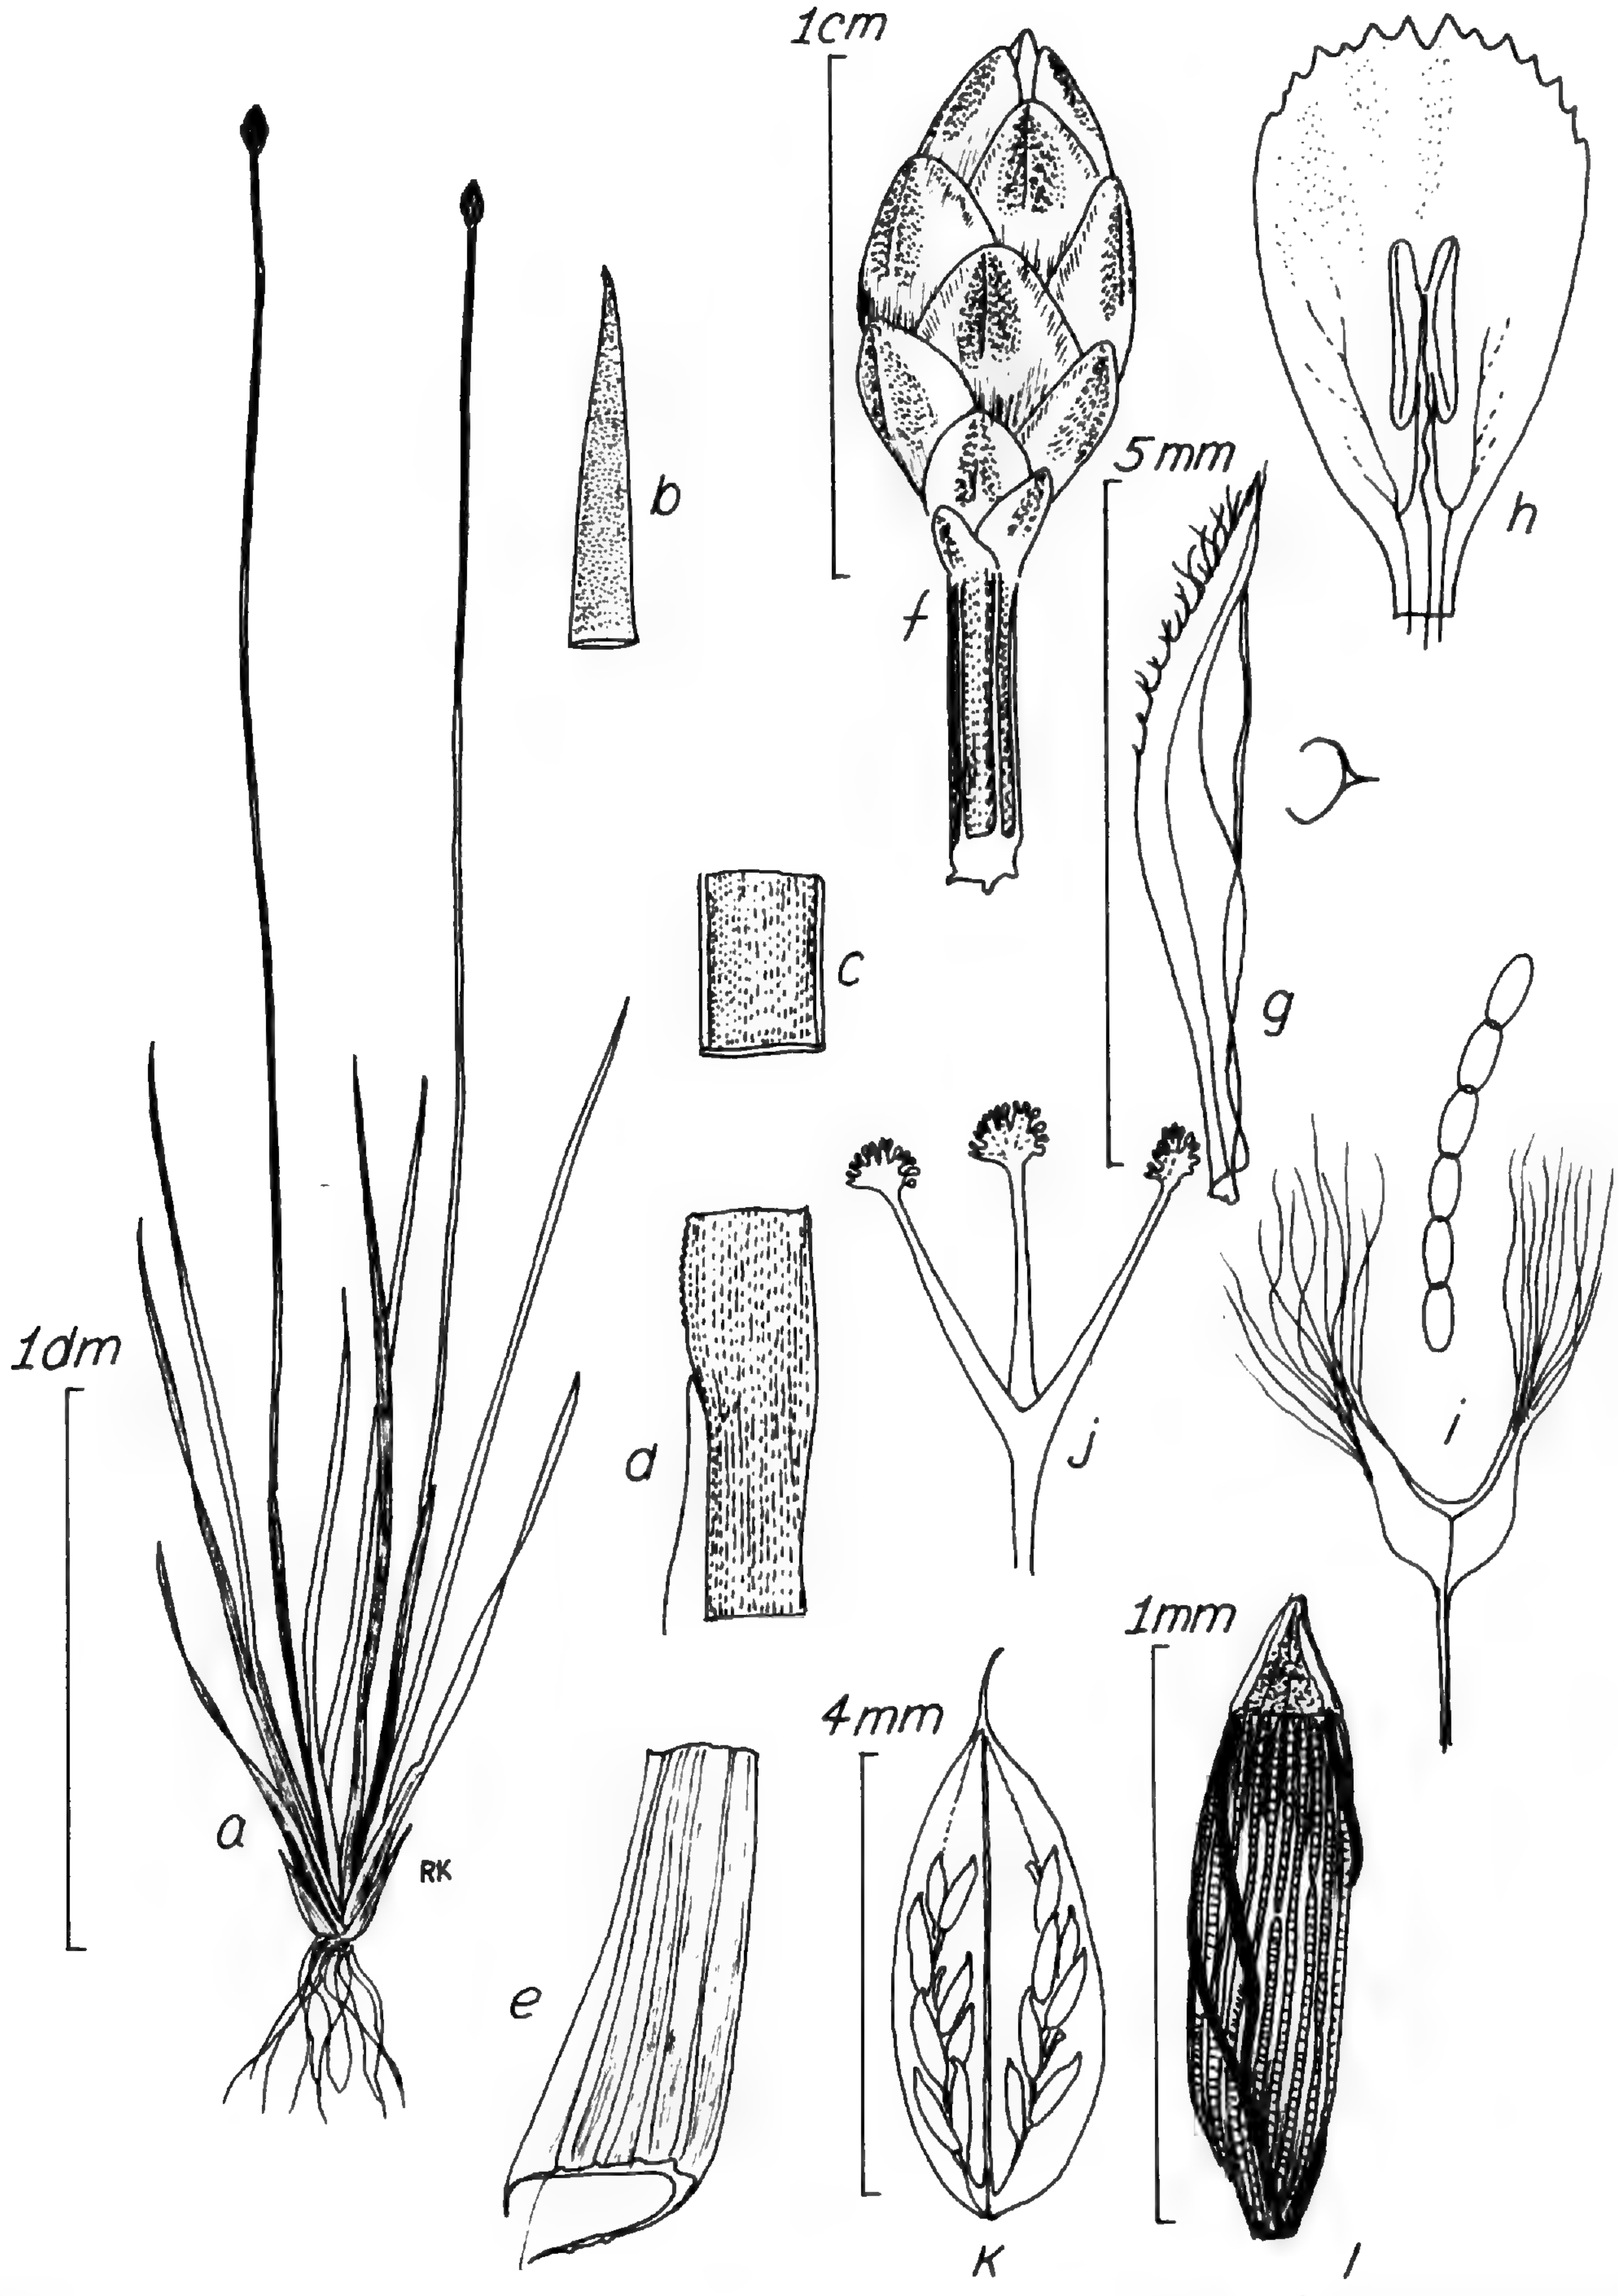

FIGURE 1. Xyris fallax (Davidse et al. 1785).—*a. Habit sketch.—b. Leaf tip.—c. Sector of leaf midblade.—d. Leaf base–blade junction.—e. Leaf base.—f. Spike.—g. Lateral sepal.—h. Petal blade, stamen.—i. Staminode, enlarged part of beard hair.—j. Stylar apex.—k. Capsule with one valve removed, showing two lines of placentation.—l. Seed.*

free, subequilateral, linear-oblanceolate, 4.5–5 mm long (often much reduced in length even in fruit), acute, red-brown, the firm broad keel lacerociliate from ca. middle to apex, sometimes villous-ciliate at apex. Petal blades unfolding in morning, broadly obovate, 4–5 mm long, yellow, the broadly rounded apex lacerodentate. Staminodia bibrachiate, the broad branches long-penicillate toward tips. Anthers oblong, ca. 1.5 mm long, deeply bifid and sagittate, on filaments ca. 1 mm long. Capsule ellipsoid or narrowly obovoid, 3–5 mm long, the placentae parietal and extending ½–⅔ up the ovulary. Seeds numerous, 1–1.5 mm long, asymmetrically cylindrical or fusiform, deep red-brown and translucent, longitudinally distinctly and closely multiribbed, the ribs often crossed or overlain by an occasional broader, deeper-brown rib.

Distribution. Trinidad South to Mato Grosso (Norte), westward into the Andean foothills; Africa.

This xyrid shows weedy tendencies, is often abundant in recently disturbed wetlands, if acid, and along fluctuating shorelines and banks. While commonest in low-elevation savanna, it may be found in wetlands at elevations of nearly 1,500 meters. In ciliation of sheath it varies considerably from totally entire to densely long-brown-ciliate.

2. Xyris laxifolia C. Martius, Fl. Bras. 24(2): 58. 1841. TYPE: Brazil. Without definite locality: Mart. Herb. no. 540 (holotype, M). Figure 2.

X. jupicai Rich. var. *major* (C. Martius) Smith & Downs in Reitz, Fl. Ill. Catarinensis, Pt. 1, fasc. xii: 9. 1965.

Robust, solitary or cespitose perennial 0.5–1.5 m tall, the bases usually suffused with red or purple, all surfaces smooth. Principal leaves erect or spreading flabellately, 4–7 dm long, the sheaths over ½ as long to longer than blades, at very base broad with scarious entire margins, red to purple or charcoal, tapering gradually, keeled into junction with blades, these broadly linear, mostly 1–2 cm wide, strongly flattened, straight, the apex abruptly incurved-acute or erect-acute, the margins thin and hyaline or slightly incrassate, the surfaces deep lustrous green. Scape sheaths shorter than leaves, proximally loosely tubular, multiribbed, deeply tinted with red, purple, or lustrous brown, distally opening and keeled, producing a short, flat, green blade. Scapes straight, stiffly linear, distally terete to oval or elliptic in cross section, sometimes 2-edged but usually ecostate, smooth, green. Spikes ovoid to cylindrical, 3–3.5 cm long, blunt to acute, green-brown, of many tightly and spirally imbricate firm bracts, the sterile ones much smaller than and grading into the fertile ones, keeled, all with distinct and usually greenish dorsal areas; fertile bracts obovate to ovate or suborbicular, convex-backed and ecarinate, 7–10 mm long, apically narrowly rounded, entire, the matrix deep to pale reddish brown, lustrous, in sharp contrast to the paler and dull dorsal areas. Lateral sepals free, oblong-curvate, 5–6.5 mm long, acute, the pale brown, thin sides subequilateral, the dark reddish brown keel wide but thin, lacerate or lacerofimbriate from ca. middle to tip. Petal blades broadly obovate, ca. 5 mm long, yellow, the broadly rounded apex erose, the base broadly cuneate. Staminodia bibrachiate, the broad, flat branches apically rebranched and long-penicillate, the cells congested with dark material, the terminal few often double. Anthers ca. 2.5 mm long, lance-oblong, shallowly bifid, deeply sagittate, on filaments 0.5–0.6 mm long. Capsule plano-convex, broadly to narrowly obovoid, 5.5–6.5 mm long, often longer than the sepals; placentation parietal. Seeds ellipsoid-fusiform, 0.7–0.9 mm long, slightly to conspicuously farinose or translucent, with 6–8 conspicuous, minutely pebbled, dark, longitudinal ribs and many slightly less prominent cross-lines.

Distribution. Southern Mexico southward through Central America and at the

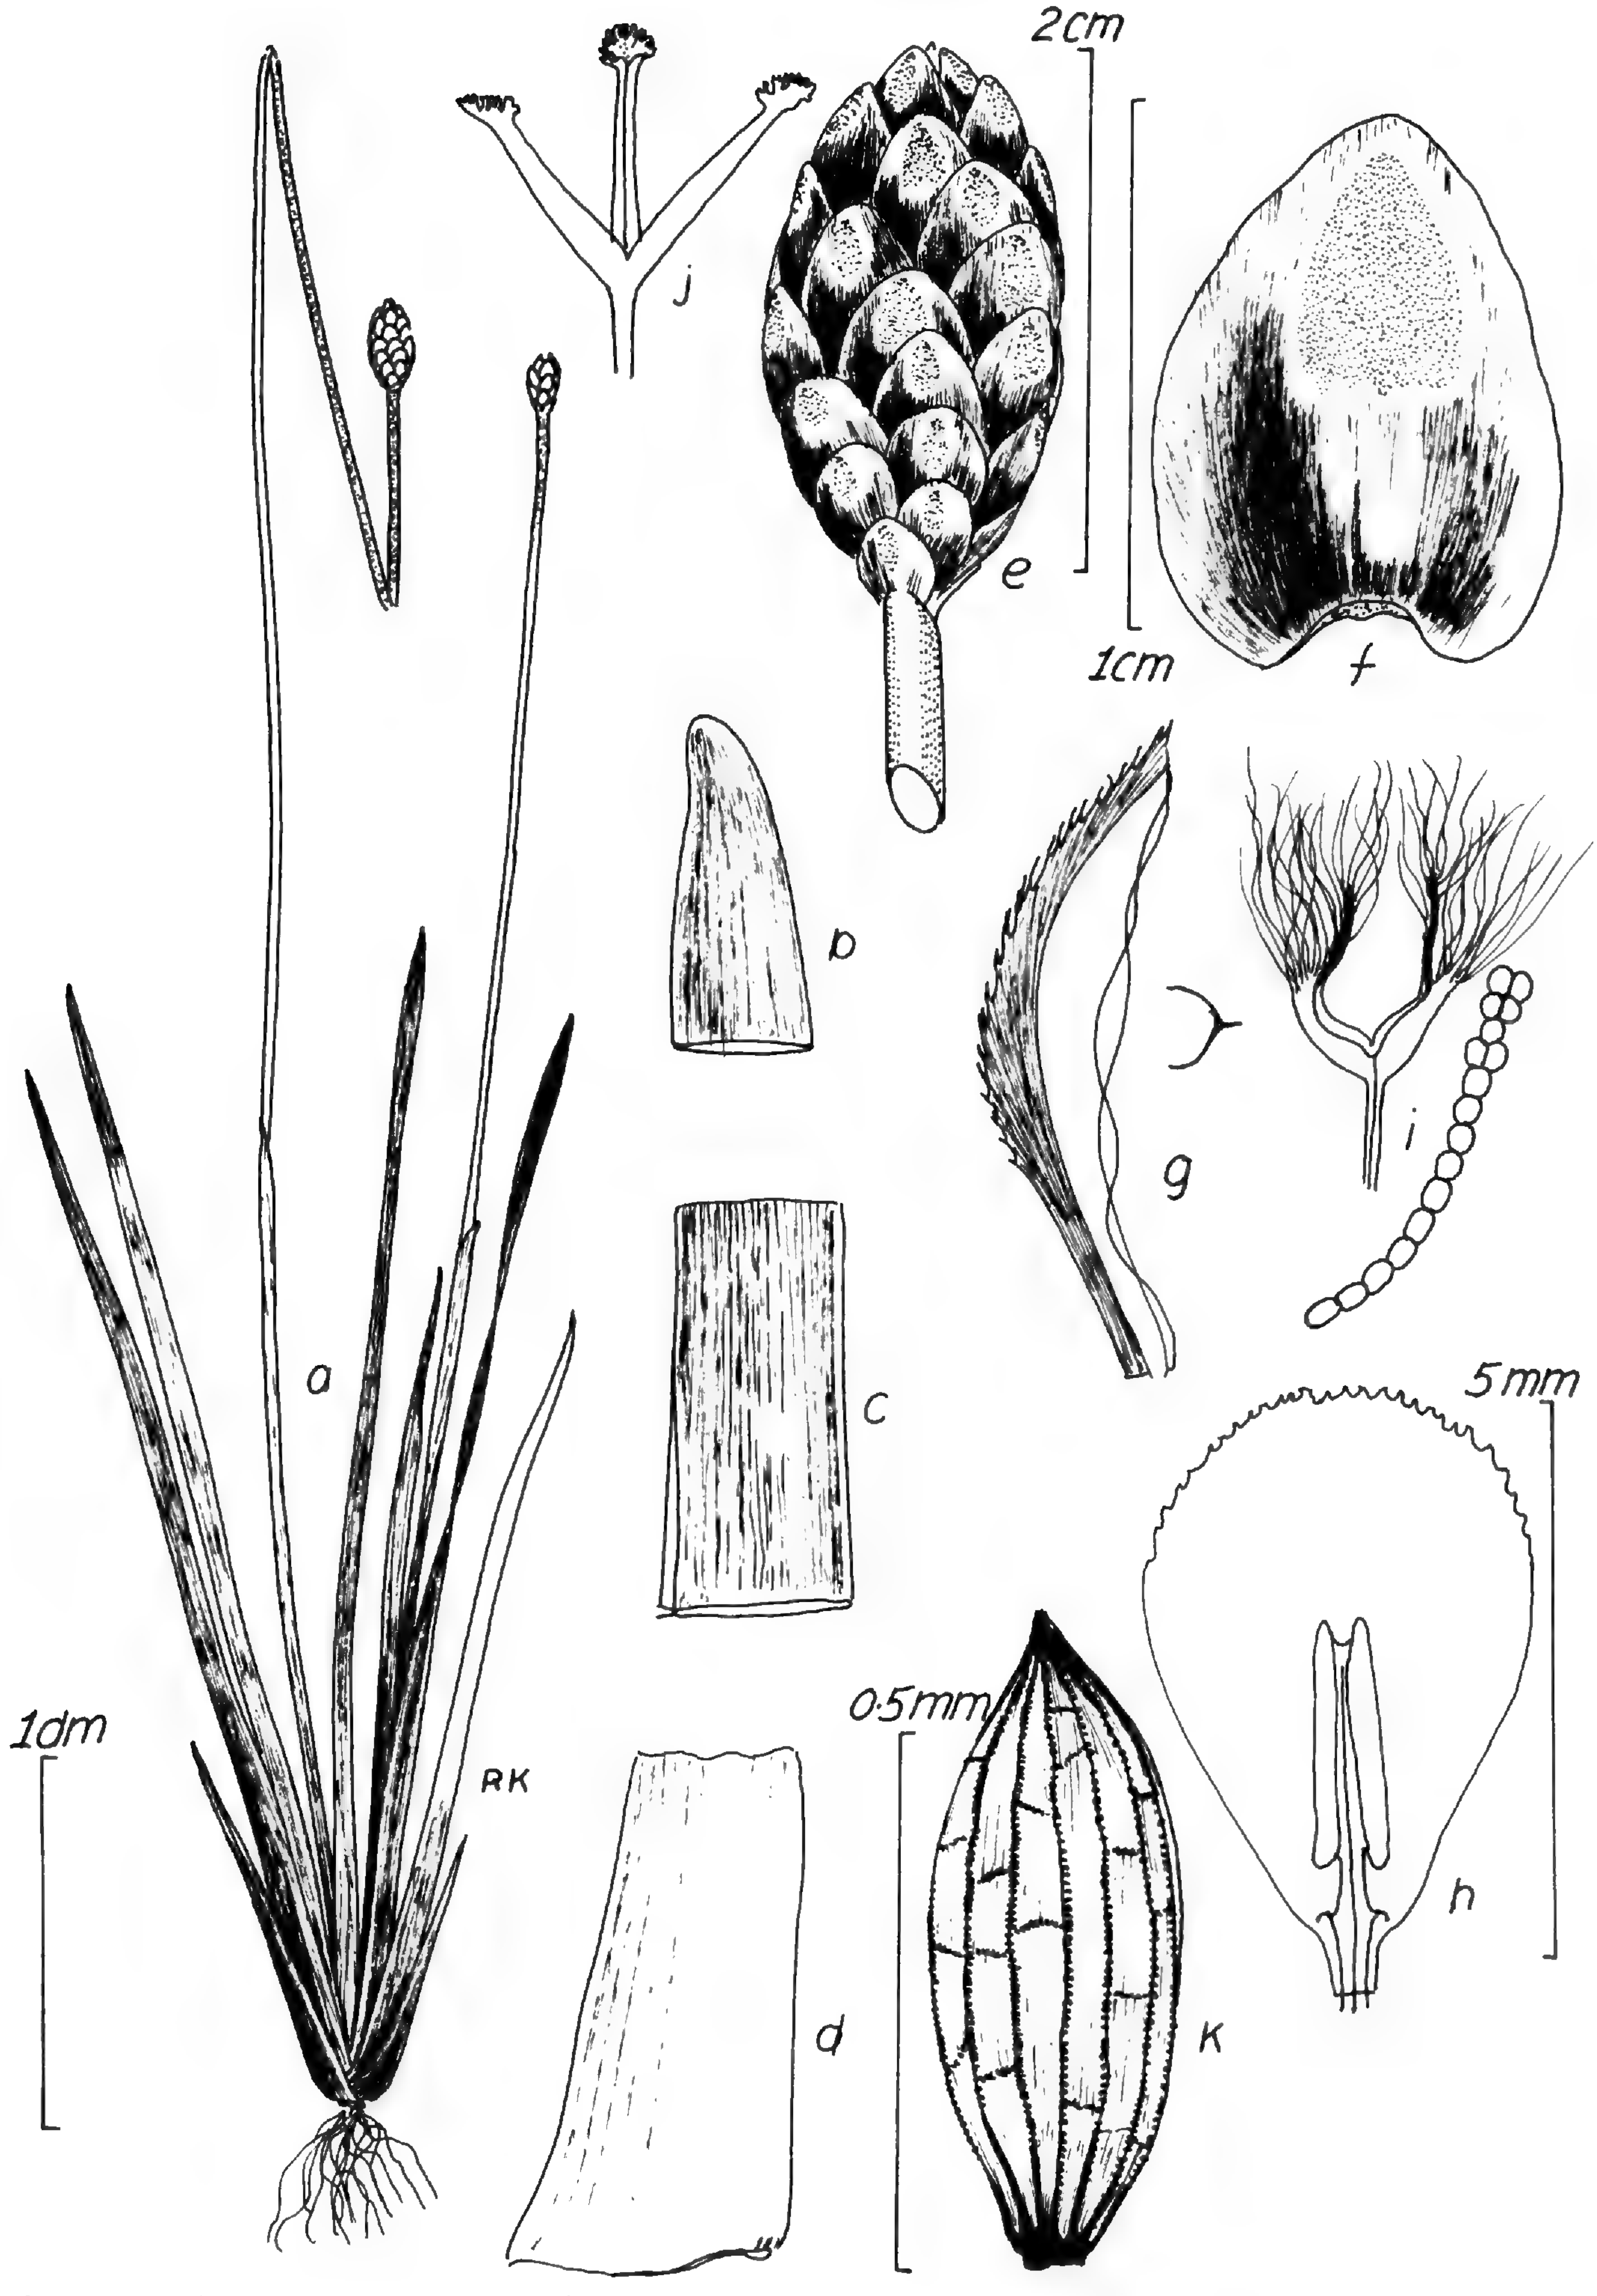

FIGURE 2. Xyris laxifolia (Davidse & Gonzales 15946).—*a. Habit sketch.—b. Leaf tip.—c. Leaf blade-sheath junction.—d. Leaf base.—e. Spike.—f. Fertile bract.—g. Lateral sepal.—h. Petal blade, stamen.—i. Staminode.—j. Stylar apex.—k. Seed.*

lower elevations south into Argentina. Coastal Plain of the southeastern United States (var. *iridifolia*).

The specimen sent from C in the type folder representing *X. macrocephala* Vahl and bearing Vahl's identification as *X. macrocephala* (Vahl script) should bear the oldest name for this species. However, the sheet has two elements on it: one is a spike of *X. ambigua* Beyr., a Mesoamerican, Caribbean, and North American species but definitely not from the type area (Cayenne, French Guiana); the other is *X. jupicai* L. C. Richard, a previously named species. This situation appears to be best handled by selecting the earliest available indisputably typified name. Material at Florence of the type collection of *X. macrocephala* (which I have seen only as photographs) appears likewise to be mixed. The main difficulty here is one of deciding the appropriate whereabouts of the lectotype and the varied interpretations of Vahl's original, and cryptic comments add much to the problem.

Xyris laxifolia, like *X. jupicai,* is a common weed of disturbed, mildly to very acid open areas and riverine forest borders. In North America it ranges from southeastern Virginia southward into northern Florida, thence west in the Coastal Plain into south-central Texas, with an outlier in Tabasco, Mexico. These northern populations are designated var. *iridifolia* (Chapm.), but even varietal distinction is difficult. In South America the species is general in wetlands, particularly at lower elevations from the Andean foothills to the Atlantic. Its most common associate xyrid is *X. jupicai* from which *X. laxifolia* differs primarily by having taller habit, broader and purple-based leaves, wider and smooth-edged scapes, larger and darker spikes with narrower bract apices. The seeds are mostly farinose. Much confusion in identification comes from larger specimens of the former and smaller specimens of the latter, also from the fact that the red pigments that so definitely mark *X. laxifolia* in the field do not persist for very many years on herbarium material or are entirely lost when specimens are treated with alcohol or formalin (as they so often are in the tropics).

3. Xyris jupicai Rich., Act. Soc. Hist. Nat. Paris I: 100. 1792. TYPE: French Guiana: "Cayenne," *LeBlond* (lectotype, P). Figure 3.

X. macrocephala f. *minor* (C. Martius) M. Kuhlmann & Kuhn, Fl. Dist. Ibiti. 34. 1947.

Annual or short-lived, perennial, solitary or tufted, 1–10 dm high, the stems contracted, mostly dying by end of season, rarely perennating by bulbous overwintering lateral buds. Leaves mostly erect or ascending, 1–6 dm long; sheaths entire, often as long as the blades, tapering gradually from a dilated, pale green, dull brown or stramineous, keeled, ribbed base to the blade, there with edges convergent and merging with blade or with a short, erect triangular ligule; blades linear, strongly flattened, straight, the apex acuminate, erect or incurved, the margins thin or narrowly incrassate, smooth or papillate, the surface yellow-green with short streaks of maroon, finely nerved. Scape sheaths much shorter than leaves, the tubular bases multicostate and twisted, stramineous, pale green or pale brown, upwardly dilating and open, keeled, then narrowing to a slightly divergent, cusplike flat blade. Scapes straight, erect, rarely somewhat twisted, proximally terete, multistriate and 1–2-costate, tan or stramineous, distally slightly compressed and 1–2-costate, green, the costae narrow but strong, usually papillose-tuberculate, rarely smooth. Mature spikes ovoid, ellipsoid or oblong, 0.5–

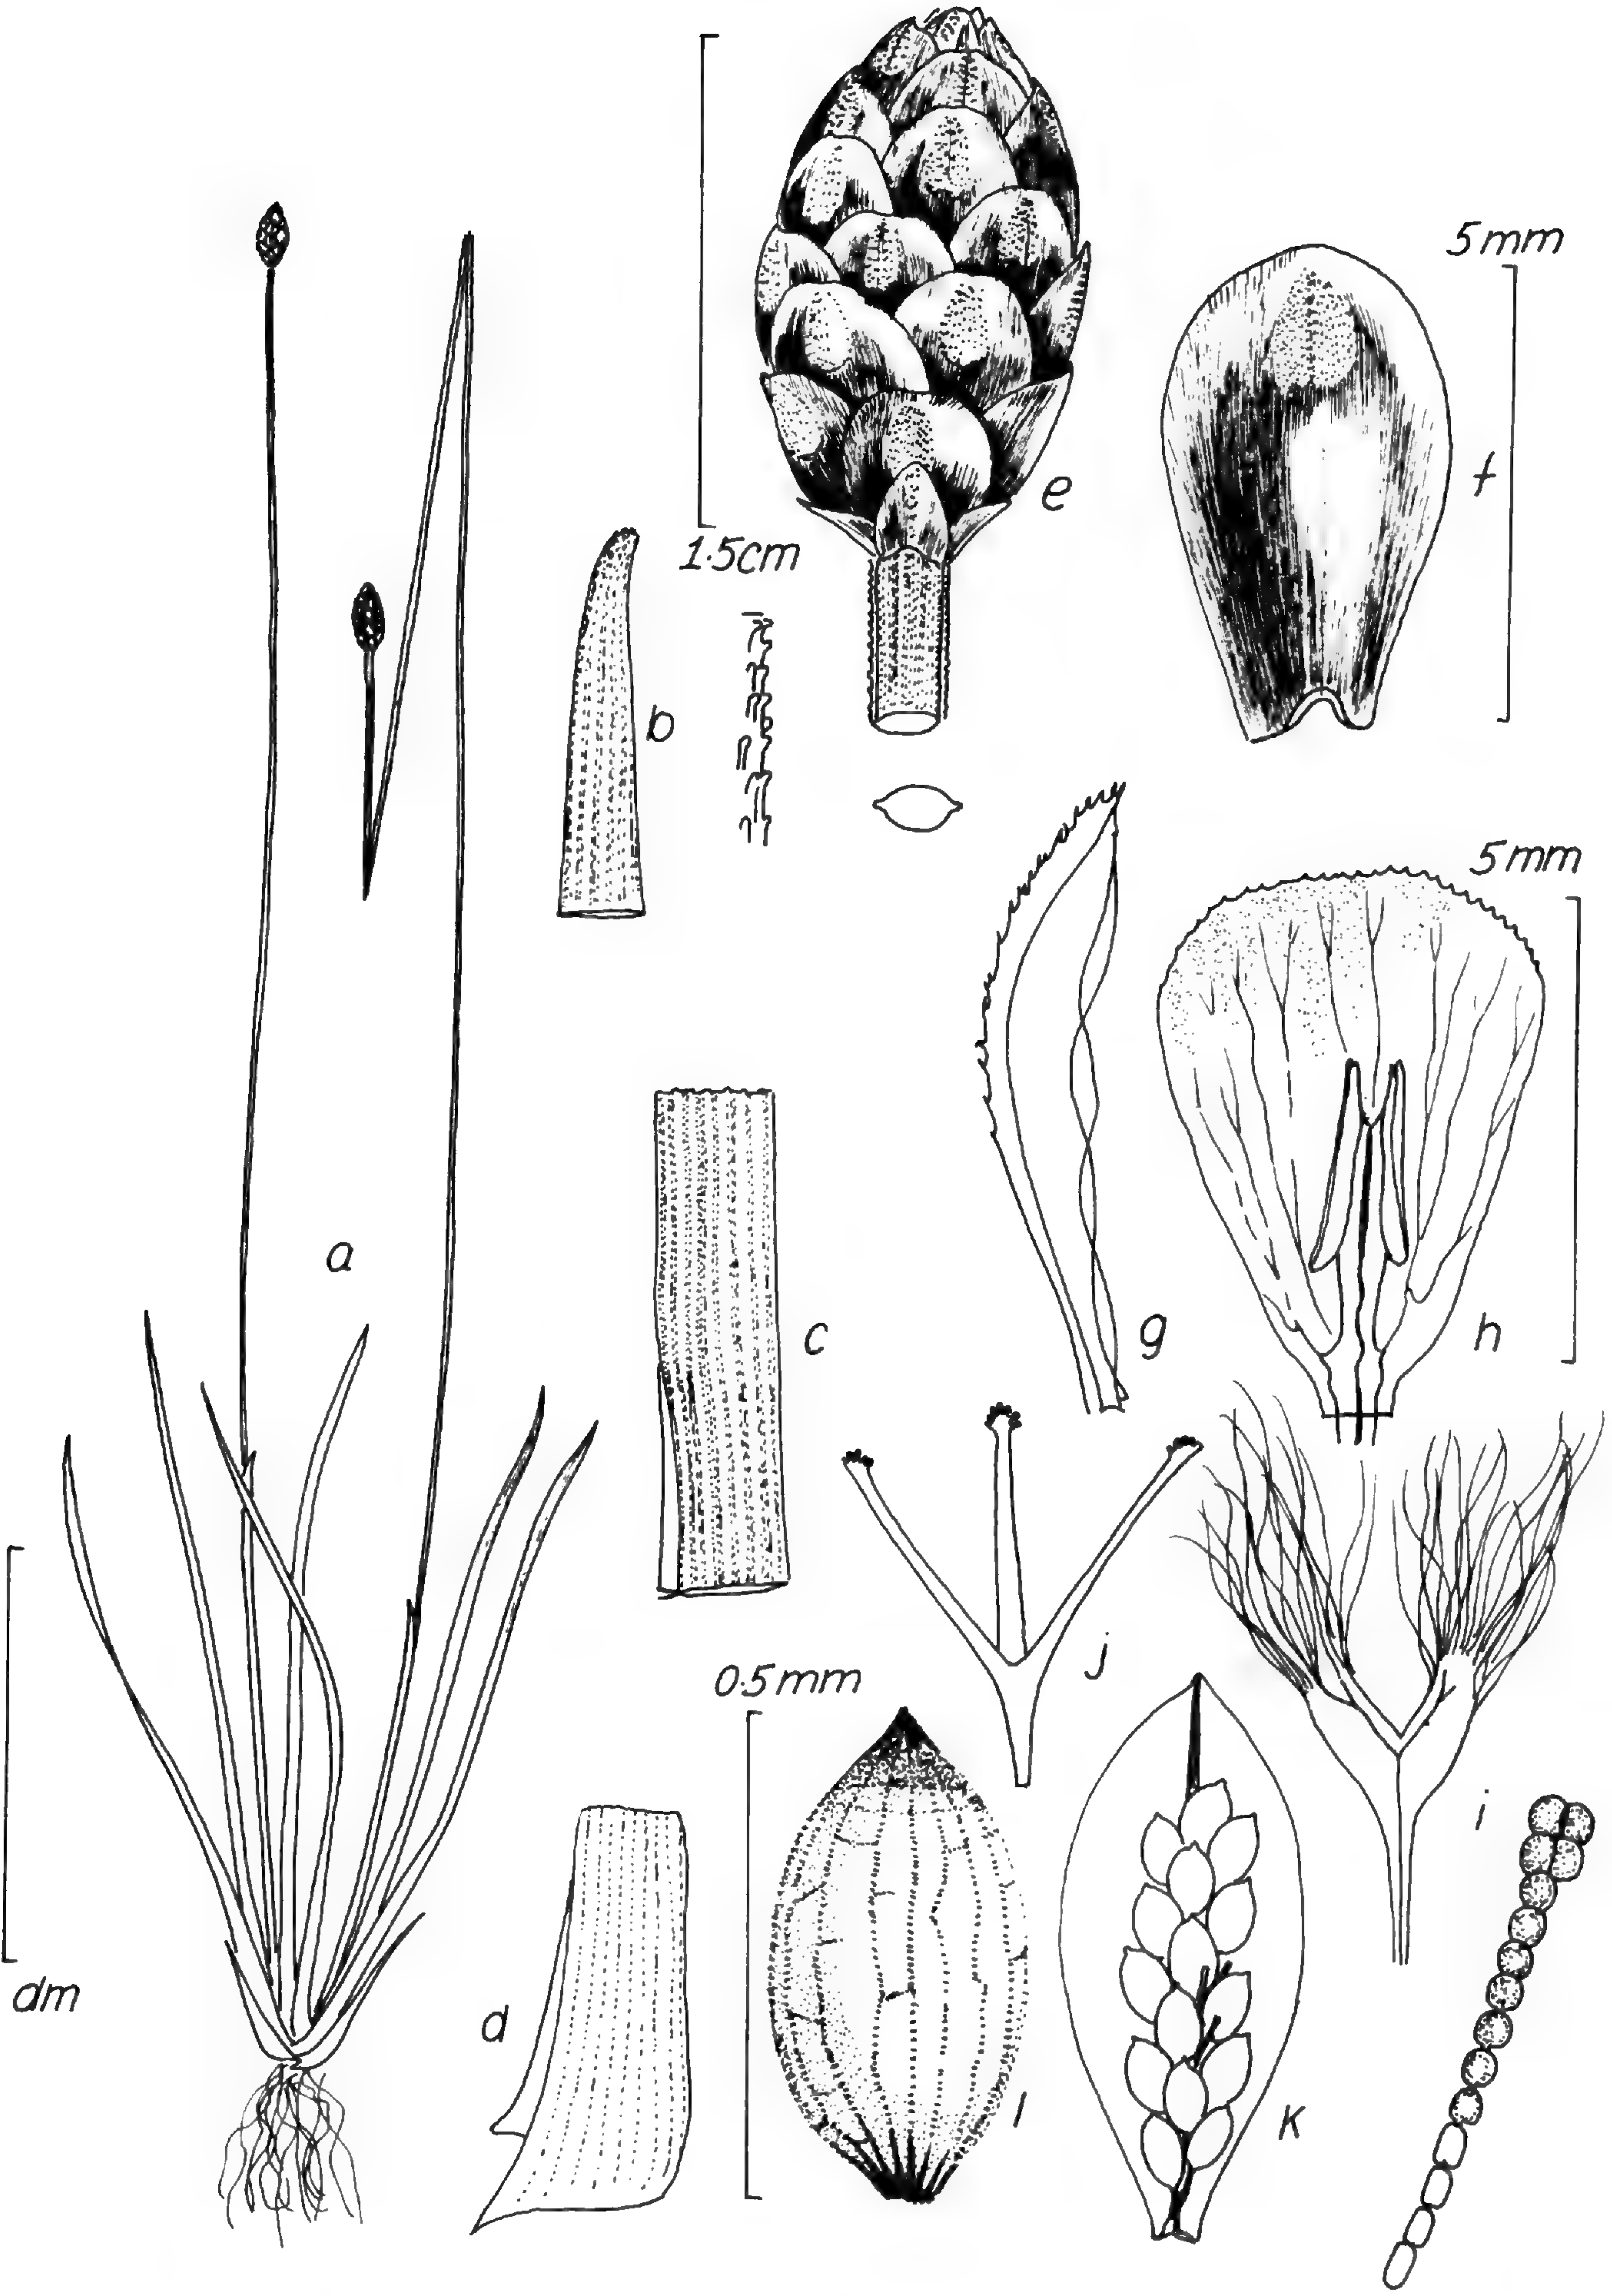

FIGURE 3. Xyris jupicai (Kral 25970). —*a. Habit sketch.—b. Leaf apex.—c. Leaf at blade-sheath junction.—d. Leaf base.—e. Spike.—f. Fertile bract.—g. Lateral sepal.—h. Petal blade, stamen.—i. Staminode, enlarged hair.—j. Stylar apex.—k. One valve of capsule.—l. Seed.*

1.5(−2.5) cm long, blunt or rarely acute, of many (several in depauperate individuals) rather loosely and spirally imbricate bracts, several of the lower ones sterile, narrower and shorter than the fertile bracts and grading into them; fertile bracts obovate to ovate, 5–7 mm long, apically rounded to broadly acute, the margin entire, aging erose, the backs strongly rounded, ecarinate, pale to dark red-brown, lustrous, the dorsal areas rectangular to elliptic, green, aging brown. Lateral sepals linear-oblanceolate, slightly curvate, from 3 mm long to equaling bracts, equilateral, very thin, usually pale green-tan, the thin but broad brownish keel lacerate from ca. middle to acute apex. Petal blades broadly obovate, ca. 3–4(−5) mm long, yellow, the broadly rounded to subtruncate apex denticulate-erose, the base cuneate. Staminodia bibrachiate with 2 broad flat branches terminally penicillate, most of the cells congested with dark material. Anthers lance-oblong, ca. 1.5 mm long, deeply bifid and auriculate on filaments ca. 1 mm long. Capsule thin, narrowly obovoid or ellipsoid, plano-convex, ca. 3–4 mm long, the placentae parietal, continuous to locule summit. Seeds broadly ellipsoid, ca. 0.4–0.5 mm long, pale amber, longitudinally with several papillate straight or anastomosing ribs and with several weaker cross-lines.

Distribution. Throughout the southeastern United States southward through the Caribbean and Central America, mostly at lower elevations, south into Argentina.

This morning-bloomer is a common wetlands weed over much of its range, generally in Central and South America, sharing its habitat with *X. laxifolia*, with which larger specimens are confused. Original material of "*X. macrocephala*" Vahl is largely *X. jupicai* (see discussion of species 2).

4. **Xyris navicularis** Griseb., Cat. Pl. Cub. 223. 1866. TYPE: Cuba: "savannas Dayanigua, *C. Wright 3229*" (presumed location of lectotype, HAC; isotypes, NY, US). Figure 4.

X. subnavicularis Malme, Ark. Bot. 13^8: 15. 1913. TYPE: Belize: Stann Creek, Honduras, Rev. *J. Robertson* (holotype, BM).

Perennial or annual, usually cespitose, to 4.5 dm tall. Leaves flabellately spreading, (4–)10–15(−20) cm long; sheaths entire or, rarely, papillose or scabridulous-edged, the broad, clasping base maroon, brown or red-brown, often papillose, narrowing gradually into the blade, the ligule lacking or inconspicuous; blades linear-gladiate, flattened, sometimes slightly twisted, sometimes curvate, 2–5 mm wide, yellow-green or maroon-tinted, the apex incurved-acute, incrassate, the edges thin, entire or more often papillate or tuberculate-scabrid, the surface smooth or with short lines of papillae or tubercles proximally. Scape sheaths shorter than leaves, terete and multicostate, lustrous brown proximally, the blade often conspicuous, leaflike. Scapes linear, sometimes twisted, distally flattened, bicarinate, 0.8–1.2 mm broad, the costae often papillose-tuberculate. Spikes narrowly ovate to oblong (0.7–)1–2(−2.5) cm long, of several to many loosely spirally imbricated, pale brown or dark brown bracts; lowest sterile bracts distinctly smaller than the fertile bracts, narrower, mostly lanceolate, keeled, acute, grading gradually into the fertile bracts, these ovate to broadly oblong or suborbicular, ecarinate or imperceptibly so, ca. 4–5 mm long, broadly rounded, the rounded backs papillate, the edges thin, at first entire, the dorsal areas subapical, lanceolate to ovate, paler, often inconspicuous (particularly in age). Lateral sepals free, equilateral, elliptic, 3.5–4.5 mm long, strongly curvate, lustrous red-brown, the keel firm but narrow, ciliate or ciliolate from near base to acute apex. Petal blades broadly obovate, ca. 5 mm long, yellow, the rounded apex crenate-erose. Staminodia bibrachiate, the flat branches at tips long-penicillate. Anthers broadly oblong, ca. 1.5–2 mm long, deeply bifid and sagittate, on filaments ca. 1.5 mm long. Capsule obovoid, 4 mm long; placentation 3-parietal. Seeds ellipsoid or ovoid, 0.5–0.6 mm long, short-caudate, with 9–10 raised and smooth longitudinal ribs per side and sev-

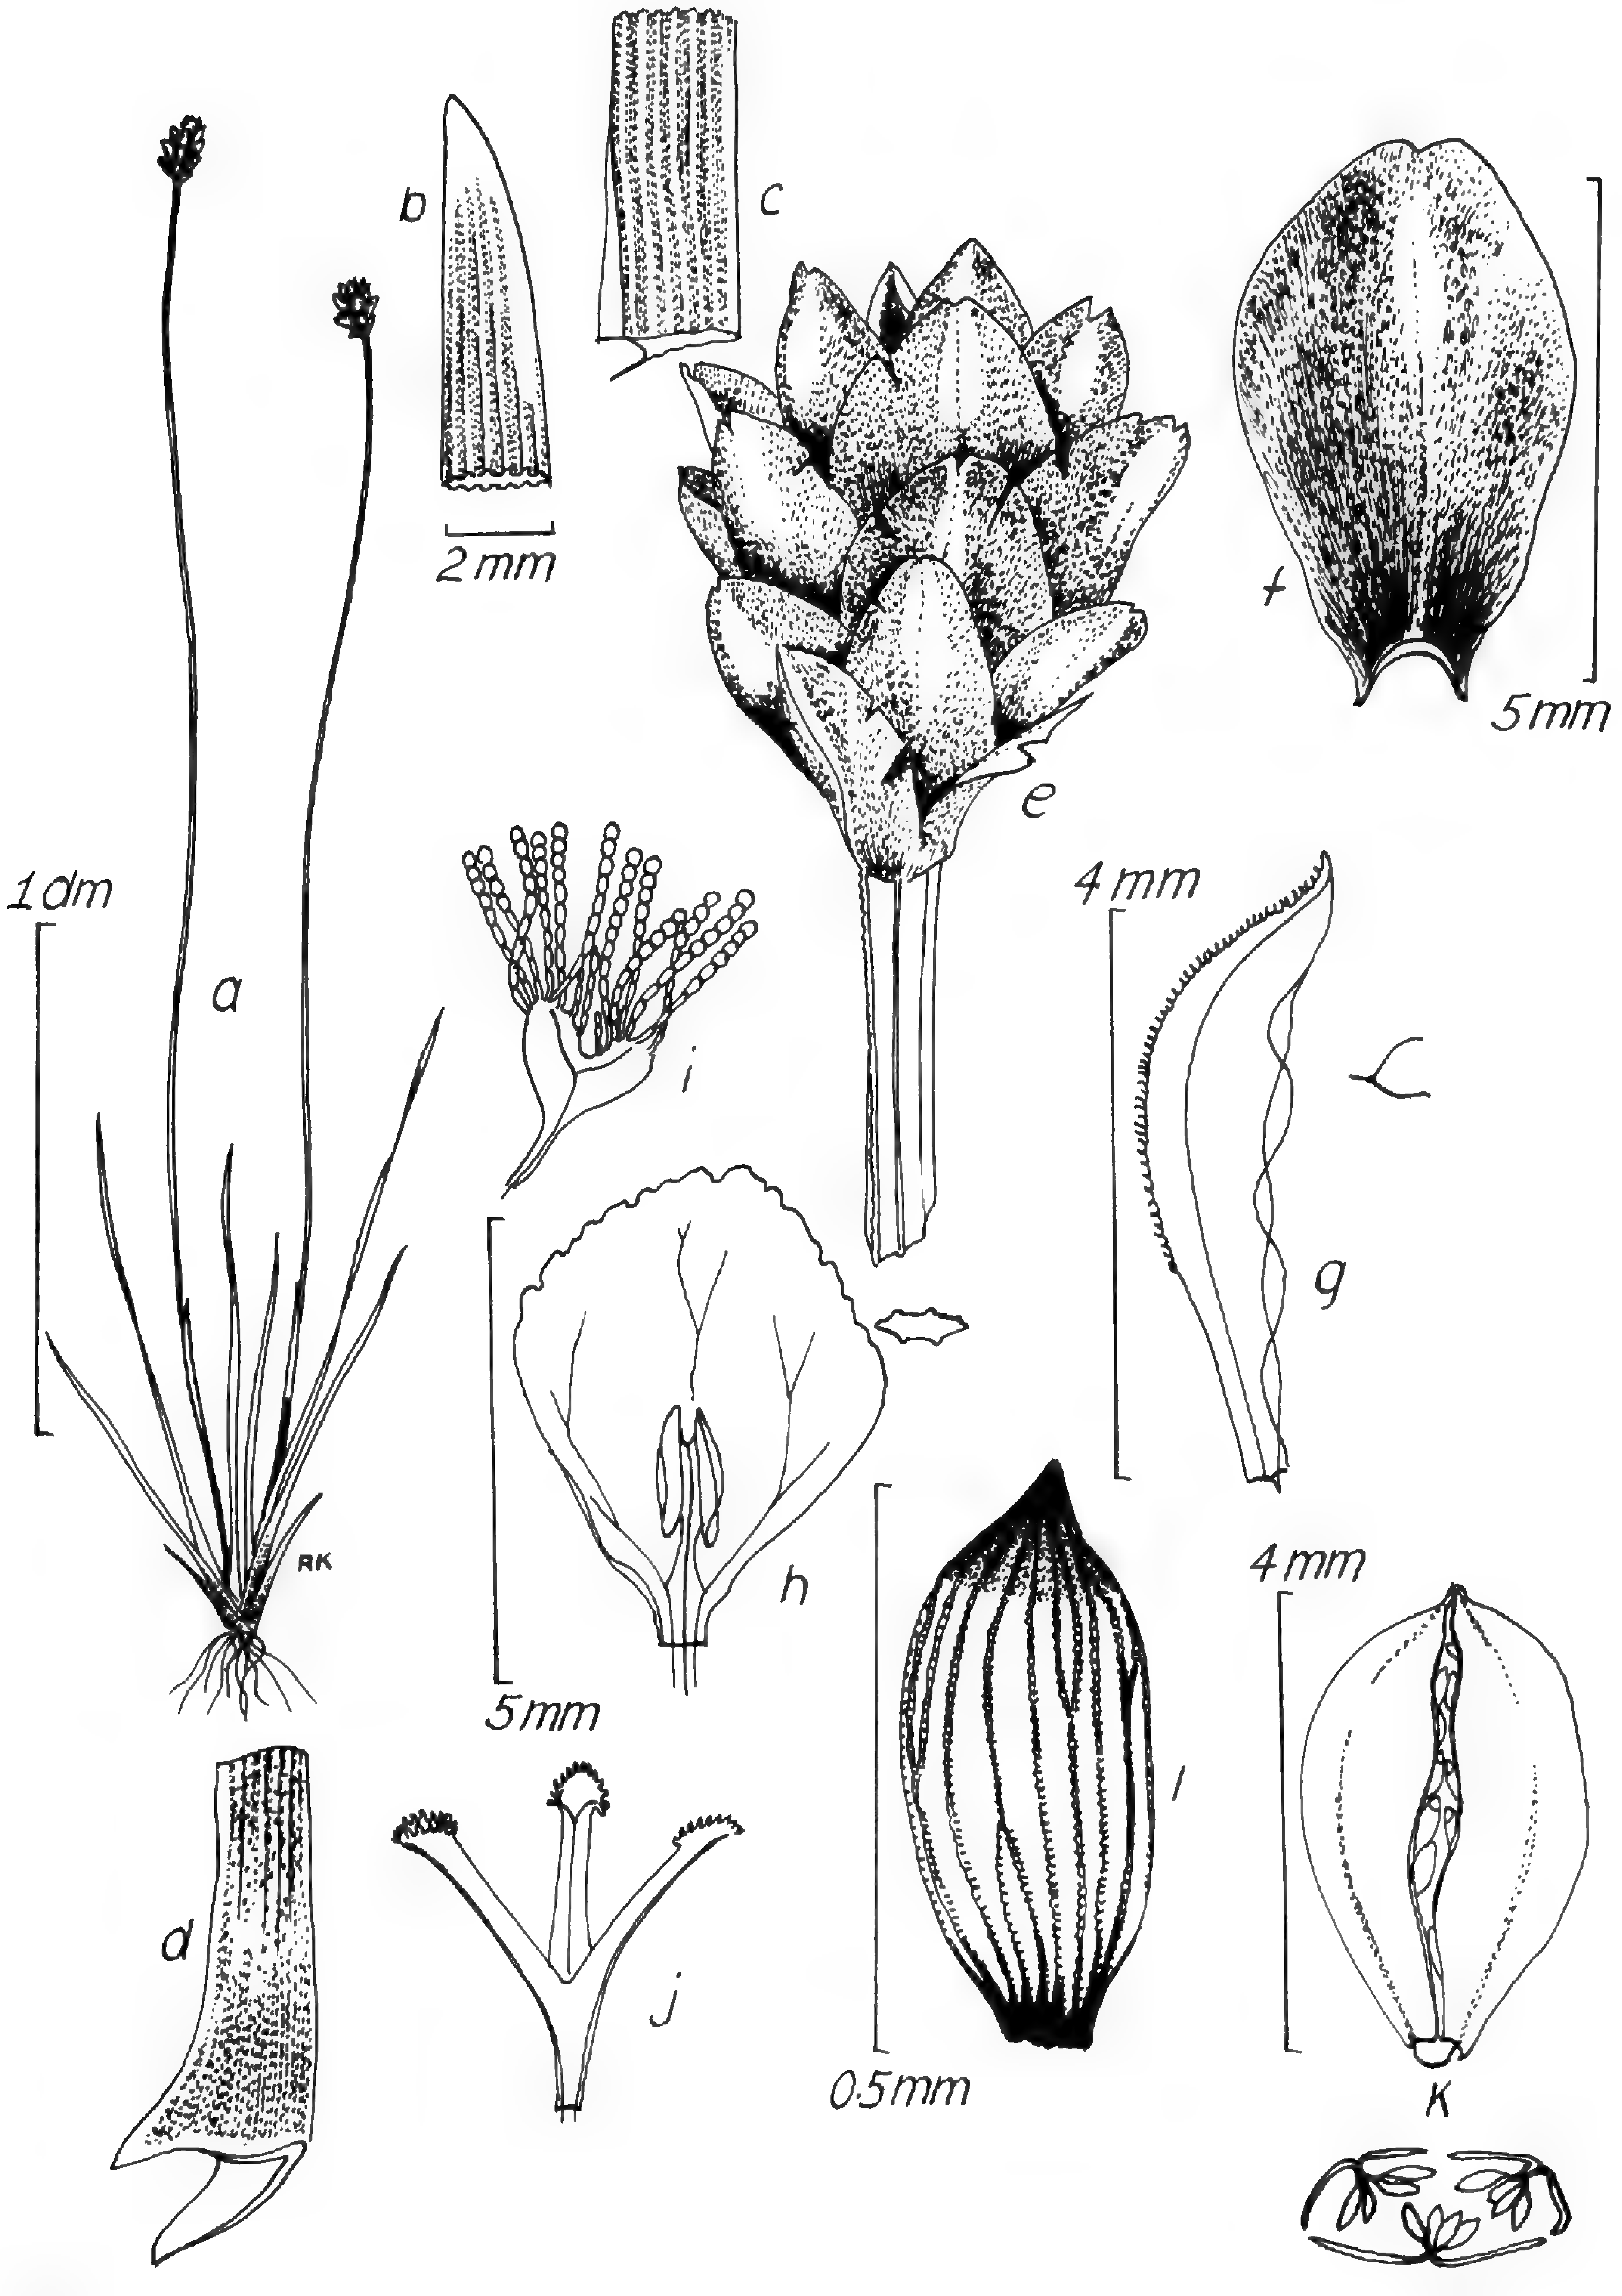

FIGURE 4. Xyris navicularis (G. Proctor 38799).—*a. Habit sketch.—b. Leaf apex.—c. Leaf blade–sheath junction.—d. Leaf base.—e. Spike.—f. Fertile bract.—g. Lateral sepal.—h. Petal blade, stamen.—i. Staminode.—j. Stylar apex.—k. Capsule (outer face, showing line of dehiscence along dorsal bundle, this revealing tips of two placental lines of seeds).—l. Seed.*

eral indistinct crosslines, deep, lustrous, translucently amber.

Distribution. Low-altitude sandy palm or pine savanna from western Cuba through Belize and Honduras southward into Nicaragua (Zelaya); Colombia.

Xyris subnavicularis Malme, supposedly distinguished by having longer leaf sheaths associated with ciliate-scabrid blades and by its indistinct dorsal areas, falls in regard to these characters well within the total range of variation of *X. navicularis*. The species definitely centers in Cuba as to abundance.

5. **Xyris anceps** Lam., Illustr. I: 132. 1791. TYPE: "Guyane francaise," Herb. Hornemann (P, photo at F). Figure 5.

X. platycaulis Poiret, Encycl. 8: 820. 1808.
X. nitida Willd. ex Dietr., Sp. Pl. 2: 372. 1833.
X. pallida C. Martius, Fl. Bras. 24, Beibl. 2: 57. 1841. TYPE: Brazil. Bahia: "litoral, Camamu," 1818, *Martius s.n.* (type, M, photo at F).
X. fontanesiana Kunth, Enum. Pl. 4: 10. 1843.
?*X. bahiensis* Steudel, Syn. Pl. Glum. 2: 287. 1855.

Low to moderately robust, solitary or cespitose, glabrous, soft-based annual (1–)1.5–8 dm high. Leaves erect to spreading flabellately, the principal ones 5–40 cm long; sheaths up to ½ as long as blades, pale brown to stramineous or pink, soft, entire, multicostate, keeled just above base, the mid costa often papillose, the edges scarious, entire, gradually narrowing to the blade, there with a ligule up to 1 mm long; blades flattened, straight, ensiform-linear, pale or deep green, bluntly incurved-acute, the edges thin, or slightly incrassate and papillose-tuberculate. Scape sheaths shorter than principal leaves, loosely tubular, multicostate, proximally lustrous brown or pale brown, distally with short, erect blades. Scapes straight or flexuous, twisted, mostly bicostate distally, even ancipital, 1–3 mm wide, the costae entire or papillose. Spikes broadly ovoid, subglobose or hemispheric, 0.4–1.5 cm long, blunt, of several thin, scarious, pale to red-brown, lustrous, spirally imbricate bracts, these with short, subapical, gray-green, lanceolate dorsal areas, or the lowest bracts with elongate-lanceolate dorsal areas. Sterile bracts few, strongly keeled, about as long as the fertile bracts, these broadly obovate to suborbicular, 4–5.5 mm long, apically rounded, entire, the backs rounded, keeled strongly toward apex. Lateral sepals free, subequilateral, linear-oblanceolate, 4–5 mm long, acuminate or narrowly acute, the keel firm, smooth, slightly broadened distally. Petal blades obovate, ca. 3 mm long, coarsely dentate at broadly rounded apex. Staminodia broadly bibrachiate, the branches distally penicillate. Anthers oblong, ca. 1 mm long, deeply bifid and sagittate, on filaments ca. 0.5 mm long. Capsule oblong-obovoid or ellipsoid, ca. 3.5 mm long, umbilicate, the valves firm, lustrous brown, the placentation parietal from base to tip of fruit. Seeds broadly ovoid or ellipsoid, 3.5–4.5 mm long, translucent, pale to deep brown, biapiculate, strongly longitudinally ribbed, sparsely and finely cross-lined.

Distribution. Widespread and weedy in open, wet, acid areas and often littoral; Africa (including Madagascar); South America from the Guianas south to southern Brazil.

6. **Xyris brachyfolia** Kral & Wanderley, sp. nov. TYPE: Brazil. Amazonas: plateau of northern massif of Serra Araca, 0°51–57′N, 63°21–22′W, 1,200 m; southern extremity of northern plateau of Serra Araca, shrub forest. Growing on floor of moist shrubby forest, 15 Feb. 1984, *G. T. Prance, I. L. do Amaral, J. J. Pipoly, A. S. Tavares, M. G. da Silva, C. D. A. da Mota & A. Cress 29079* (holotype, INPA; isotypes, NY, VDB). Figure 6.

Planta perennis, caespitosa, glabra, 4–5 dm alta. Caules breves. Radices graciles. Folia principalia curta, suberecta, brunneola, nitida, vaginis scaporum breviora, persaepe stricte vagina, vel usque ad 5 cm longa, vulgo vagina; vaginae albovillosiciliatae, ad basin gradatim dilatatae, in laminas gradatim decrescentes, eligulatae; laminae leviter compressae, excurvatae, acutae, integrae. Vaginae scaporum elongatae, usque ad 1 dm longae, multicostatae, tortae, nitidae. Scapi graciles, erecti, torti, apicem versus teretes, multistriati vel valde costati, 0.7–0.9 mm crassi. Spicae pauciflorae, ellipsoideae, tum anguste obovoideae,

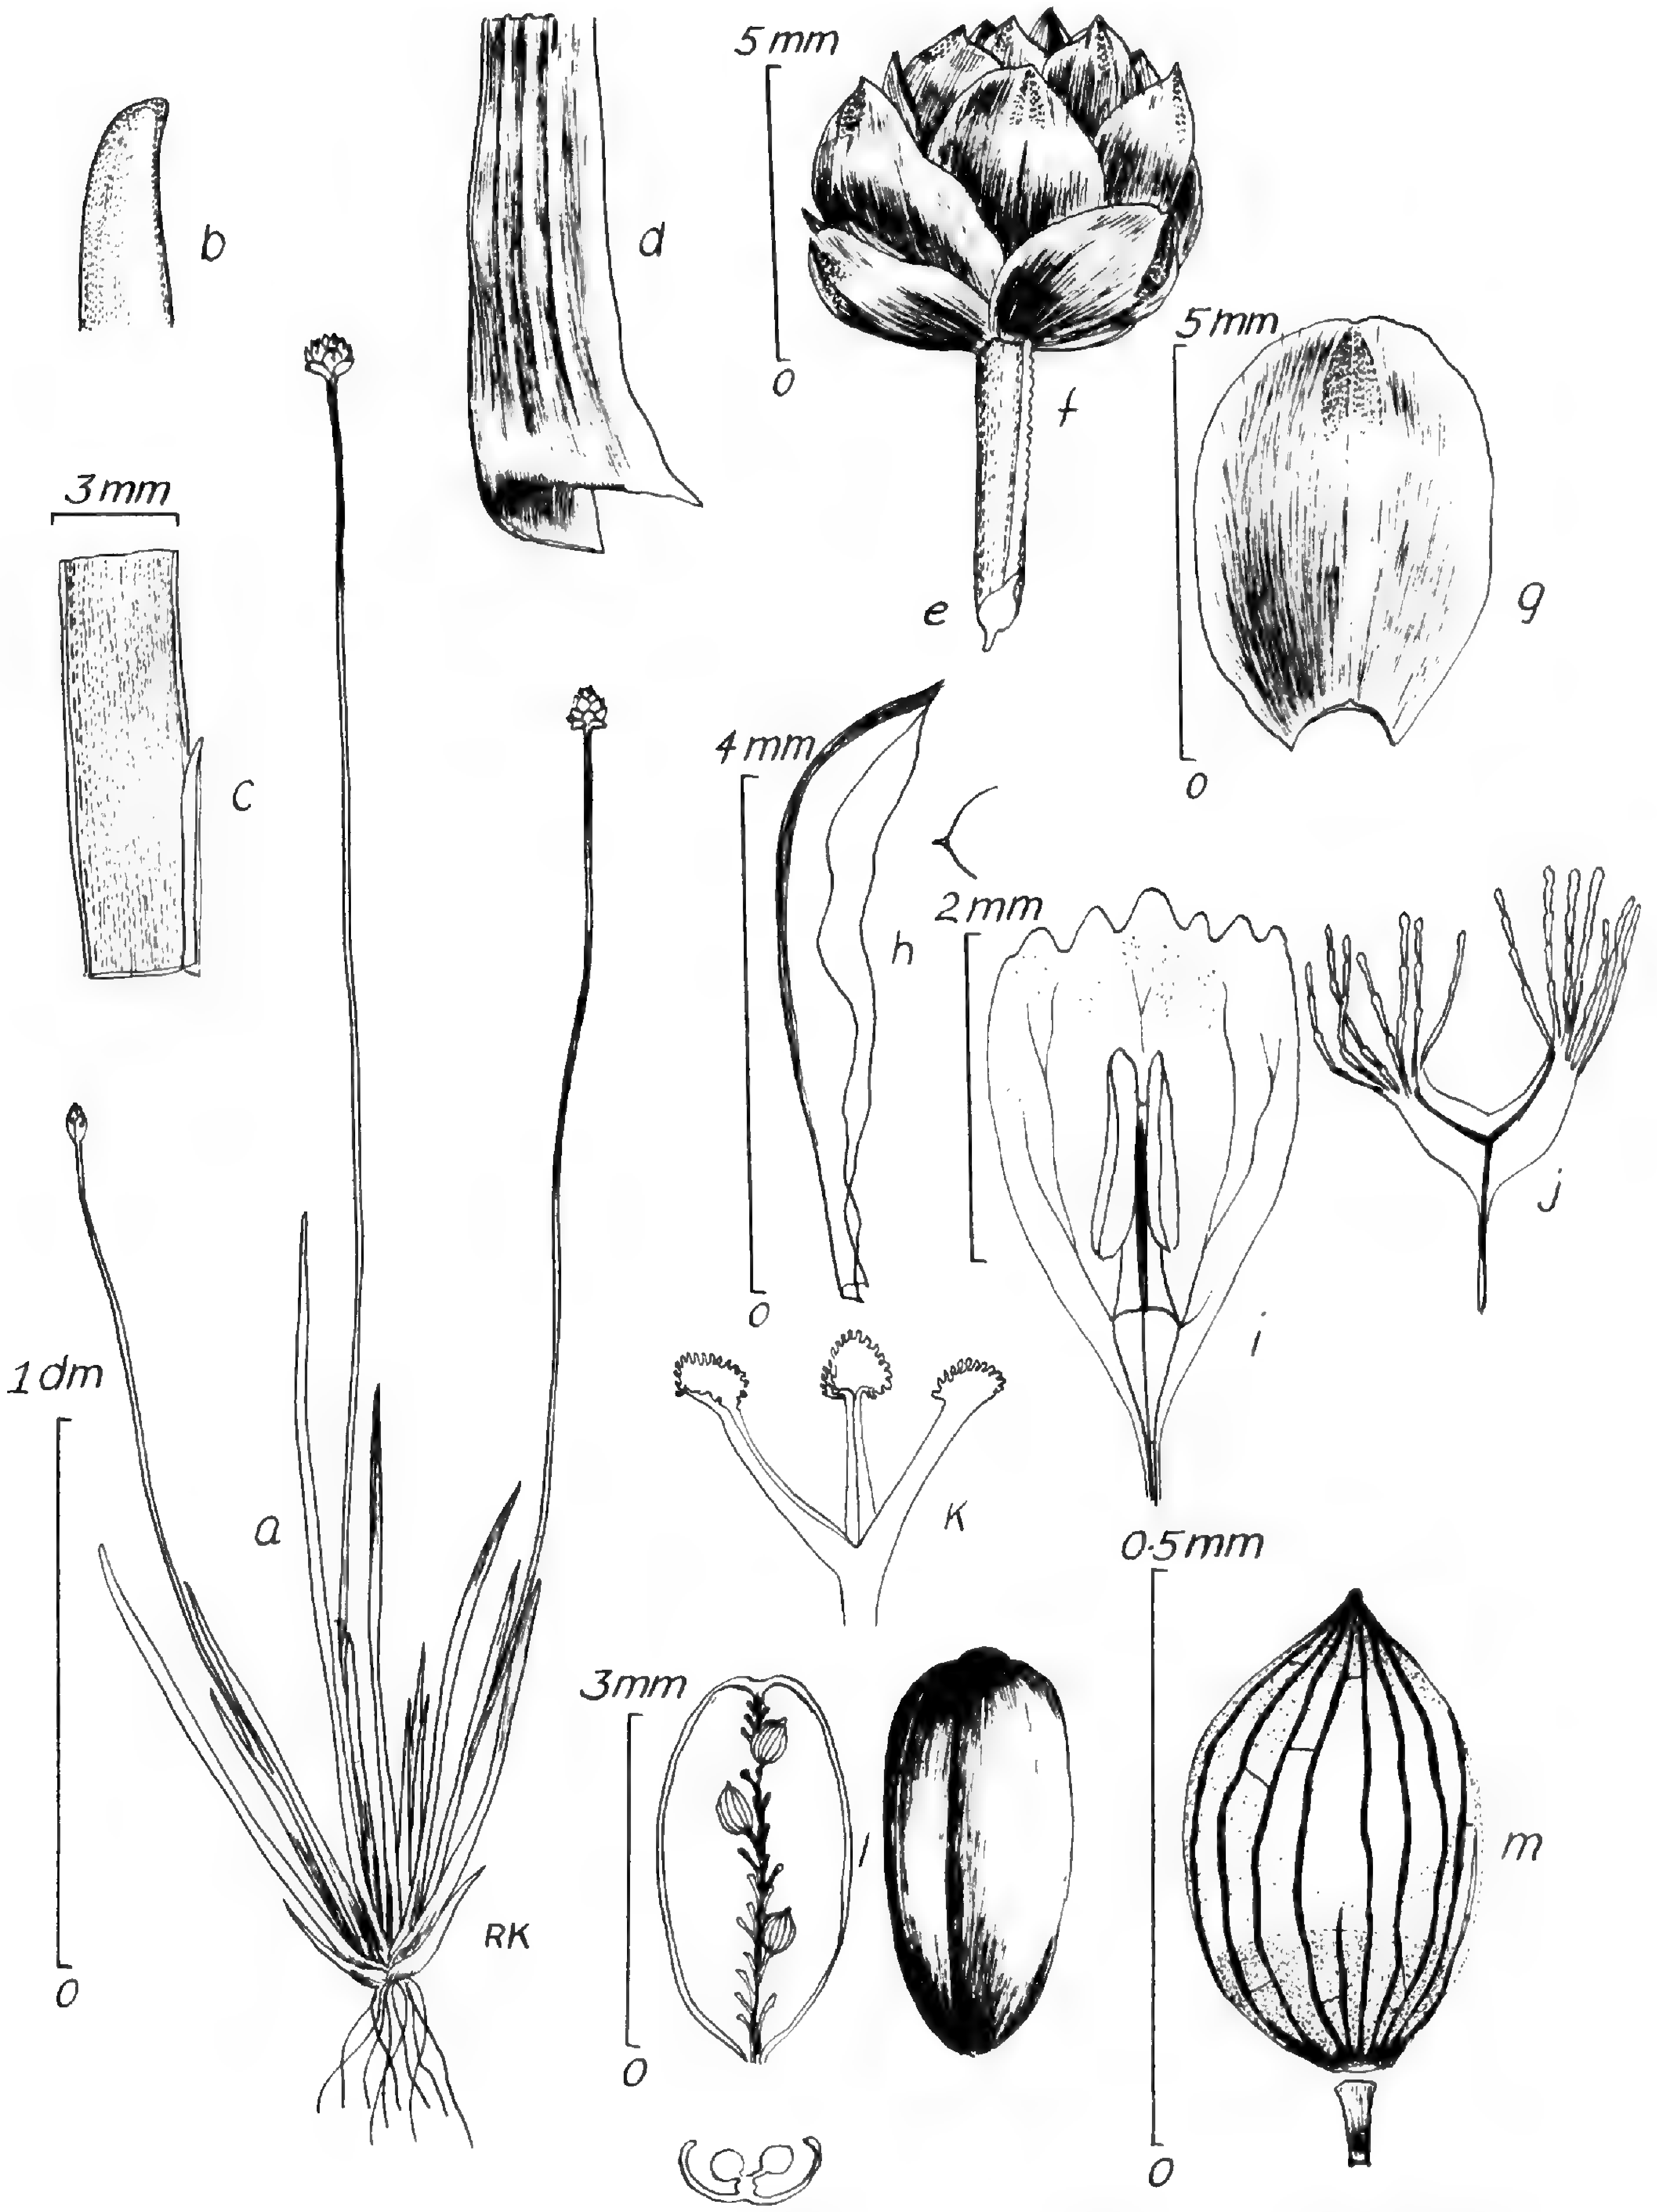

FIGURE 5. Xyris anceps (Austin et al. 6950). —*a. Habit sketch.*—*b. Leaf tip.*—*C. Leaf blade–sheath sector.*—*d. Leaf base.*—*e. Upper scape.*—*f. Spike.*—*g. Fertile bract.*—*h. 5–7 mm longae. Bracteae laxae spiraliter imbricatae, area dorsali conspicue; bracteae steriles 5–6, infimis late ovatis vel suborbiculatis, 1–2 mm longis, margine scariosis et dorsaliter albovillosis, superioribus ovatis, 3.5–4.5 mm longis, rotundatis, integris; bracteae fertiles ovatae, 4.5–5 mm longae, rotundatae, integrae, matrice brunneola, nitida, area dorsali ovata, viridula, mediana vadosi costali. Sepala lateralia libera, subaequilateralia, lanceolata, ca.

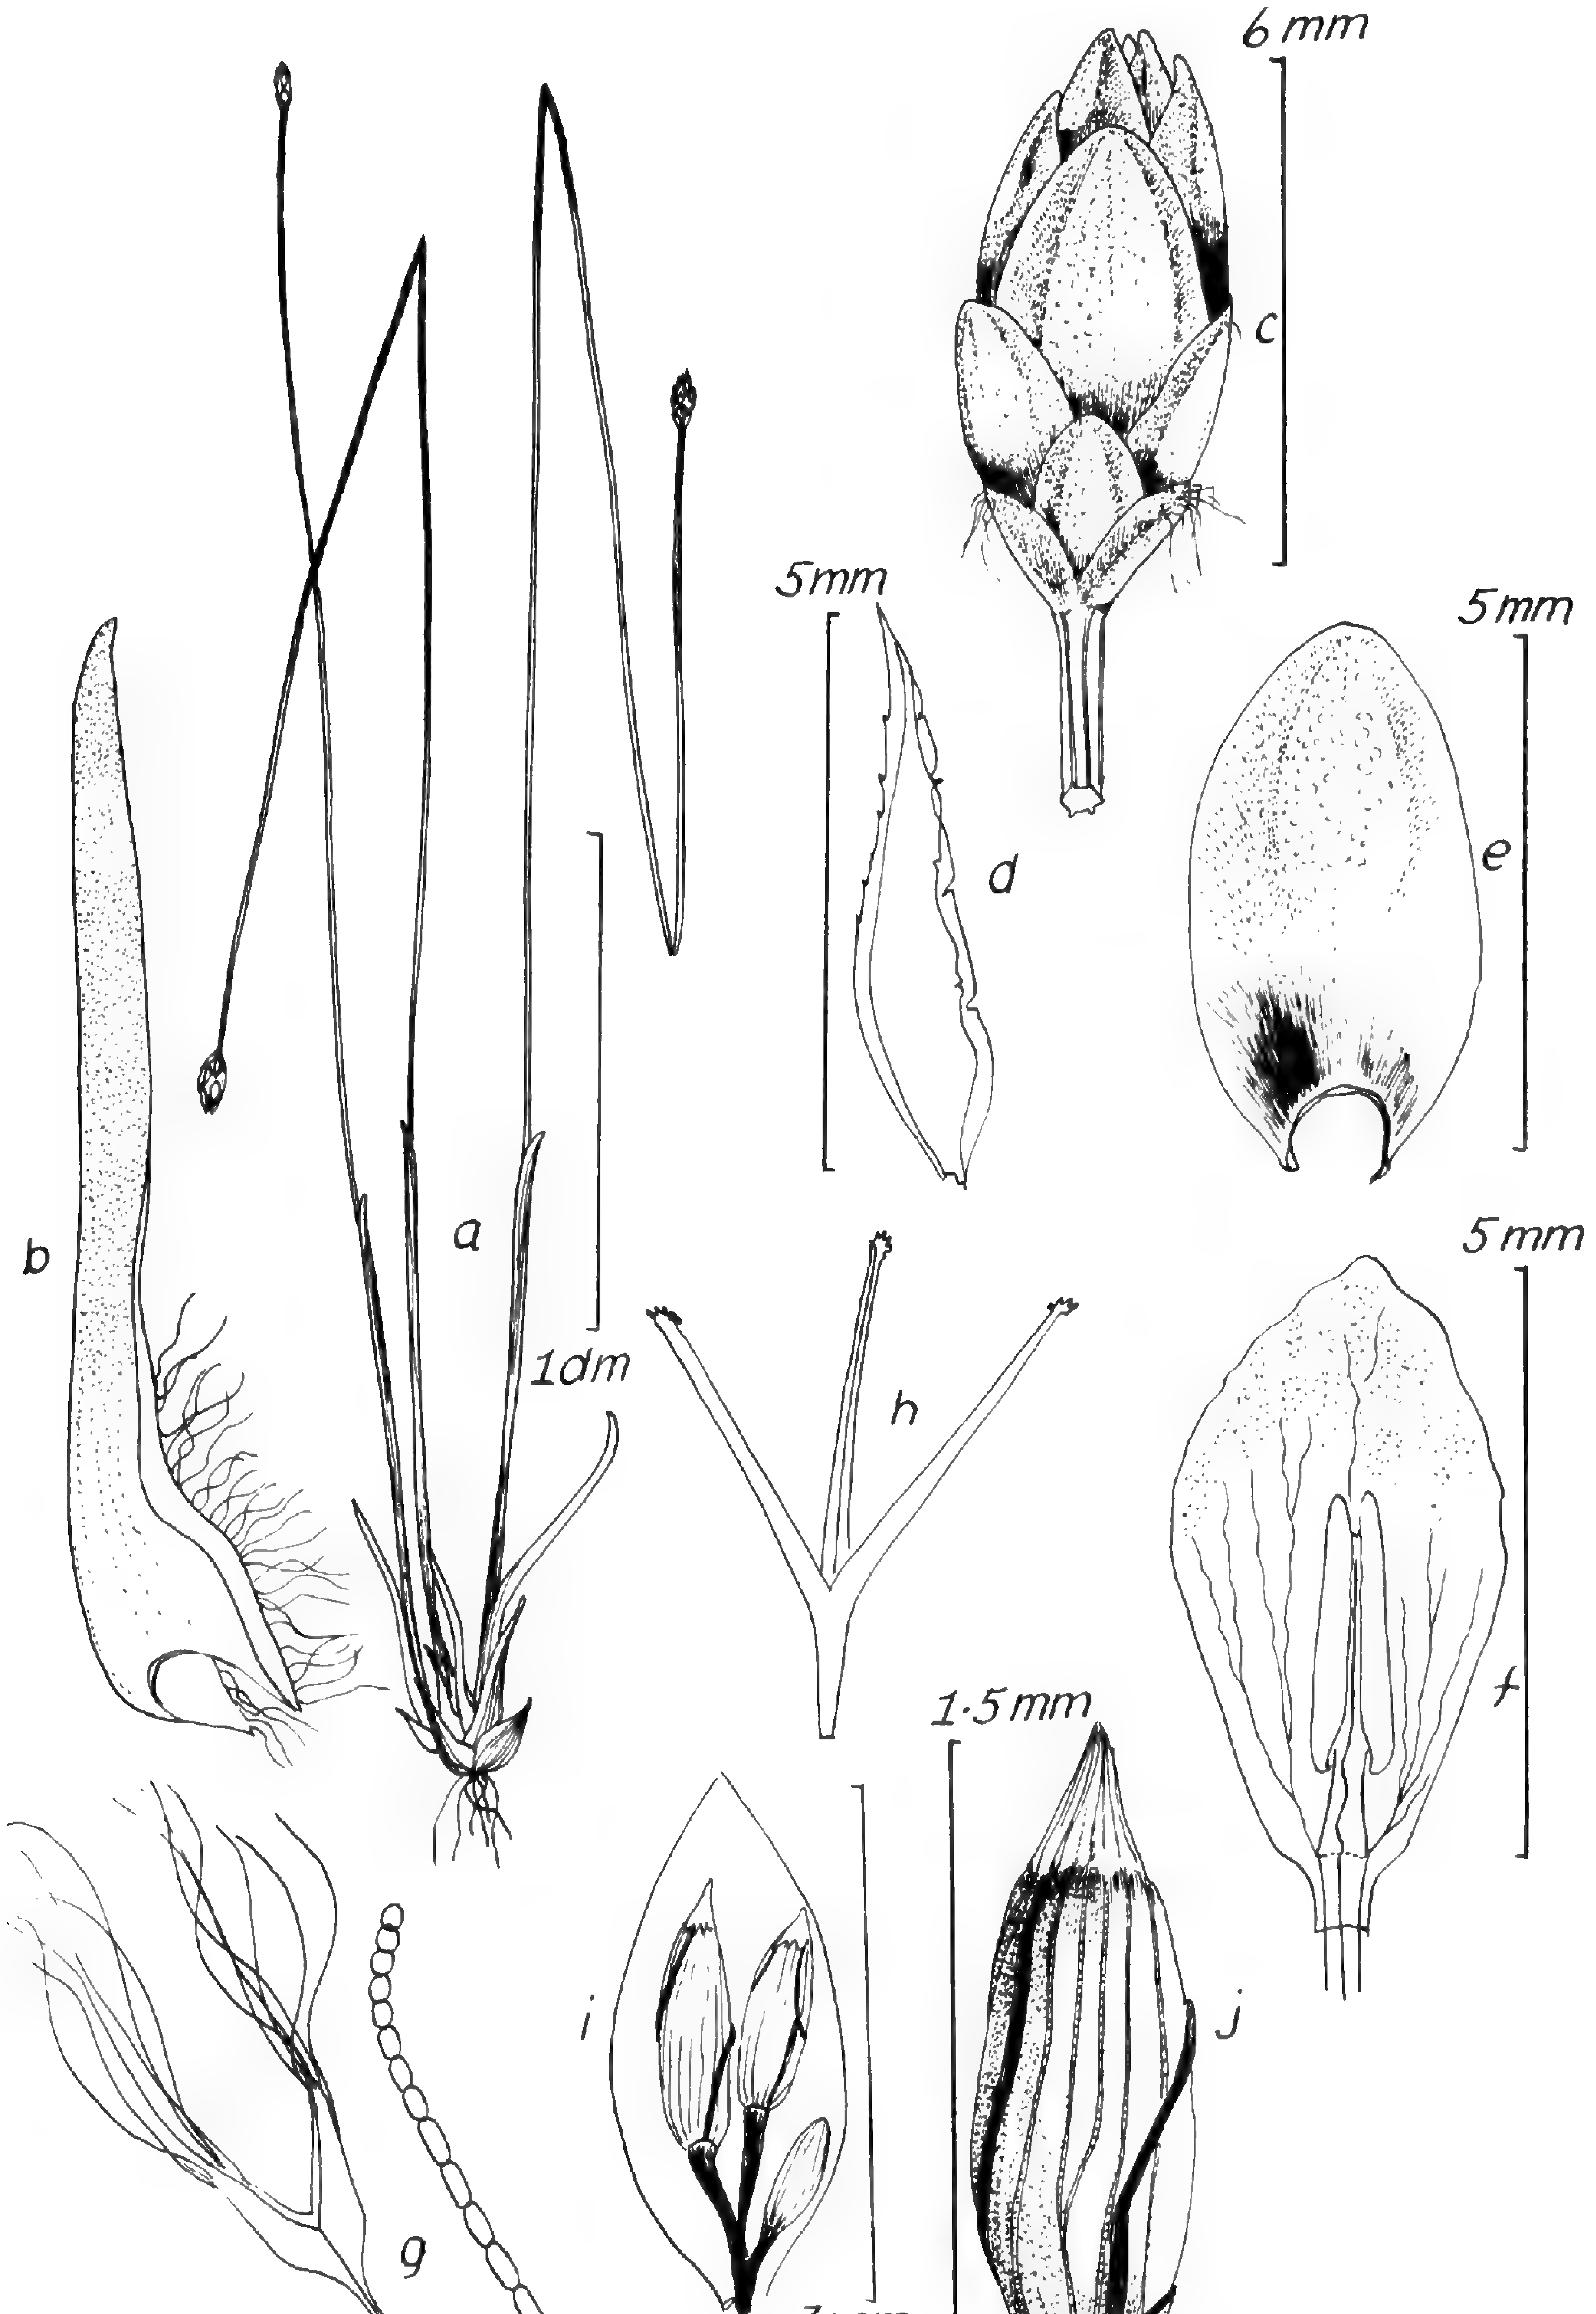

FIGURE 6. Xyris brachyfolia (Prance et al. 29079).—*a. Habit sketch.*—*b. Principal leaf.*—*c. Spike.*—*d. Lateral sepal.*—*e. Fertile bract.*—*f. Petal blade, stamen.*—*g. Staminode and beard hair.*—*h. Stylar apex.*—*i. Valve of capsule with attached placenta, seeds.*—*j. Seed.*

5 mm longa, acuta, delicatula, leviter curvata, ala carinali distaliter distante scabrolacera vel scabrida. Lamina petalorum obovata, luteola, ca. 5 mm longa, anguste rotundata, integra. Staminodia bibrachiata, brachiis longipenicillatis. Antherae lanceolatae, 1–1.2 mm longae; filiis ca. 1 mm longis. Capsula ca. 3 mm longa, ovoidea, placenta basalis-parietalis. Semina fusiformes, ca. 1.5 mm longa, translucentia, atroferruginea, valde longitudine costalis.

Cespitose perennial, smooth, 4–5 dm high. Stems short. Roots slender and fibrous. Principal leaves short, suberect, brownish, lustrous, shorter than the scape sheath, often strictly sheath, up to 5 cm long, then mostly sheath; sheaths white-villous-ciliate, gradually broadening to base, gradually narrowing to apex, eligulate; blades lightly flattened, excurvate, acute, entire. Scape sheaths elongate, to 1 cm long, multicostate, twisted, shining, short-bladed or cuspidate. Scapes slender, erect, twisted, terete toward apex, multistriate to shallowly costate, 0.7–0.9 mm thick. Spikes few-flowered, ellipsoid, becoming narrowly obovoid, 5–7 mm long. Bracts spirally and loosely imbricate, the dorsal area conspicuous; sterile bracts 5–6, the lowest broadly ovate to suborbicular, 1–2 mm long, marginally scarious and dorsally white-villose, the uppermost ovate, 3.5–4.5 mm long, rounded, entire; fertile bracts ovate, 4.5–5 mm long, rounded, entire, the matrix brown, lustrous, the dorsal area ovate, green, medially shallowly costate. Lateral sepals free, subequilateral, lanceolate, ca. 5 mm long, acute, delicate, slightly curvate, the keel distally distantly scabrolacerate or scabrid. Petal blades obovate, yellow, ca. 5 mm long, narrowly rounded, entire. Staminodes bibrachiate, the branches long-penicillate. Anthers lanceolate, 1–1.2 mm long, on filaments ca. 1 mm long. Capsule ca. 3 mm long, ovoid, the placentae basal-parietal. Seeds fusiform, ca. 1.5 mm long, translucent, deep red-brown, strongly ribbed longitudinally.

This species is morphologically closest to extremes of *X. fallax* Malme and is particularly noteworthy because of its transitional placentation type: basal-parietal. This is a further indication of the weakness of sections in *Xyris* based primarily on placentation. The long and strongly ribbed seeds with strong, irregularly raised outer seed coat are hardly distinguishable from those of *X. fallax*; pigmentation of leaves and scapes is likewise within the range of that species. However, the distinctly pale-villous patches on the spike bracts are notable and distinct. The sheath borders are consistently long-ciliate.

7. **Xyris neblinae** Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 26, fig. 11A–E. 1963. TYPE: Venezuela. T. F. Amazonas: summit savanna near west escarpment 2 km north of Cumbre Camp, occasional, 1,800 m, Cerro de La Neblina, Río Yatúa, 12 Jan. 1954, *B. Maguire, J. J. Wurdack & G. S. Bunting 37243* (holotype, NY; isotypes, US, VEN). Figure 7.

Tall, rushlike, cespitose, brittle perennial to 1 m tall, the stems contracted. Leaves erect, to 7 dm long; sheaths less than ½ as long as blades, firm, eciliate, dull-castaneous, nearly black, narrowing gradually from an abruptly dilated, deepset base to blade, at blade level with an erect, truncated ligule broader than leaf blade base; blades narrowly linear, terete except at the often narrow and dorsiventrally flattened base, ca. 1–1.5 mm thick, multiribbed; conic-subulate apically, the surface smooth except toward papillate base. Scape sheaths shorter than principal leaves, fluted, apically short-bladed. Scapes flexuous, twisted, terete distally, ca. 1 mm thick, ecostate, striate, sometimes papillate. Spikes ellipsoid to lance-ovoid, 1–2 cm long, acute and attenuate, reddish brown, of many, loosely and spirally imbricated papillose bracts with distinct, paler, red-brown to green dorsal areas, these with a low midnerve; sterile bracts several, oblong or narrowly ovate, slightly to much shorter than the fertile bracts, the lowest smallest and keeled, grading gradually into the fertile bracts, these ca. 8 mm long, broadly oblong, ciliolate, the backs convex and ecarinate, the apex broadly to narrowly rounded. Lateral sepals free, subequilateral, lineal, ca. 8–10 mm long, sometimes exsert-

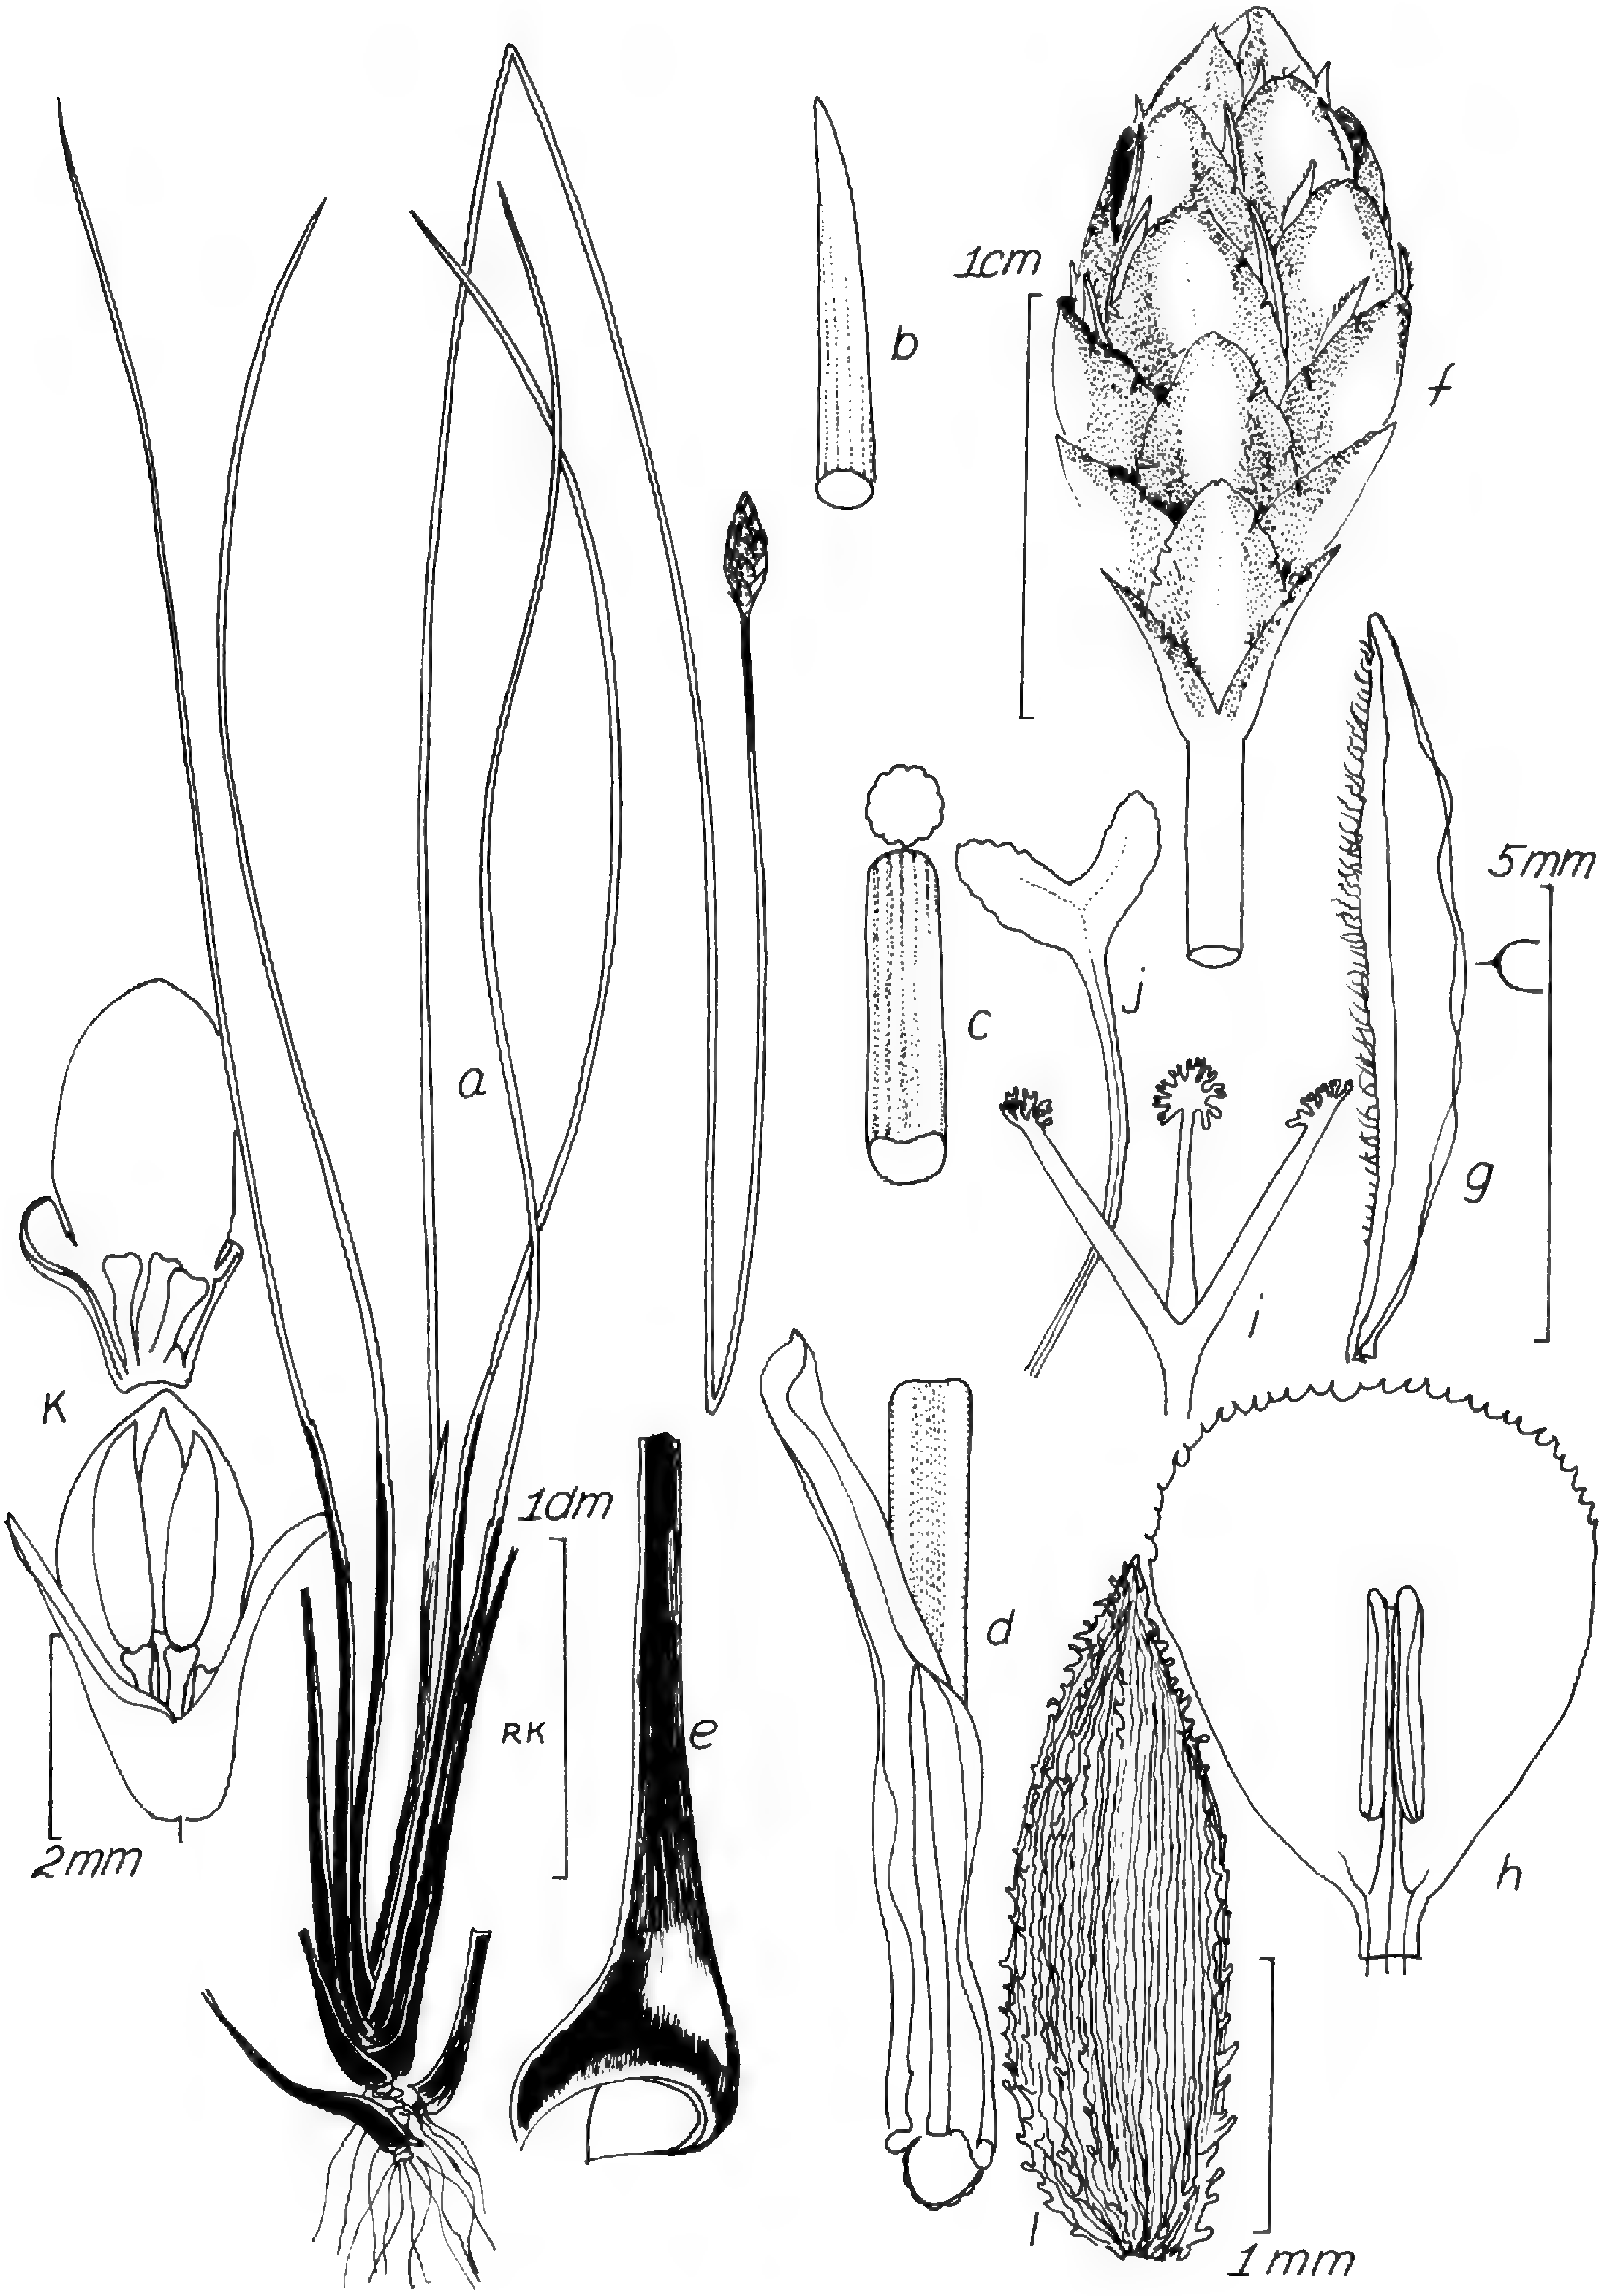

FIGURE 7. Xyris neblinae (Maguire et al. 37243).—*a. Habit sketch.—b. Leaf apex.—c. Sector of leaf blade a few cm above sheath apex.—d. Leaf sheath–blade junction.—e. Leaf base.—f. Spike.—g. Lateral sepal.—h.*

ed, the narrow, red-brown keel red-ciliolate or villosulous-ciliate from near base to the acute but blunt apex. Petal blades broadly obovate, 7–8 mm long, yellow, the broadly rounded apex lacerodentate. Staminodia bibrachiate, the short, broad, flat branches without hairs. Anthers lance-oblong, 2–2.5 mm long, emarginate, shallowly auriculate, on filaments ca. 1 mm long. Capsules obovoid, 4–4.5 mm long, the placentation basal, the funiculi stubby, the valves firm, dehiscing only ⅔ down, lacking septa. Seeds few, mostly 3–4 per capsule, cylindric, 2.5–3 mm long including a pale apiculus 0.5 mm long, the surfaces deep amber, longitudinally finely ribbed, the ribs (particularly toward base and tip of seed) muriculate, papillate or tuberculate.

Distribution. Known only from the type area, in wet rocky savanna.

This rare species, so far known only from Cerro de La Neblina, most resembles the brittle, rushlike *X. juncifolia* Maguire & Smith of Cerro Guaiquinima of neighboring Estado Bolívar in Venezuela. However, that species has leaf bases brown (rather than castaneous or near black), strongly inequilateral (versus equilateral) sepals, bearded (versus beardless) staminodia, and shorter and smoother seeds. Nonetheless, the superficial resemblance is striking.

8. **Xyris juncifolia** Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 26, fig. 10A–E. 1963. TYPE: Venezuela. Bolívar: common in Cumbre Camp, 2,000 m, Cerro Guaiquinima, Río Paragua, 25 Dec. 1951, *B. Maguire 32750* (holotype, NY; isotype, US). Figure 8.

Slender, rushlike, cespitose, brittle perennial to 1 m high, the stems contracted or short-ascending and short. Leaves erect or ascending, 4–6 dm long; sheaths dull brown or red-brown, less than ½ as long as blades, eciliate, narrowing gradually from a slightly dilated base to leaf blade, there producing an erect, firm, broad, rounded ligule to ca. 2 mm long; blades terete, fluted, narrowly lineal, to 1.5 mm thick, toward base above ligule usually deeply sulcate, toward apex narrowing to a blunt, callused tip. Scape sheaths much shorter than leaves, tubular and multiribbed proximally, opening distally, slightly dilated, with a cusplike, blunt-tipped blade. Scapes slightly flexuous and twisted, about the width of leaf blades or slightly wider, wandlike, distally terete, sometimes shallowly grooved. Spikes ellipsoid to obovoid, 1.5–2 cm long, reddish brown, acute, basally attenuate, of many tightly spirally imbricate, ciliolate bracts with distinct, deeper brown dorsal areas, the sterile bracts numerous, broadly ovate, broadly rounded, much smaller than and grading into the fertile bracts; these obovate, ca. 6 mm long, rounded-folded, ecarinate but with a pale, low midrib, the apex broadly rounded, aging lacerate. Lateral sepals free, strongly inequilateral, oblong-curvate, ca. 5 mm long, acute or blunt, the dark red-brown, firm keel ciliolate, toward apex reddish fimbriolate. Petal blades broadly elliptic or broadly obovate, ca. 5 mm long, the broadly rounded apex lacerate. Staminodia bibrachiate, the narrow flat branches distally long-penicillate. Anthers ca. 1.5 mm long, oblong, deeply bifid and sagittate, on filaments ca. 1.5 mm long. Capsule broadly obovoid, slightly compressed, ca. 3 mm long, the placentation basal, the valves producing low septa. Seeds few, ellipsoid-cylindrical, ca. 1.5 mm long, apiculate, deep amber, longitudinally rather coarsely 20–24-ribbed.

Distribution. Locally frequent, summits of tepuis Guaiquinima and Jaua, Bolívar, and tepuis Duida and Paru, Amazonas, Venezuela.

←
Petal blade, stamen.—i. Stylar apex.—j. Staminode.—k. Capsule; below with seeds on funicles, valves separating naturally, above with two valves removed, showing seedless funicles.—l. Seed showing ribbing and muriculation (seeds much darker than shown).

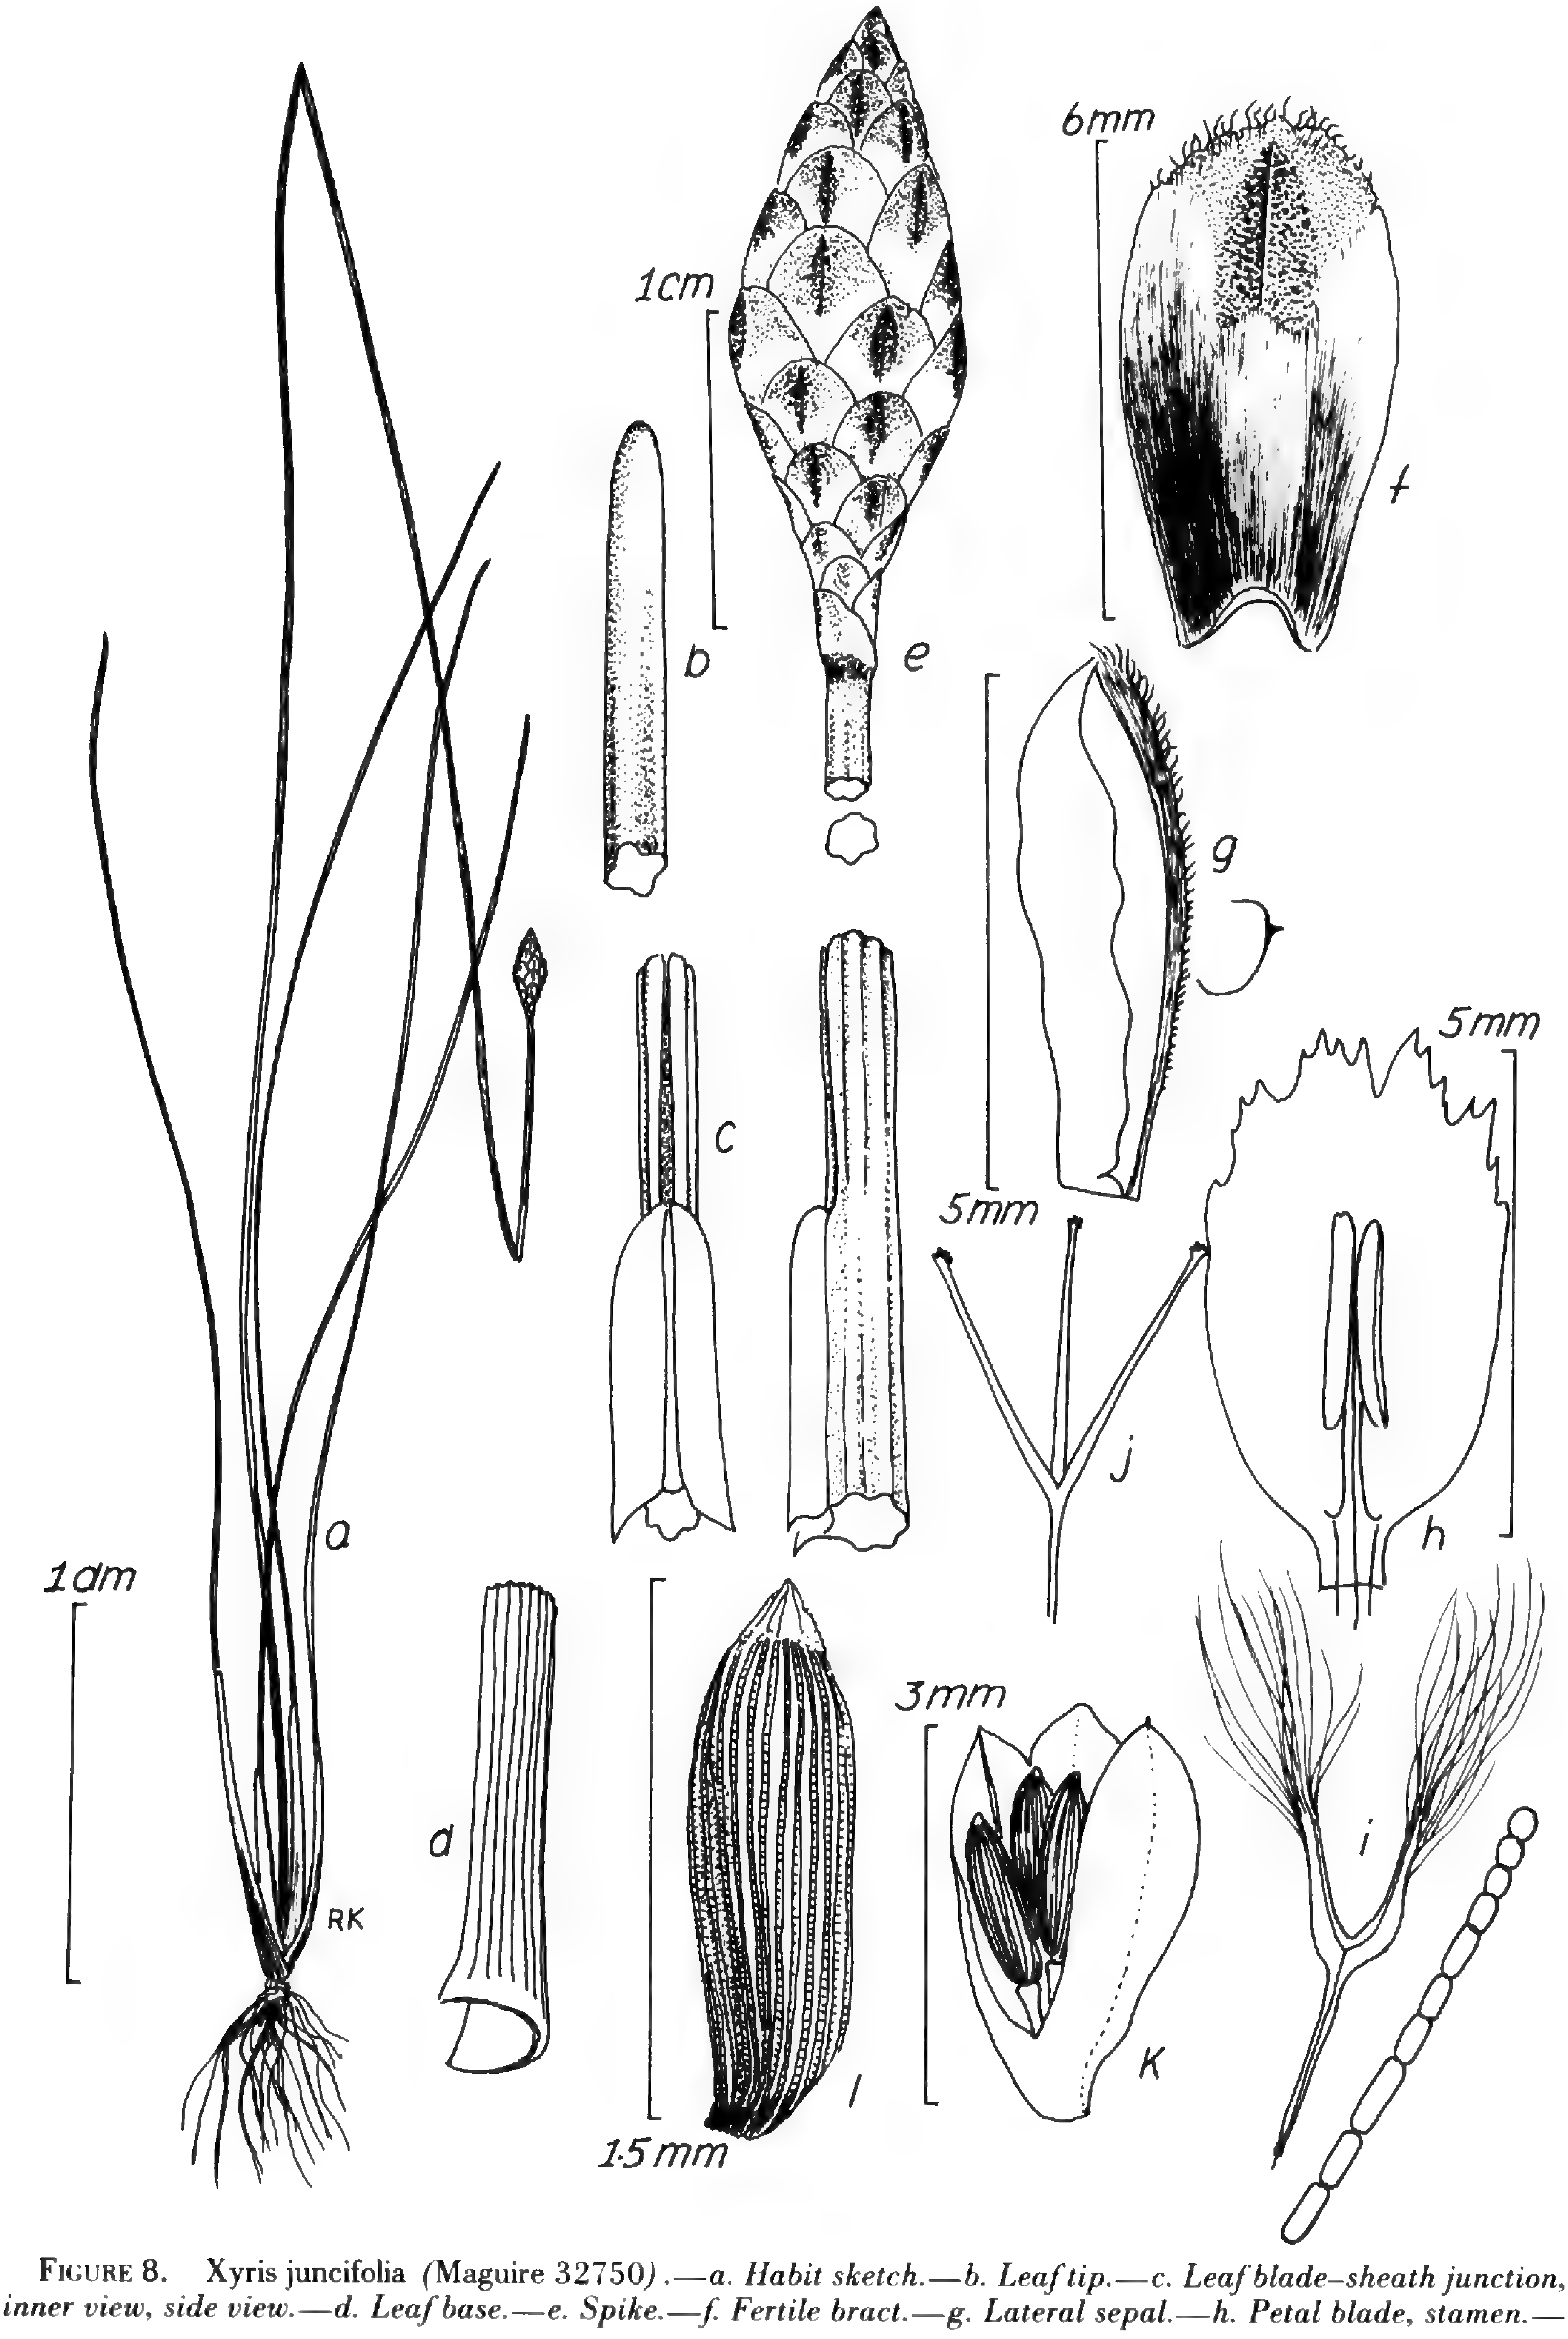

FIGURE 8. Xyris juncifolia (Maguire 32750).—*a. Habit sketch.*—*b. Leaf tip.*—*c. Leaf blade–sheath junction, inner view, side view.*—*d. Leaf base.*—*e. Spike.*—*f. Fertile bract.*—*g. Lateral sepal.*—*h. Petal blade, stamen.*—

This species, with its fusiform-ellipsoid spikes; terete, rushlike, brittle foliage; and distinct dorsal areas, most resembles *X. neblinae* of Cerro Neblina but differs in its inequilateral (rather than equilateral) lateral sepals and brownish (rather than castaneous) base. These two species and the Colombian *X. terrestris* form a complex of brittle-foliaged, rushlike xyrids closest to *X. atriceps* Malme subsp. *neblinensis*. Known until 1951 only from the type locality, *X. juncifolia* has now been collected from Cerro Jaua (*Steyermark et al. 109427*, NY, VEN), from Cerro Duida (*Steyermark 124560*, NY, VEN), and from Paru (*Cowan & Wurdack 31185*, GH, NY, US), as well as several times more from the type region.

9. **Xyris lanulobractea** Steyerm., Fieldiana, Bot. 28(1): 109, fig. 16D–H. 1951. TYPE: Venezuela. Bolívar: swampy ground, 1,200 m, Kavanayen, Gran Sabana, 26 Oct. 1944, *J. A. Steyermark 59336* (holotype, F; isotypes, US, VEN). Figure 9.

Slender, rushlike, cespitose, hard-based, glabrous perennial 4–7 dm high, the stems contracted. Leaves erect, 2–4 dm long; sheaths entire, elongate but less than ¼ of blade length, deep glossy red-brown, the backs ecarinate, the sides tapering gradually into blade, there with an erect ligule to 3 mm long; blades terete or oval in cross section, 0.5–0.7 mm thick, fluted, slightly flattened and deeply sulcate at base above ligule, apex tapering-subulate-conic or with very tip dilated clavately. Scape sheaths much shorter than leaves, tubular at base, multicostate, twisted, open at apex, keeled, stubby-bladed. Scapes slightly twisted, straight or flexuous, terete distally, ca. 1 mm thick. Spikes broadly ovoid to obovoid, 0.7–1(–1.5) cm long, blunt, dull brown, attenuate, the many spirally imbricate bracts with conspicuous dorsal areas; sterile bracts several, ovate, narrowly to broadly rounded, ecarinate, the lowest evidently much smaller than the fertile bracts, grading into them; fertile bracts broadly elliptic to obovate, ca. 6 mm long, with broadly rounded, white-villosulous borders, convex and ecarinate backs, and reddish brown, obovate or broadly elliptic dorsal areas. Lateral sepals strongly curvate, elliptic, ca. 4 mm long, thin, the broad firm keel ciliolate below middle, increasingly pale-villous-fimbriate above middle. Petal blades broadly obovate to suborbicular, yellow, ca. 5 mm long, the rounded apex serrulate-dentate. Staminodia bibrachiate, the slender recurved branches densely penicillate-pilose. Anthers oblong, 1 mm long, bifid and sagittate, on filaments ca. 1 mm long. Capsule obovoid, ca. 2 mm long, placentation basal, the valves without septa. Seeds few on short, stubby funicles, cylindrical or lance-ovoid, amber, 1.1–1.3 mm long, often angulate, finely ribbed longitudinally.

Distribution. Low to medium-elevation savanna, southeast Venezuela (Bolívar), Guayana, and contiguous northern Brazil (Amazonas).

Additional specimens examined. BRAZIL. AMAZONAS: rd. to Igarapé Preto ca. 60 km SE of Transamazon Hwy., 2 July 1979, *Calderon et al. 2743*; Mun. Sta. Elena, 2 Dec. 1982, *Steyermark & Liesner 127486* (VDB, VEN).

This slender morning bloomer is most similar superficially to *X. globosa* Nilsson, differing in its somewhat more slender habit, more tapering (rather than bulbous) base, more consistently terete leaf blades, ligulate sheath apex, plumose (rather than beardless) staminodes, and broader petal blades. Brazilian collections of *X. globosa* may well turn out to be *X. lanulobractea*.

10. Xyris terrestris Idrobo & Lyman B. Smith, Caldasia 6(29): 208, fig. 10. 1954. TYPE: Colombia. Vaupés: "Cerro de Caenda" (sabanas), 380–670 m, Río Kubiyu, 4 Nov. 1952, *H. García-Barriga 15090* (holotype, COL; isotypes, GH, NY, US). Figure 10.

Solitary or small-clumped, slender, smooth perennial 3–5 dm high, the stems short, erect from a short, stout, horizontal or ascending rhizome. Leaves mostly erect or ascending, twisted, 1–2.5 dm long; sheaths much less than ½ as long as blades, entire, proximally rich, lustrous red-brown or castaneous, strongly dilated at very base, thence upward gradually narrowing into an erect, narrowly triangular, chaffy ligule 3–6 mm long; blades filiform-linear, flexuous, terete or elliptic or rounded-angulate in cross section, 0.5–0.6 mm thick, yellow-green, blunt-conic at apex, longitudinally with a single, spiral, shallow to deep, papillate, usually rusty-colored sulcus. Scape sheaths shorter than leaves, with shorter blades similar to those of leaves. Scapes linear, twisted and flexuous, distally terete, ca. 0.5–0.6 mm thick, ecostate but multistriate. Spikes ellipsoid, or lance-ovoid, 0.7–2 cm long, subacute, attenuate-based, of numerous, spirally imbricate, stiff, brownish bracts, the sterile bracts numerous, the lowest lance-triangular, keeled, much smaller than, and grading into, the fertile bracts, these mostly broadly obovate, broadly to narrowly rounded apically, 4–5 mm long, the margins entire to erose in age, the back rounded, ecarinate, with strong but small, red-brown to yellow-brown, elliptic dorsal areas. Lateral sepals strongly curvate, oblong, ca. 4 mm long, free, very inequilateral, the broad, deep, reddish brown keel scabrociliate from near base to blunt apex. Petal blades obovate, ca. 4 mm long, yellow, the broadly rounded apex erose-denticulate. Staminodia bibrachiate, the flattened branches long-penicillate. Anthers oblong, ca. 2 mm long, shallowly bifid and auriculate, on filaments ca. 0.5 mm long. Capsule narrowly obovoid-apiculate, brown, 2–2.5 mm long, dehiscing only ⅔ way to base, the placenta massive and basal, the funiculi short, broadly clavate. Seeds several, cylindric-fusiform, 1.3–1.5 mm long, red-amber, irregularly anastomosing-ribbed longitudinally.

Distribution. Sandy savannas, Vaupés, southeastern Colombia, rare.

Additional specimens examined. COLOMBIA. VAUPÉS: Mesa de Yambi savanna, 15–16 Apr. 1953, *Schultes & Cabrera 14235A* (COL, GH, NY, U, US); Araracuara savannas, Río Caquéta, 6 Sept. 1959, *Maguire & Fernandez 44163* (NY).

There are so many species shared by border states in Colombia and Venezuela that it is reasonable to expect this plant to be found in T. F. Amazonas in Venezuela, where there is much savanna suitable for it.

11. Xyris scabridula Steyerm., Fieldiana, Bot. 28(1): 111. 1951. TYPE: Venezuela. T. F. Amazonas: around rills on rocky dry ridgetop, Brocchinia Hills, 1,700–1,900 m, Cerro Duida, 1 Sep. 1944, *Steyermark 58168* (holotype, F; isotypes, NY, VEN). Figure 11.

Slender, cespitose perennial 1.8–4 dm high, the stout stems mostly contracted. Leaves shorter than scape sheaths, strongly flexuous and twisted, mostly erect; sheaths eciliate, ¼ or less of blade length, firm, at very base deep red-brown or castaneous, strongly ribbed, lustrous, becoming roseate or purple above, scabridulous, narrowing gradually to blade; blades variously elongate, strongly rib-angled in cross section, also deeply sulcate, narrowly linear, ca. 1 mm thick, reddish or purplish and pale-

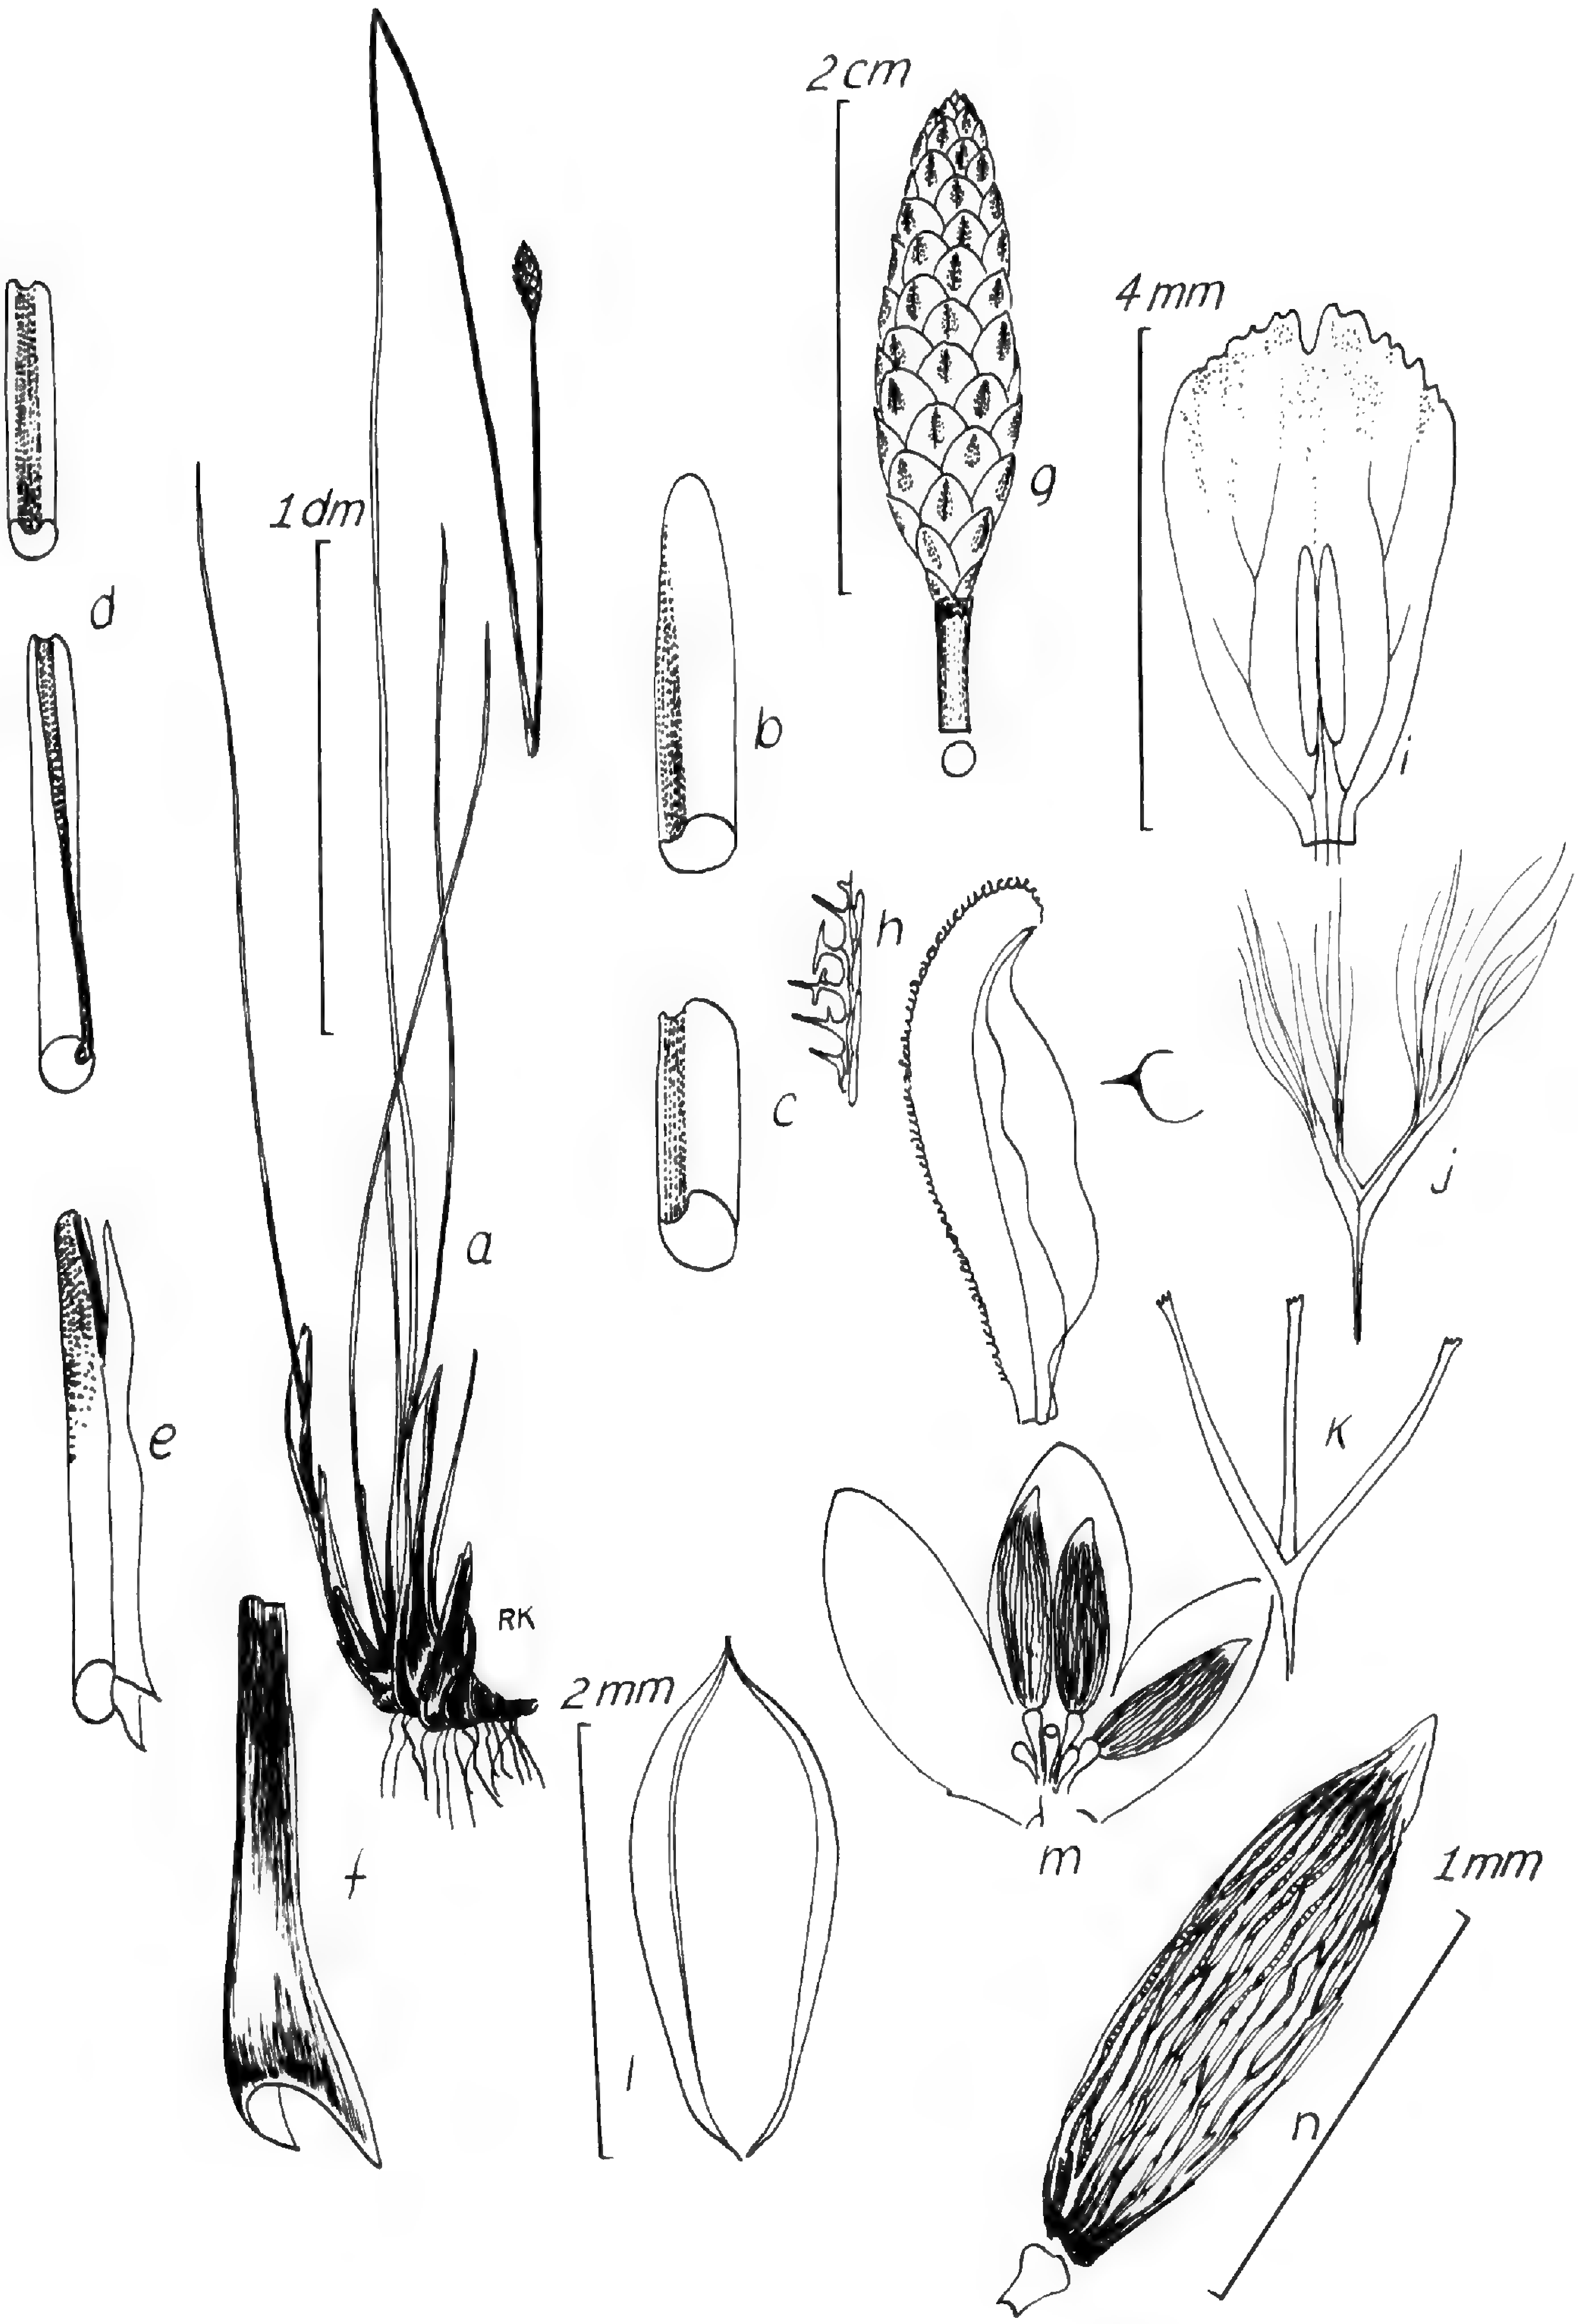

FIGURE 10. Xyris terrestris (Schultes & Cabrera 19179).—*a. Habit sketch.*—*b. Leaf apex.*—*c. Leaf blade a few cm below apex.*—*d. Further down leaf blade than c (and more reduced).*—*e. scabridulous toward base, smooth, green toward tip, narrowed abruptly to a blunt, callused apex. Scape sheath much shorter than blade, mostly tubular, twisted, strongly multicostate, reddish brown or pink at base, distally with a short, blunt cusp. Scapes twisted and flexuous, subterete toward apex, ca. 0.8 mm thick, with 1–3(–4) strong, smooth costae and some less distinct ribs, or nearly ecostate, proximally strongly multicostate. Spikes ovoid, 7–8 mm long, of several erect, spirally imbricate, ecarinate, brown, definitely papillate bracts without dorsal areas, the sterile bracts several, the lowest much smaller than the fertile bracts, orbicular or reniform, gradually grading into fertile bracts, these 4–5 mm long, broadly obovoid, broadly rounded apically, appearing entire but minutely papillate-ciliate. Lateral sepals free, equilateral, elliptic and strongly curvate, ca. 4 mm long, obtuse, the keel rusty-ciliolate.

Distribution. Cerro Duida, Territorio Federal Amazonas, and Chimantá Massif, Estado Bolívar, Venezuela.

Additional specimens examined. VENEZUELA. BOLÍVAR: savanna summit of Macizo Chimantá, *Huber & Colella 9001* (NY, VDB, VEN); *Huber & Steyermark 7162* (NY, VDB, VEN); *Huber et al. 9070* (NY, VDB, VEN); *Huber 9576* (NY, VDB, VEN); *Steyermark & Wurdack 1010* (F); *Steyermark et al. 115922* (F); *Steyermark 128429* (VDB, VEN).

This taxon has some affinity to *X. subglabrata* Malme of lower elevations in T. F. Amazonas, Venezuela, but has smoother spikes with no evident dorsal area. It also resembles *X. stenophylloides* Malme, an equally rare plant from the same area, whose leaf blades, though very narrow, are flattened. None of these species are much collected, so that comparisons of flowers and seeds are not yet made.

12. Xyris atriceps Malme, Bull. Torrey Bot. Club 58: 325. 1931. TYPE: Venezuela. T. F. Amazonas: forming tussocks, 6,700 ft., Cerro Duida, Ridge 15, Aug. 1928–Apr. 1929, *G. H. H. Tate 688* (lectotype, NY; isolectotype, US).

Densely tufted, slender, low to tall perennials 2–6 dm high, the stems short to elongate, up to 5 cm long. Leaves elongate, linear to filiform, erect or ascending, 1.5–3 dm long; sheaths deep reddish brown to nearly black, lustrous, smooth to papillose-rugulose apically, less than ½ as long as blades, entire, tapering evenly from broad, ecarinate base to distinct, firm or thin, erect, broad ligule 2–10 mm long, there broader than the usually terete blade; blades deep green, linear to filiform, 0.5–1 mm thick, sometimes fluted, usually with a median ventral sulcus, the apex blunt, broadly rounded or truncate, rarely conic, smooth, the surfaces smooth except toward the often rugulose-papillose base. Scape sheath shorter than leaves, loose, often purplish, rarely pink, the blade short, erect, blunt. Scapes flexuous or straight, twisted, terete, 0.5–1 mm thick, smooth or white-puncticulate from sunken stomata. Spike ovoid to oblong or obovate-turbinate, 0.5–1.5 cm long, the base attenuate, of several pale to deep brown or castaneous, spirally loosely imbricate bracts without distinct dorsal areas. Sterile bracts up to 6, erect or squarrose-tipped, triangular to obovate, entire to lacerate or ciliolate-villosulous-bordered, smaller than and grading into the fertile bracts, these oblong to obovate, 3.5–8 mm long, entire to villosulous-ciliate, ciliolate or pectinate-lacerate, the backs broadly rounded, smooth to papillose. Lateral sepals free, subequilateral, straight or curvate, linear or oblong-linear, 3.5–7 mm long, acute, sides pale brown, keels deep reddish brown, ciliolate to densely villous-ciliate. Petal blades broadly obovate to suborbicular, 6–7 mm long, the broadly rounded apex coarsely erose. Staminodia bibrachiate, the branches long-penicillate, or staminodia absent (subsp. *marahuacae*). Anthers oblong to lance-oblong, 2–2.5 mm long, shallowly bifid apically, deeply sagittate at base, on filaments ca. 1 mm long. Capsule cylindric to ovoid or ellipsoid, ca. 3–4 mm long, placentation appearing central but capsule valves with septa from base to near apex. Seeds several, deep reddish brown, cylindric or ellipsoid, 1.5–2 mm long, including a short-

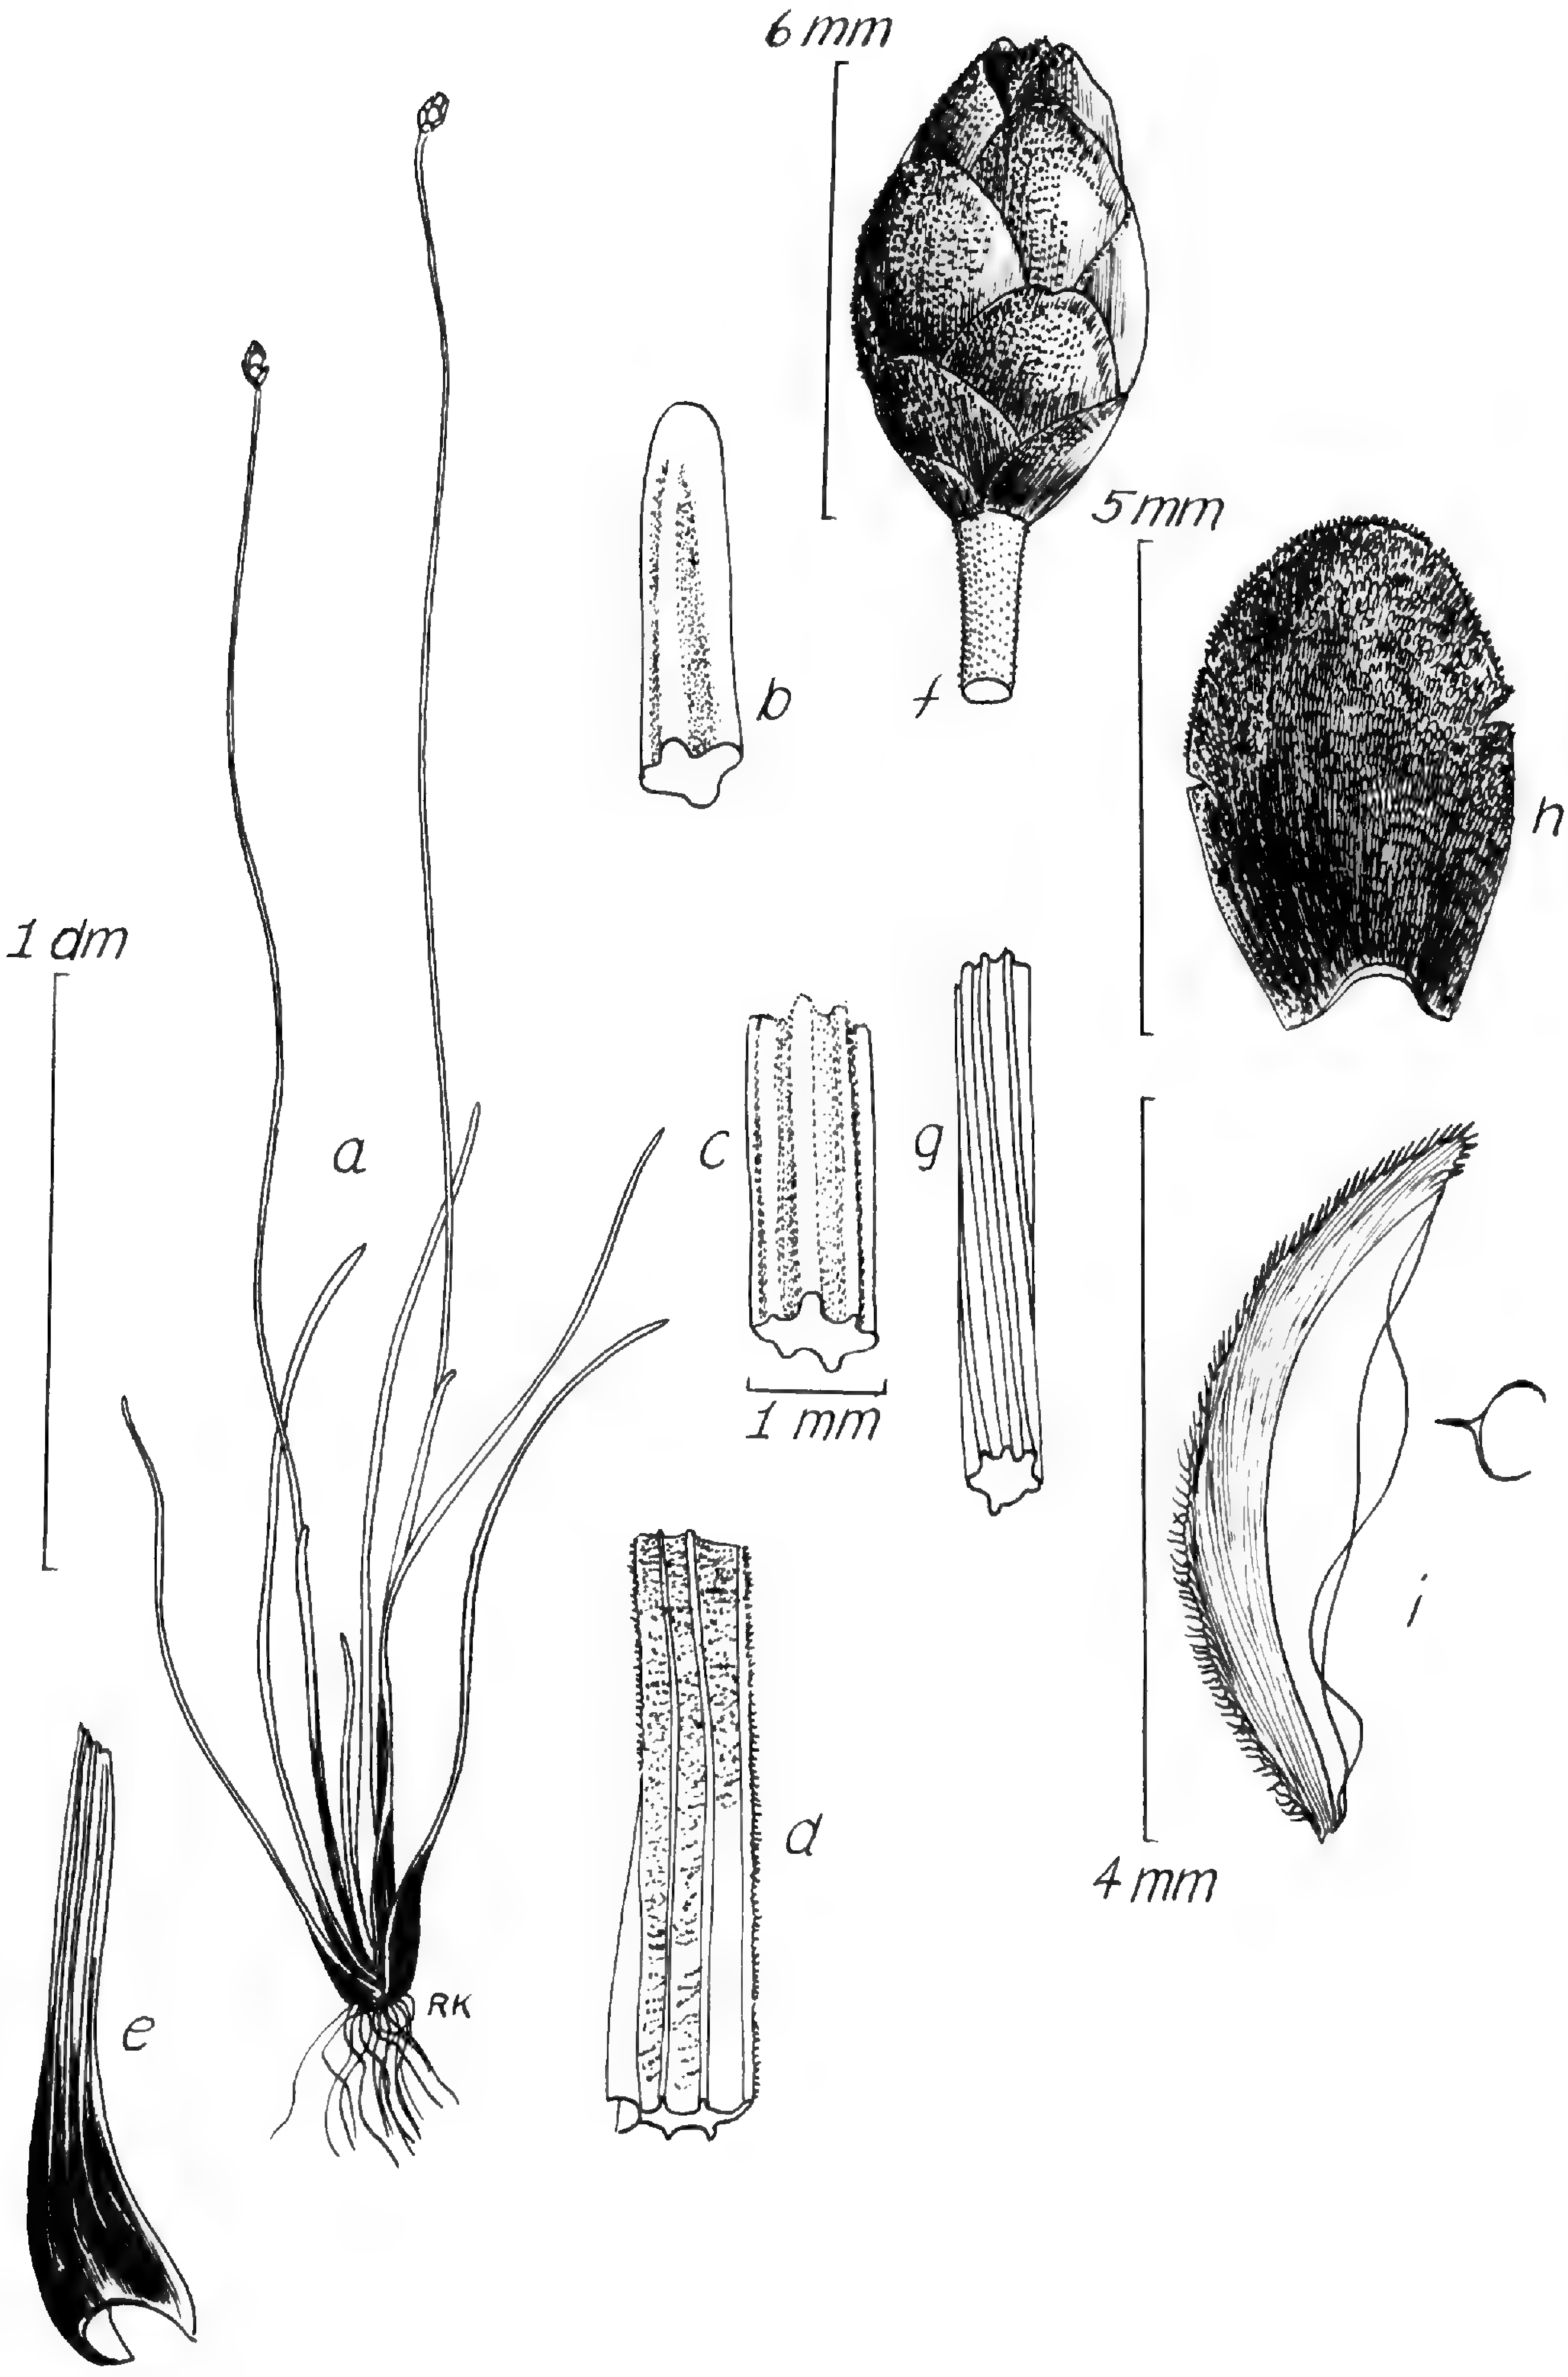

FIGURE 11. Xyris scabridula (Steyermark 58168).—*a. Habit sketch.—b. Leaf apex.—c. Leaf sector at midblade.—d. Leaf blade-sheath junction.—e. Leaf base.—f. Spike, scape apex.—g. Midscape.—h. Fertile bract.—i. Lateral sepal.*

conic, pale appendage, the seed body finely but distinctly longitudinally ribbed.

Distribution. This species appears to be confined to higher elevations in the higher tepuis of Bolívar and T. F. Amazonas, Venezuela (and probably contiguous Brazil), and sorts to four fairly distinct morphologies, here given rank of subspecies, keyed as follows:

KEY TO SUBSPECIES OF *XYRIS ATRICEPS*

1a. Spikes narrowly obovoid; leaf blades lacking sulcus; bracts subentire, with a low costa distally, the bract margins ciliolate with yellowish hairs .... subsp. *neblinensis*
1b. Spikes narrowly to broadly obovoid; leaf blades sulcate at least ventrally; bracts becoming lacerate, ecostate distally, the bract margins various.
  2a. Spikes under 1 cm long; leaf blades under 1 mm thick; bearded staminodia present.
    3a. Spike broadly obovoid, base strongly attenuate; bract edges distally white ciliate and erect .... subsp. *atriceps*
    3b. Spike narrowly obovoid or ellipsoid or ovoid, base short-attenuate if at all so; bract edges sordidly villosulous, usually becoming very lacerate, subsquarrose .... subsp. *chimantensis*
  2b. Spikes 1–1.5 cm long; leaf blades ca. 1 mm thick; staminodia absent .... subsp. *marahuacae*

12A. **Xyris atriceps** Malme subsp. **atriceps.** Figure 12A (in part).

Spikes broadly obovoid, attenuate-based, ca. 7 mm long, the bracts erect, the margins white ciliate; staminodial beard present; seeds ca. 1.5 mm long.

Distribution. This subspecies is still known only from southern Cerro Duida, the type area. Additional material from the type area is *Steyermark 58185* (F, US).

12B. **Xyris atriceps** subsp. **chimantensis** Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 19–20. 1963. TYPE: Venezuela. Bolívar: locally frequent, Río Tirica, 1,925 m, 5 Feb. 1955; Chamantá Massif, *J. A. Steyermark & J. J. Wurdack 485* (holotype, NY; isotype, US). Figure 12A, a–f, g (left)–i (left).

Spikes ellipsoid or narrowly obovoid, ca. 6–7 mm long, acute at base, the bracts loosely imbricate, narrower than in type, the margins at first sordidly villosulous, later becoming much lacerate, spreading; staminodial beard present; seeds ca. 1.5 mm long.

Distribution. Abundant locally in high savanna of Chimantá Massif and taxonomically closest to subsp. *atriceps.* Now frequently collected from the summit elevations of the Massif as follows.

Additional specimens examined. VENEZUELA. BOLÍVAR: *Huber et al. 9066* (NY, VDB, VEN); *Steyermark et al. 115852* (VEN), *128008* (VEN, VDB), *128958* (VEN, VDB), *128810* (VEN), *129908* (MYF, VDB, VEN); *Steyermark 128167* (VEN), *128854* (VEN).

12C. **Xyris atriceps** subsp. **marahuacae** Kral & Lyman B. Smith, subsp. nov. TYPE: Venezuela. T. F. Amazonas: Dept. Atabapo, Cerro Marahuaca, cumbre, parte central de la meseta Sur-Este, al lado de una grieta, a lo largo de la Quebrada Yekuana, afluente del Río Negro, 3°40′30″N, 65°26′20″W, 2,560 m, 10–12 Oct. 1983, *Steyermark 129579* (holotype, VEN; isotype, VDB). Figure 12B.

Planta fragilis, perennis, caespitosa, 4–5 dm alta, glabra. Radices graciles. Caules breves aut elongatis, usque ad 5 cm longi. Folia principalia erecta, usque ad 3 dm longa, torta, flexuosa, vaginis scaporum longiora; lamine 6–10-plo vaginis longiores, anguste lineares, teretes, 1–3-sulcatae, ca. 0.8–1.2 mm crassae, olivaceae, ad basin ventraliter profunde sulcatae; apices peranguste conici; vaginae ecarinatae, nitidae, atrocastaneae, integrae, ad basin dilatatae, in laminas gradatim, tum abrupte decrescentes, ad apicem ligulatae, ligula rigida erecta linearo-triangulata, usque ad 1 cm longa. Vaginae scaporum prope basin castaneae, apicem versus apertae, laminis elongatis, laminis foliorum similibus sed angustioribus. Scapi leviter torti, teretes, ca. 1 mm crassi, multistriati, olivacei vel brunneoli. Spicae multiflorae, anguste vel late obovoideae, ca. 1 cm longae, obtusae. Bracteae erectae, laxe spiraliter imbricatae, firmae, ecarinatae, rigidae, fuliginosae, sine area dorsali, ad apicem villosiciliatae, tum valde laceratae, eciliatae; bracteae steriles ovatae, plures, fertilibus breviores, in fertiles gradatim transientes; bracteae fertiles late obovatae, 7–8 mm longae, ad apicem late rotundatae. Sepala lateralia libera, subaequilatera, oblanceolata, atrobrunneola, 6.5–7 mm longa, leviter curvata, obtusa; ala carinali a medio ad apicem aut solum

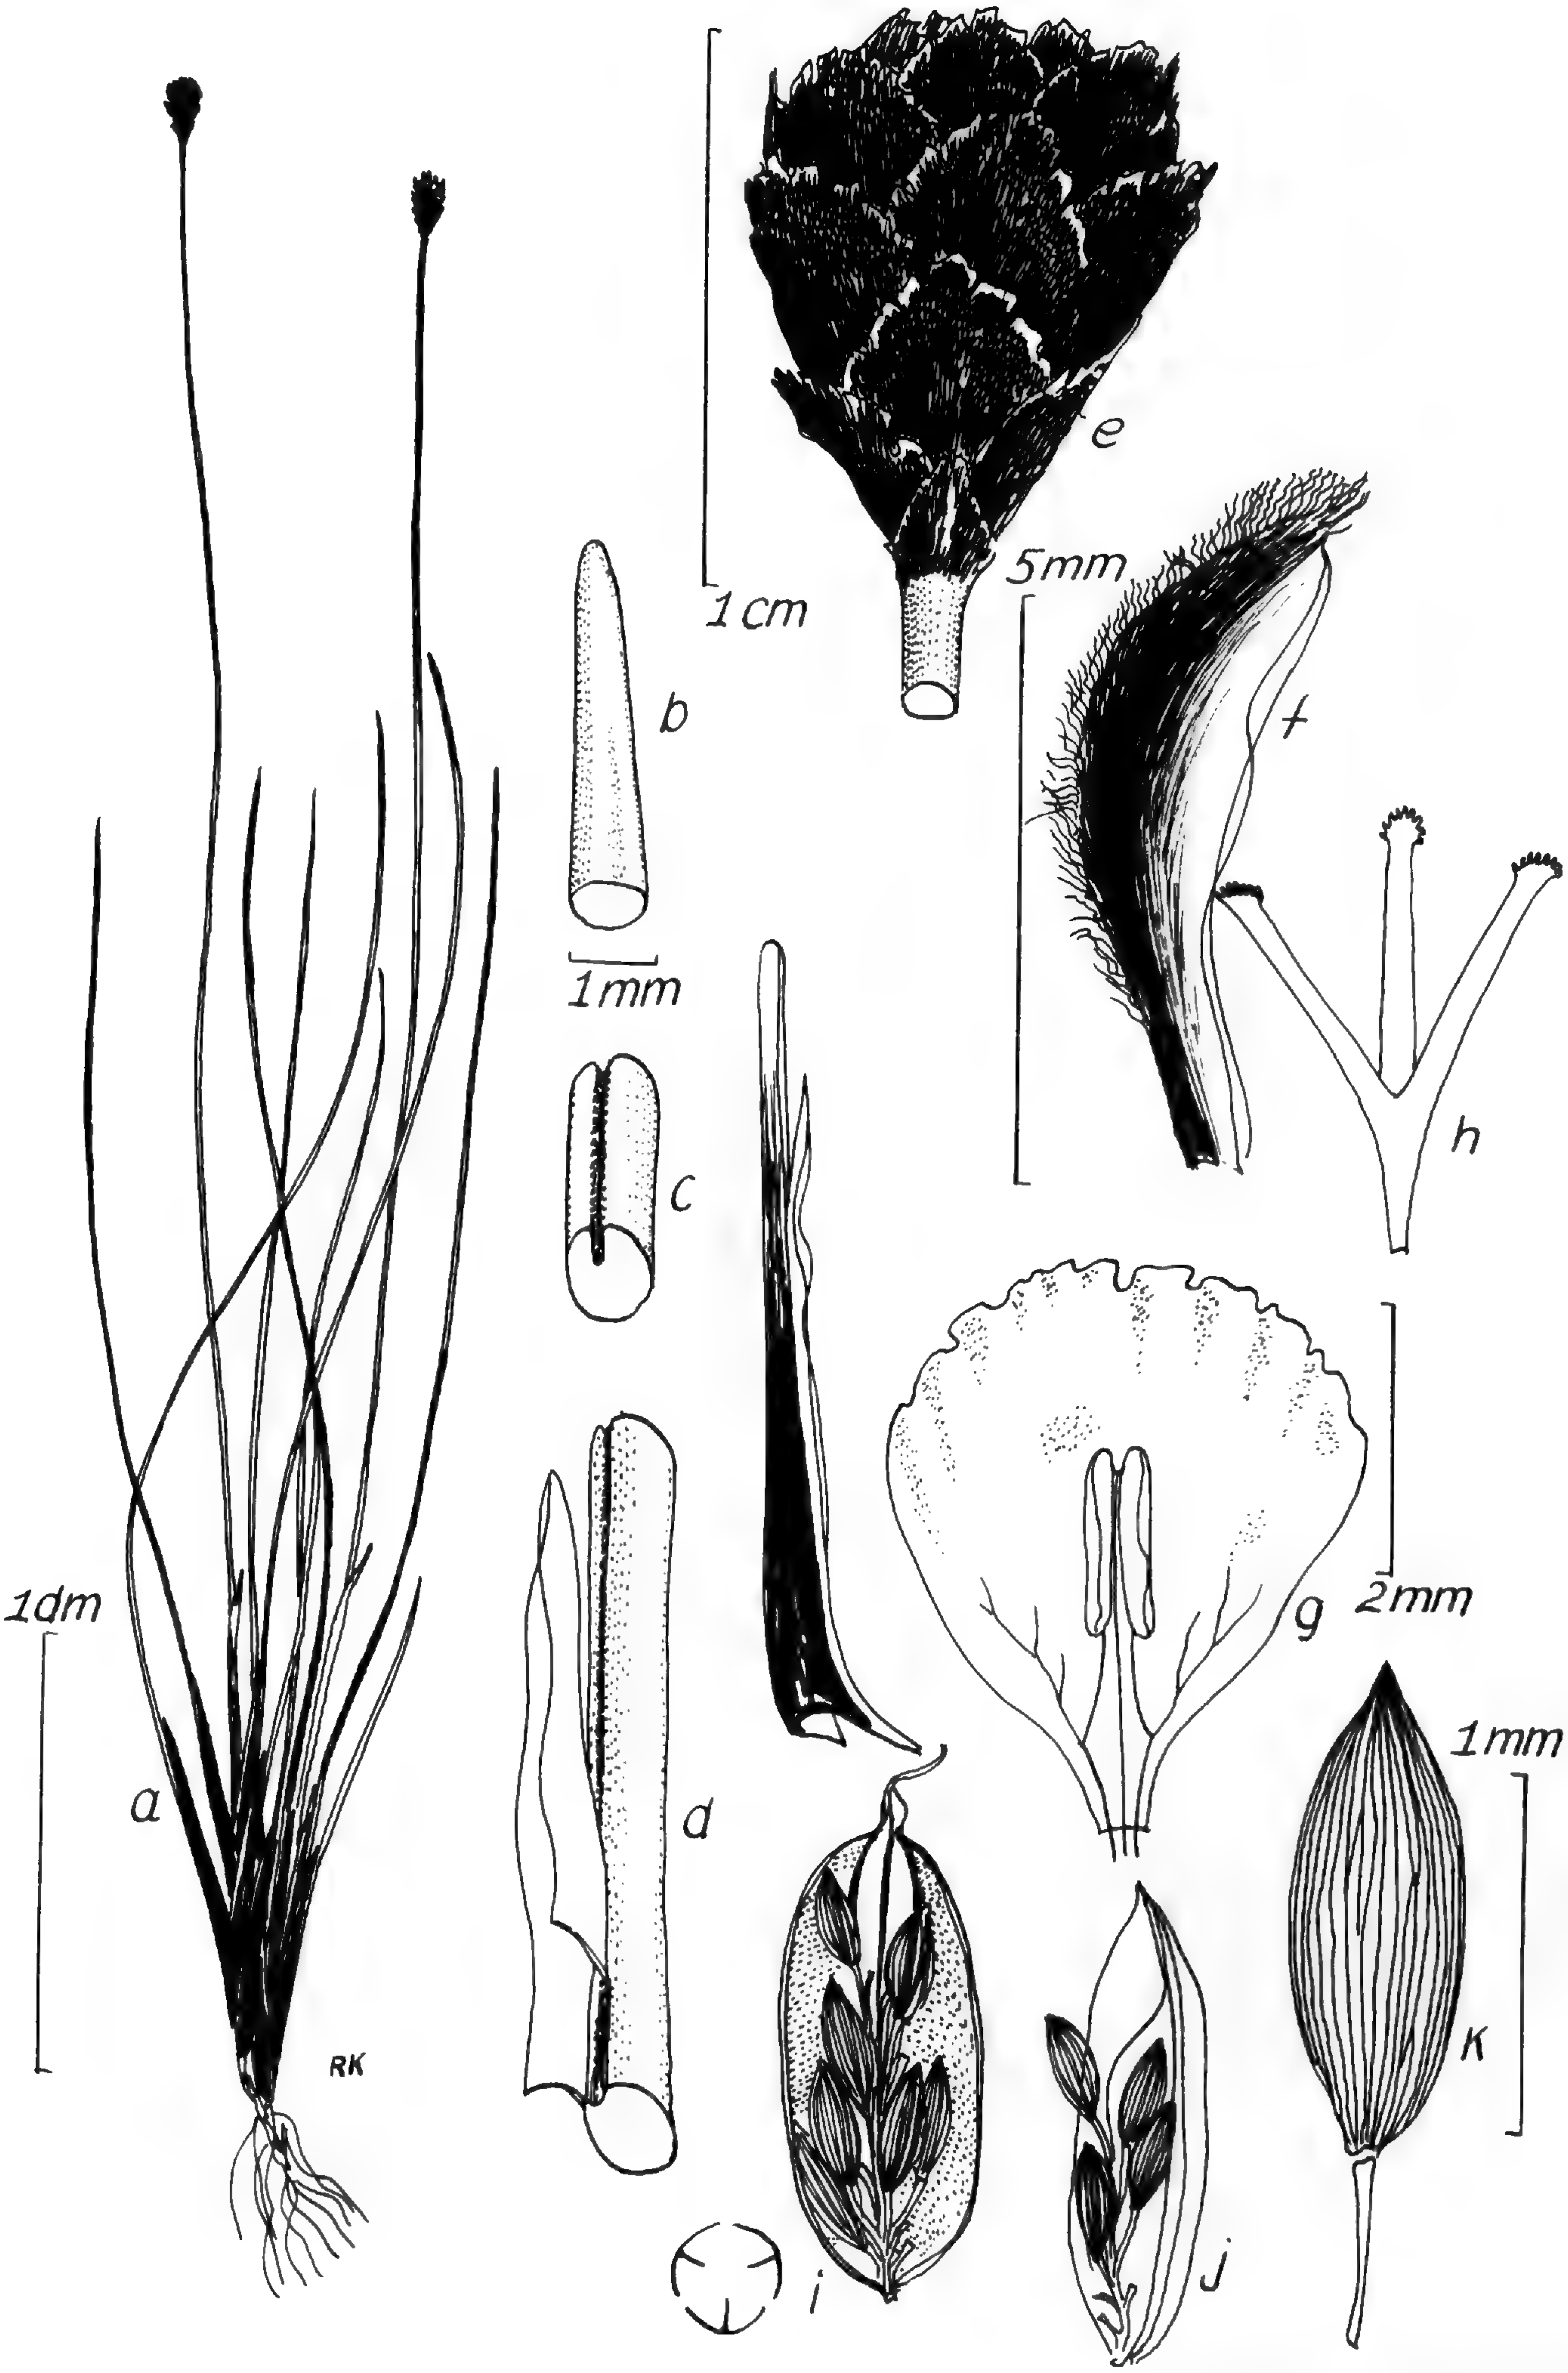
FIGURE 12B. Xyris atriceps *subsp.* marahuacae *(from the type).—a. Habit sketch.—b. Leaf apex.—c. Leaf blade, midblade sector.—d. Leaf sheath-blade junction (at left); leaf base (at right).—e. Spike.—f. Lateral*



sepal.—g. Petal blade, stamen.—h. Stylar apex.—i. Capsule, idealized section showing two septa (stippled), placentation, vascular supply to funiculi).—j. Valve removed, showing ovular attachment to inner edge of valve septum.—k. Seed (from quasimature fruit).

ad apicem villosifimbriolata. Laminae petalorum late obovatae, ca. 6–6.5 mm longae, apice late rotundatae. Staminodia nulla. Antherae oblongae, ca. 2 mm longae, leviter emarginatae et auriculatae; filiis ca. 1.5 mm longis, latis. Capsula matura ellipsoidea, ca. 4 mm longa, valvis capsulae profunde septatis a medio ad basin. Semina numerosa, ellipsoidea, ca. 1.5 mm longa, translucida, longitudine multilineata.

Brittle, tufted, glabrous perennial 4–5 dm high. Roots slender. Stems short or elongate, up to 5 cm long. Main leaves erect, to 3 dm long, twisted, flexuous, longer than the scape sheaths; blades 6–10 times longer than the sheaths, narrowly linear, terete, 1–3-sulcate, ca. 0.8–1.2 mm thick, olive-green, deeply sulcate ventrally at base; tips narrowly conic; sheaths ecarinate, shining, deep castaneous, entire, dilated at base, narrowing gradually, then abruptly, to blades, ligulate at apex, the ligule rigid, erect, linear-triangular, to 1 cm long. Scape sheaths castaneous toward base, opening toward apex, elongate-bladed, with blades similar to those of leaves but narrower. Scapes slightly twisted, terete, ca. 1 mm thick, multistriate, olivaceous to brown. Spikes multiflorous, narrowly to broadly obovoid, ca. 1 cm long, obtuse. Bracts erect, loosely spirally imbricate, firm, ecarinate, rigid, sooty brown, without dorsal area, villous-ciliate at apex, aging strongly lacerate, eciliate; sterile bracts ovate, several, shorter than the fertile bracts and passing gradually into them; fertile bracts broadly obovate, 7–8 mm long, broadly rounded at apex. Lateral sepals free, subequilateral, oblanceolate, deep brown, 6.5–7 mm long, slightly curvate, obtuse; keel villous-fimbriolate from middle to tip or solely at tip. Petal blades broadly obovate, ca. 6–6.5 mm long, broadly rounded apically. Staminodia none. Anthers oblong, ca. 2 mm long, slightly emarginate and auriculate; filaments broad, ca. 1.5 mm long. Quasimature capsules ca. 4 mm long, ovoid, with valves deeply septate from middle to base; seeds numerous, ellipsoid, ca. 1.5 mm long, translucid, longitudinally prominently multilined.

Paratypes. All from the same massif as the type: 2–9 Feb. 1975, *S. S. Tillett et al. 752-333* (NYF, US, VEN); 16 Feb. 1981, *Steyermark et al. 124371* (NY, VDB, VEN); 1–2 Feb. 1982, *Steyermark et al. 126038* (VDB, VEN); 2 Feb. 1982, *Steyermark et al. 126038* (VDB, VEN); 1–2 Feb. 1982, *Steyermark et al. 125992* (VDB, VEN); 9–10 Feb. 1982, *Steyermark et al. 126293* (VDB, VEN); 26 Mar. 1982, *Steyermark & Delascio 129201, 129224* (VDB, VEN); 12–13 Oct. 1983, *Steyermark 129476* (MO, VDB, VEN).

This subspecies, abundant on summits of Cerro Marahuaca, is robust as is subsp. *neblinensis* and has the thickest spikes and leaves, lacks staminodia, and has very distinctively villose sepal keels and tips, with tips of young bracts also densely villous-ciliate.

12D. Xyris atriceps subsp. **neblinensis** Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 19. 1963. TYPE: Venezuela. T. F. Amazonas: Cerro de La Neblina, Río Yatua, locally abundant, east escarpment of Upper Caño Grande basin, at 1,900 m, summit, 1,200–2,200 m, *B. Maguire, J. J. Wurdack & C. K. Maguire 42416* (holotype, NY; isotypes, GH, K, US). Figure 12A, g (right), i (left),

Leaves mostly esulcate; spikes narrowly obovoid, the bracts light brown, entire, with a low costa toward apex, the margin ciliate with short, yellowish hairs. Seeds ca. 2 mm long, the longest in the complex.

Distribution and remarks. This subspecies appears to be relatively common in the high, wet open paramolike summit elevations along the Neblina Massif and has been found by several collectors.

Additional specimens examined. VENEZUELA. T. F. AMAZONAS: Neblina Massif: *Liesner 16000* (MO, NY, VDB, VEN); *Maguire et al. 37244, 42342* (NY, US); *Steyermark 103966* (NY, US, VEN); *Thomas & Plowman 3080* (MO, NY, VDB, VEN). BOLÍVAR: Chimanta Massif, *Huber et al. 10151* (MYF, VDB, VEN) (intermediate between this and the subsp. *chimantensis*).

13. Xyris involucrata Nees in J. Bot. (Hooker) 2: 397. 1840. TYPE: "British Guiana, *Schomburgk 1054*" (lectotype, K; isolectotypes, K, L). Figure 13.

X. asterocephala Seub. in C. Martius, Fl. Bras. 3(1): 219. 1855.

Solitary or tufted, rather soft-based, stiff, short-lived perennial 2–6 dm high, the stems

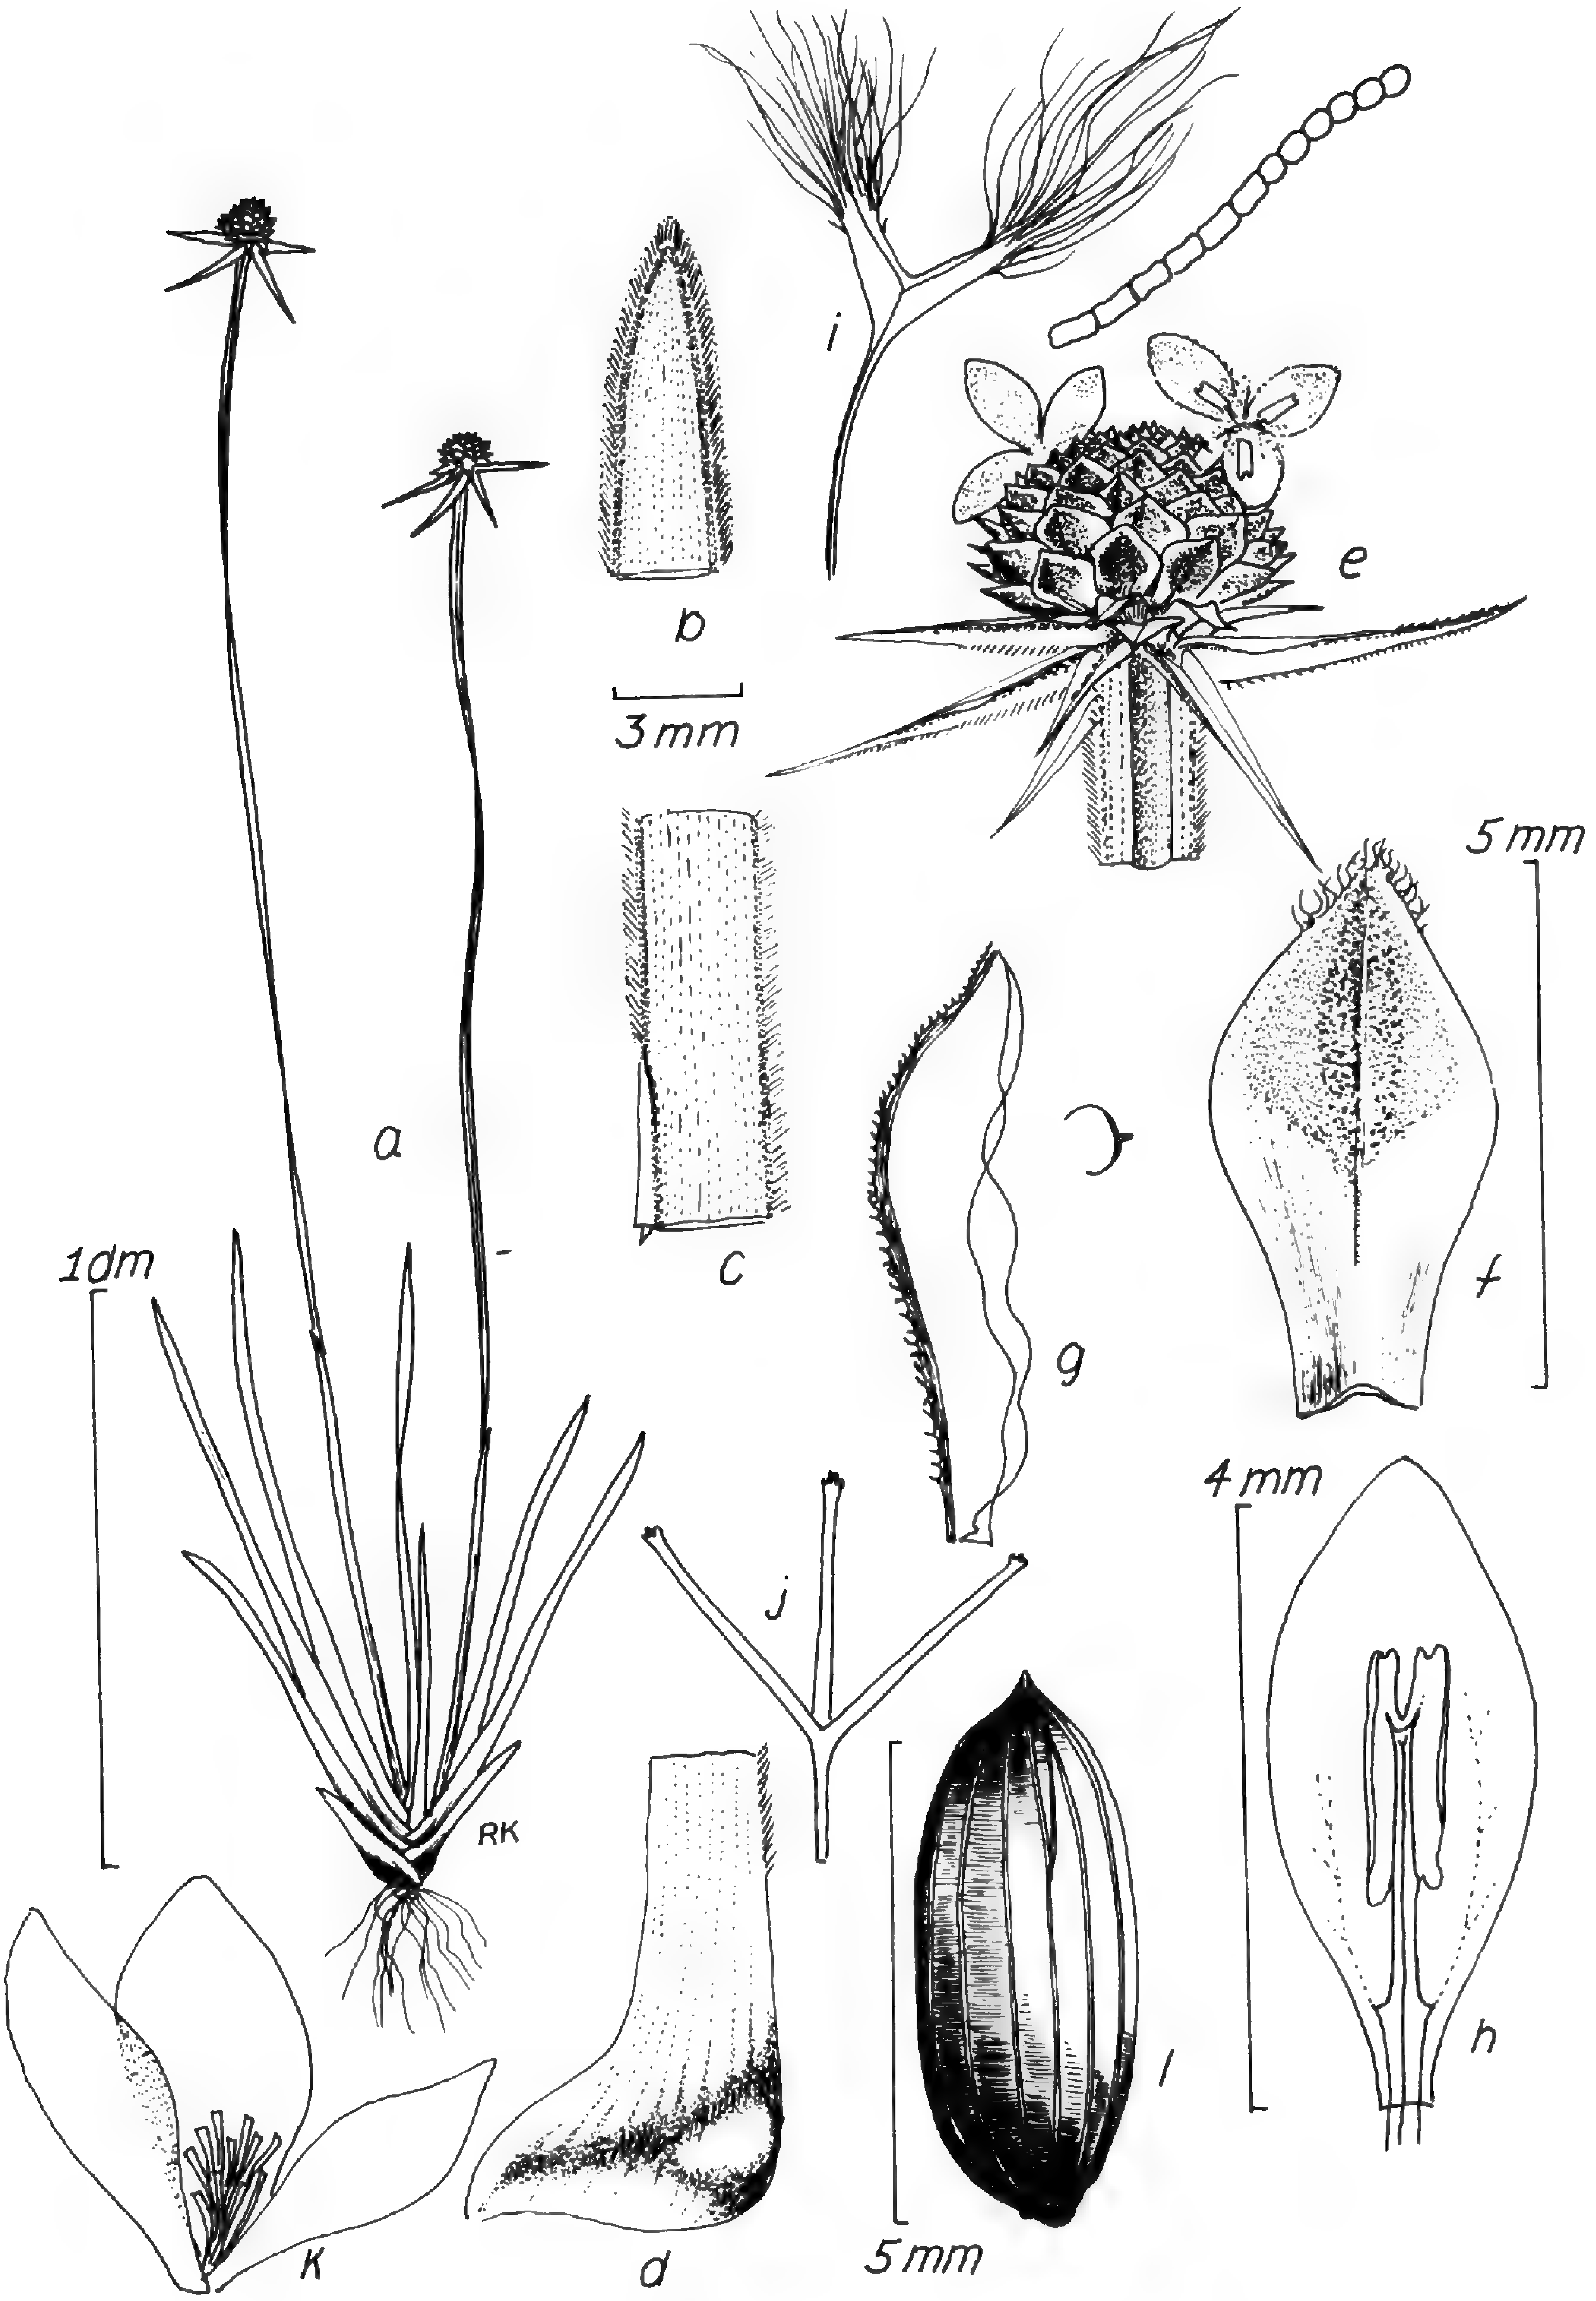


FIGURE 13. Xyris involucrata (Koyama & Agostini 7261).—*a. Habit sketch.—b. Leaf tip.—c. Leaf blade-sheath junction.—d. Leaf base.—e. Spike.—f. Fertile bract.—g. Lateral sepal.—h. Petal blade, stamen.—i. Staminode.—j. Stylar apex.—k. Open capsule.—l. Seed.*

contracted. Leaves spreading flabellately 1–3 dm long, the sheaths entire, equal in length to blade or longer, sharply keeled, often castaneous at very base, abruptly dilated, green or stramineous above, narrowing gradually to blade, eligulate; blades broadly linear, flat, 3–7 mm wide, at apex abruptly rounded or broadly incurved-acute, bright pale green with submarginal reddish borders, edges white-ciliate. Scape sheaths shorter than leaves, sharply keeled, short-bladed. Scapes rigid, straight or slightly twisted, ancipital, strongly flattened distally, 3–4 mm wide, edges pale-ciliate, surface on either side of the strong and subterete scape center low-ribbed, smooth. Spikes hemispherical to broadly ovoid or subglobose, 0.5–1 cm long (sometimes longer in fruit), the bracts in tight flat spirals, the lowest several bracts sterile, foliaceous, spreading leaflike, the bases strongly ciliate-keeled, the blades ciliate as in leaves, the inner sterile bracts progressively shorter, grading into the fertile bracts, the fertile bracts ca. 4(–5) mm long, firm, erect or spreading, rhombic or oblong-obovate, acute or short-acuminate, often villosulous-ciliate at apex, the shallowly convex-rounded backs with a large, medially papillate, rhombic, reddish brown dorsal area, bisected medially by a narrow but evident midrib. Lateral sepals free, subequilateral, oblong-curvate, ca. 3 mm long, blunt, thin, the darker, firm keel reddish ciliate or ciliolate from below middle to tip. Petal blades elliptic, 4–5 mm long, acute, entire, yellow. Anthers oblong, ca. 1.5 mm long, deeply bifid and sagittate, on filaments ca. 1 mm long. Staminodia bibrachiate, the flat triangular branches apically plumose with penicillate hairs. Capsule broadly obovoid, planoconvex, ca. 2 mm long, the placentation basal, the valves not producing septa. Seeds ellipsoid-cylindric, 0.5–0.6 mm long, apiculate, dark amber, lustrous, longitudinally with a few narrow but distinct ribs and very finely cross-lined.

Distribution. Low- and high-altitude wet savanna (up to 1,500 meters), southeastern Colombia eastward across the Guayanas into Surinam, southward into the Amazon Basin of northern Brazil.

As in the capitate-spiked, involucrate xyrids, this one, which blooms from late morning into the afternoon, has several lovely pale yellow flowers simultaneously. This effect, along with that of the bright pale green, red-bordered leaves and bracts and the gaudy, eryngiumlike inflorescences, makes it one of the more handsome plants of the Guayana boglands. Its affinities are with the recently described *X. egleri* Smith & Downs of Pará, Brazil, a smoother plant with shorter involucral bracts, and with the following species, here described as *X. pallidula*, likewise from Pará.

14. Xyris pallidula Kral & Wanderley, sp. nov. TYPE: Brazil. Amazonas: Mun. Humaita, estrada Humaita–Jacarecanga, km 150, a 60 km ao Sul. Campo natural, solo arenoso. Erva de 40 cm de altura; flores amarelas, 21 June 1982, *L. O. A. Teixeira, A. J. Fife, K. McFarland, C. D. A. Mota, J. L. dos Santos, S. P. Gomes & B. W. Nelson 1263* (holotype, INPA; isotypes, NY, VDB). Figure 14.

Herba perennis, caespitosa, 6–7 dm alta, glabra. Caules breves. Radices graciles. Folia principalia leviter flabellate expansa, 10–17 cm longa, vaginis scaporum parum breviora; vaginae elongatae, integrae, laminis 1–2-plo laminis longiora, pallide rufobrunneolae, e basi ad apicem gradatim decrescentes, eligulatae; laminae valde compressae, anguste lineario-gladiatae, 2–3 mm latae, pallide olivaceae, margine pallide ferruginea, leviter incrassata, papillosa, apice incurvato-acuta. Vaginae scaporum basin versus multicostatae, ferrugineae, nitidae, apicem versus valdae carinatae, lamina ut in laminis foliorum sed breviore. Scapi rigides, lineares, leviter torti, pallide olivacei, apicem versus in sectio transversali elliptici, laterale valde acute bicostati. Spicae multiflorae, late ovoideae vel turbinatae ad hemisphericae, ca. 10 mm longae, involucratae, pallide brunneolae. Bracteae involucrales plures, expansae, subuliformes, 7–15 mm longae, abrupte in bracteas spicae transientes; bracteae spicae rhomboideo-obovatae, 5–7 mm longae, firmae, ad apicem acuminato-subulatae, integrae, sine area dorsali. Sepala lateralia libera, aequilateralia, valde curvata, oblonga, 4–5 mm longa, obtusa, ad apicem albovillosiciliata, ala carinali ciliati, apicem versus persaepe rufofimbriolati. Laminae petalorum obovatae, luteolae, ca. 5 mm longae, acutae, integrae. Staminodia bibrachiata longipenicillatis. Antherae oblongae, vadosae bifidae et sagittatae, ca. 1 mm longae, filiis ca. 0.5 mm longis. Capsula et semina non visa, sed placenta basalis.

Cespitose, smooth perennial 6–7 mm high. Stems short. Roots slender. Principal leaves

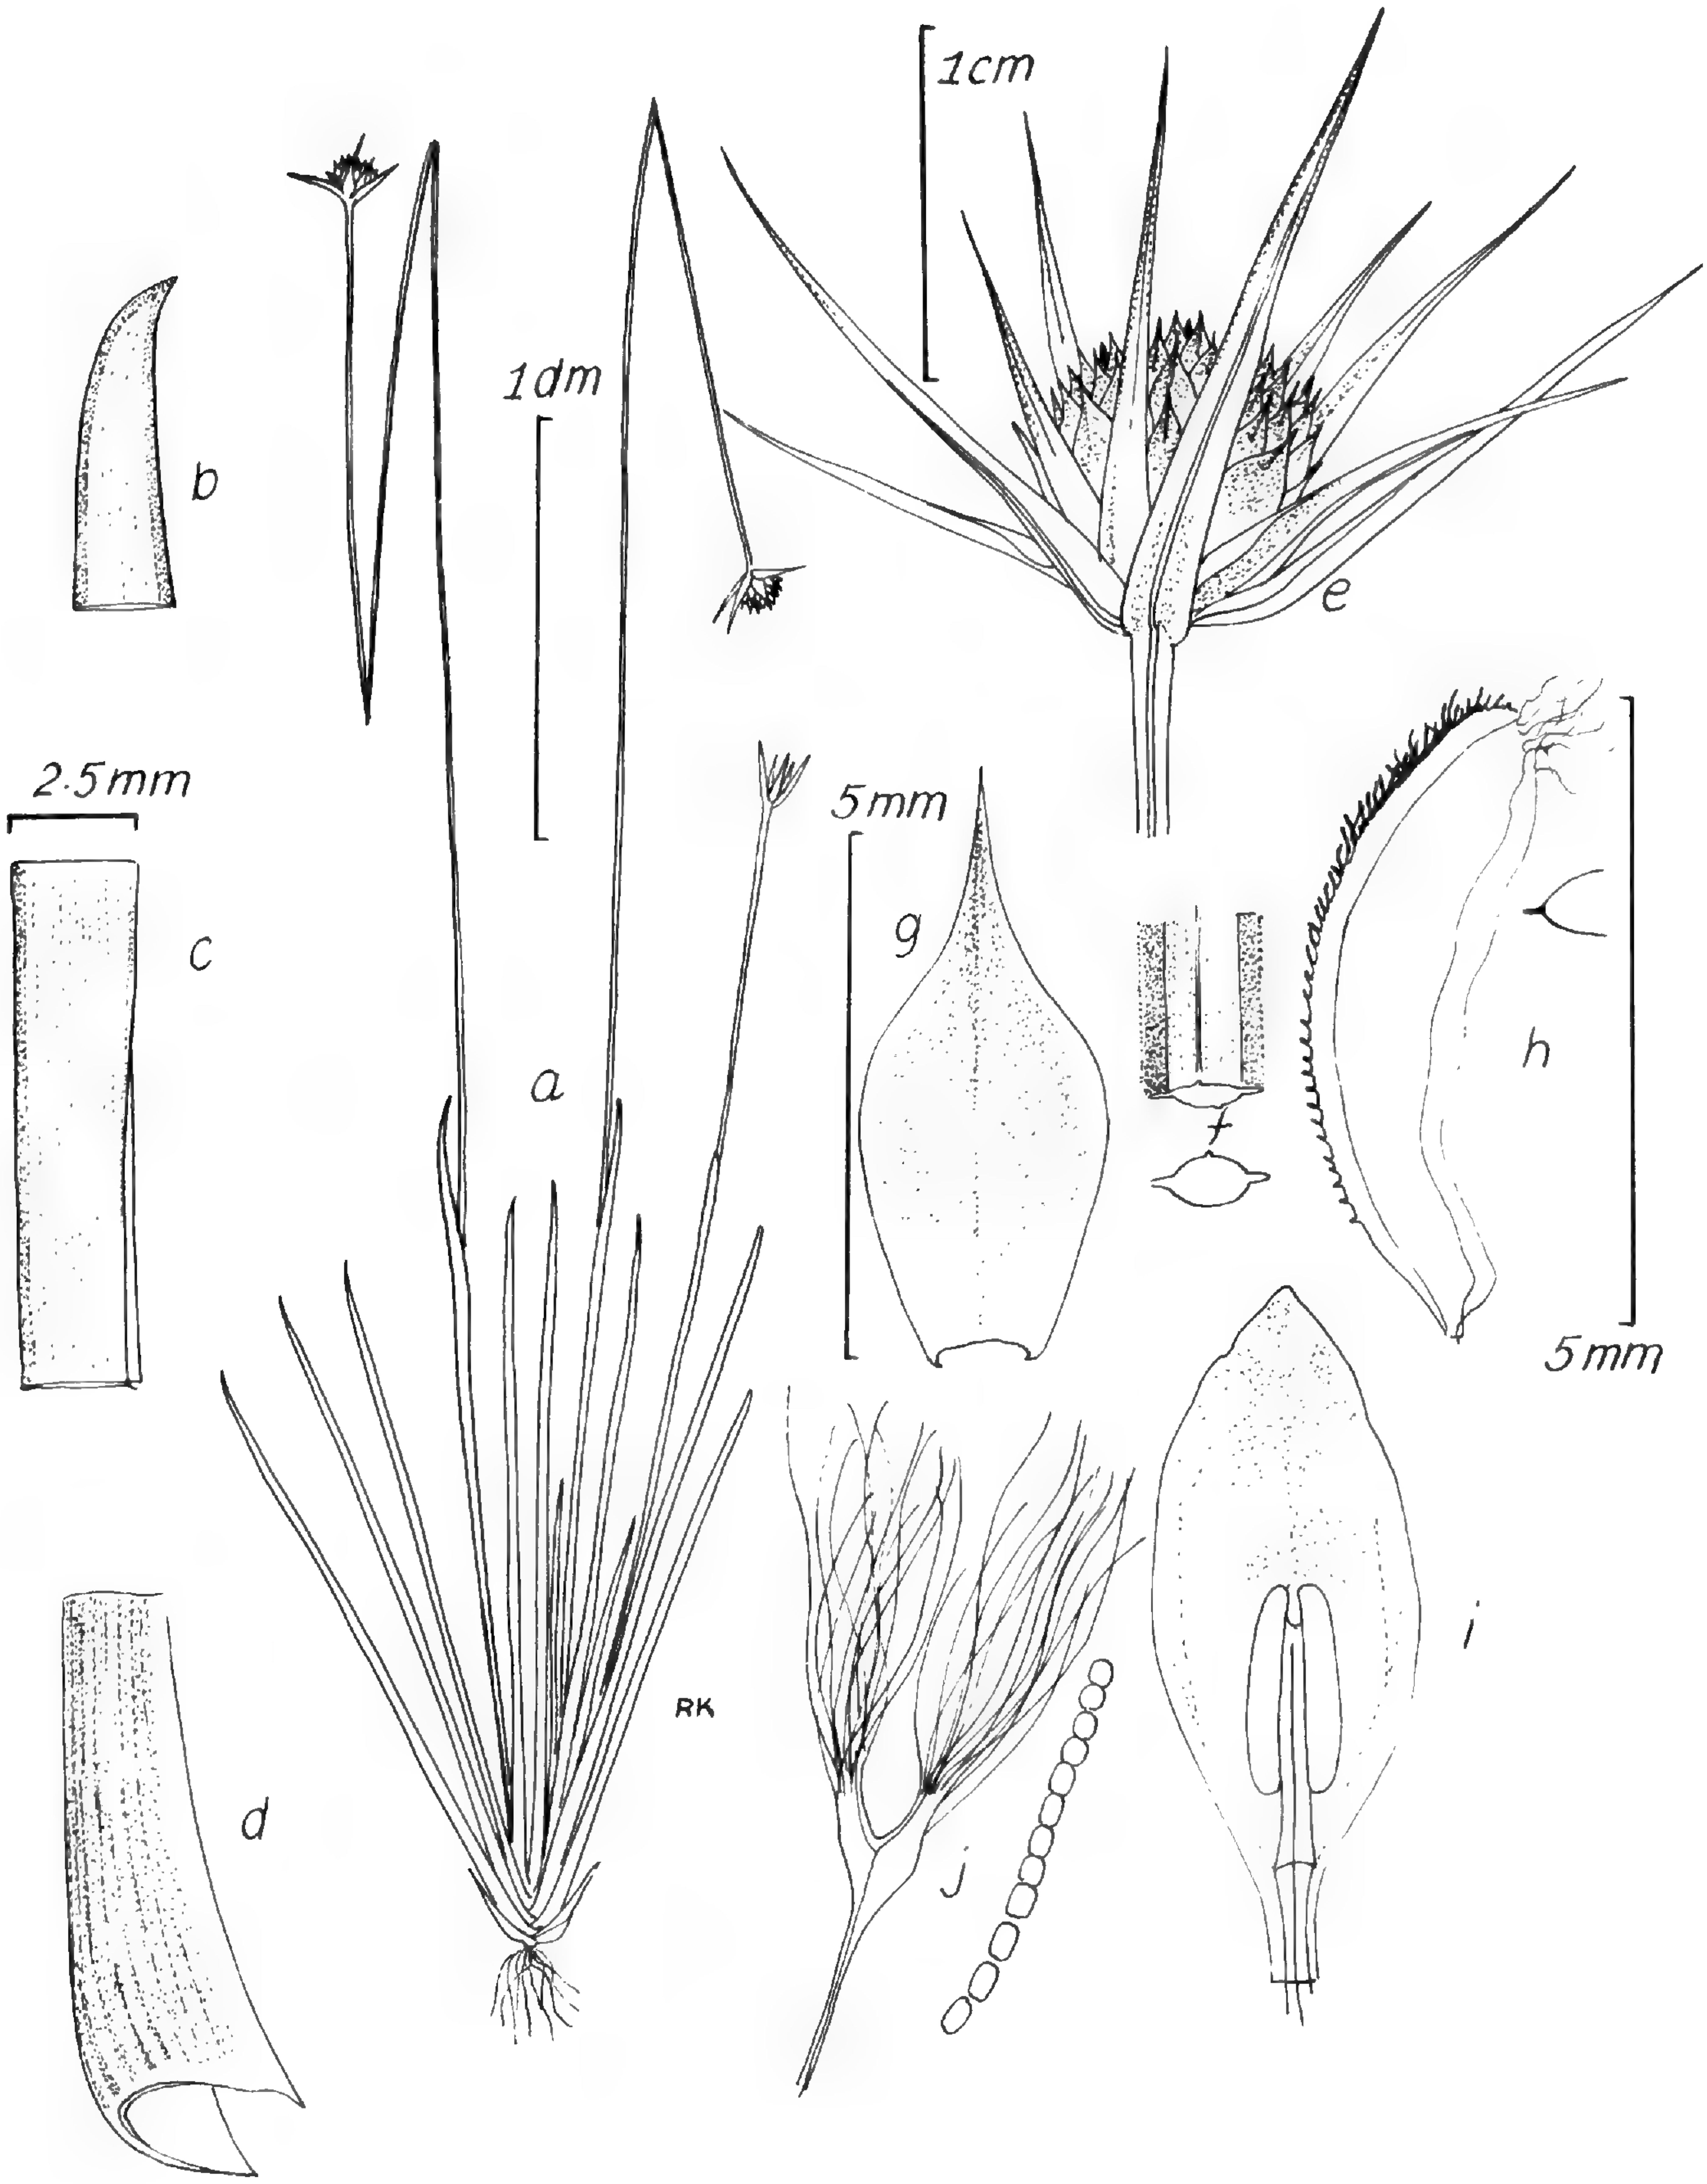

FIGURE 14. Xyris pallidula (Teixeira et al. 1263).—*a. Habit sketch.—b. Leaf tip.—c. Leaf blade–sheath junction.—d. Leaf base.—e. Spike.—f. Upper scape.—g. Fertile bract.—h. Lateral sepal.—i. Petal blade, stamen.—j. Staminode and beard hair.*

slightly spreading flabellately, 10–17 cm long, somewhat shorter than the scape sheaths; sheaths elongate, entire, 1–2 times longer than the blades, pale reddish brown, gradually narrowing from dilated base to apex, eligulate; blades strongly flattened, narrowly linear-gladiate, 2–3 mm wide, pale olive, the margins pale red-brown-bordered, slightly thickened, papillose, the apex incurved-acute. Scape sheaths multicostate toward base, reddish, shining, strongly carinate toward apex, with blade as in leaves but shorter. Scapes rigid, linear, slightly twisted, pale olive, mostly elliptic in cross section toward apex, strongly and acutely bicostate laterally. Spikes multiflorous, broadly ovoid to turbinate or hemispheric, ca. 10 mm long, involucrate, pale brown; involucral bracts several, spreading, subulate, 7–15 mm long, abruptly grading into bracts of spike; spike bracts rhombic-obovate, 5–7 mm long, firm, apically acuminate-subulate, entire, without dorsal area. Lateral sepals free, equilateral, strongly curvate, oblong, 4–5 mm long, obtuse, white-villous-ciliate at apex, the keel ciliate, frequently red-fimbriolate toward apex. Petal blades obovate, yellowish, ca. 5 mm long, acute, entire. Staminodia bibrachiate, long-penicillate. Anthers oblong, shallowly bifid and sagittate, ca. 1 mm long, the filaments ca. 0.5 mm long. Fruit and seed not seen, placentation basal.

This species, yet known only from the type material, is clearly related to the widespread *X. involucrata* but is easily distinguished by the lack of a castaneous "patch" on the leaf sheath base, by the eciliate leaf blades and bracts, and by the definitely subulate-tipped spike bracts.

15. Xyris bicephala Gleason, Brittonia 3: 155. 1939. TYPE: Venezuela. Bolívar: Auyan-tepui, 220 m, Gran Sabana, Dec. 1937–Jan. 1938, *G. H. H. Tate 1114* (holotype, NY). Figure 15.

Robust, cespitose, thick- and hard-based perennial 2.5–10 dm high, the stems stout, short or elongate to 2 dm. Leaves spreading flabellately, 2–5 dm long; sheaths with entire margins, castaneous or near black, ⅔ or more as long as blades, tapering evenly to blade, there imperceptibly short-ligulate; blades broadly linear, flat, 5–10 mm wide, the apex abruptly narrowed and rounded, incurved-acute, or narrowly rounded, the edges densely pale-pilose, densely ciliate or ciliolate, surfaces deep green, low-nerved. Scape sheath loose, shorter than leaves, distally ciliate-carinate, short-bladed. Scape flattened-ancipital, densely albociliate, 2.5–4 mm wide, bispicate (rarely monospicate). Spike broadly ovoid, obovoid or subglobose, 0.8–1.5 mm long, deep brown or castaneous, the bracts rigid, with or without a small, paler, elliptic, subapical dorsal area; sterile bracts many, ovate-triangular, smaller than and grading into the numerous fertile bracts, these broadly elliptic-ovate to oblong, 5–8 mm long, narrowly to broadly rounded, entire to erose or finely lacerate (rarely also red-ciliolate), lustrous toward base, dull toward tip, backs slightly rounded, ecarinate. Lateral sepals free, equilateral, linear-oblanceolate and often excurvate, 5.5–6.6 mm long, pale brown with firm, dark keel, this red-ciliolate or red-fimbriolate from middle to apex. Petal blades broadly obovate, 5.5–6 mm long, yellow, apically obtuse and erose. Staminodia bibrachiate, the slender branches long-villous-penicillate from base to tip. Anthers oblong, emarginate and auriculate, ca. 2 mm long, on filaments ca. 1 mm long. Capsule narrowly ellipsoid, 4–4.5 mm long, the placentation basal-axile (septa detaching from central axis and falling with valves). Seeds few, cylindric-fusiform, often curvate, 2.5–3 mm long, including a pale, narrowly conic appendage (separated outer integument), and with numerous pale, flattened, longitudinal ribs.

Distribution. Common in boggy rapateaceous savanna at medium to high elevations, the Guayana Highland of Estado Bolívar, Venezuela, eastward into the Pakaraima Mountains of Guayana.

This, the only known species of bispicate *Xyris*, unfolds its pale yellow blooms in the morning. Its dark bracts usually have inconspicuous but often detectable dorsal areas. It may intergrade with *X. decussata* Gl. and with *X. albescens* Steyerm., both of which it strongly resembles in bract and seed characters. It and several other species of the Guayana Highlands hitherto considered part of a well-defined section, "*Nematopus*," are showing septate ovary and fruit, and axile placentation.

16. Xyris teinosperma Idrobo & Lyman B. Smith, Caldasia 6: 224. 1954. TYPE: Colombia. Vaupés: Yapoboda, 10 Dec. 1943, *P. M. Allen 3195* (holotype, COL; isotype, MO). Figure 16.

Sturdy solitary to densely cespitose perennial 5–8 dm high, the stems short and stocky. Leaves mostly spreading flabellately, 4–6 dm long; sheaths entire, in longer leaves less than ½ as long as blades, the dilated bases castaneous and lustrous, upwardly green or stramineous, keeled, tapering evenly to blades, there eligulate or with a narrow thin ligule to 3 mm long, the blades linear, flattened, straight and stiff, 4–10 mm wide, tapering slightly above middle then abruptly narrowed at apex to an incurved or erect, narrowly rounded or broadly acute, thickened tip; margins cartilaginous-thickened, pale, smooth; surfaces deep yellow-green, finely nerved, smooth. Scape sheaths much shorter than leaves, closed below, multicostate, distally keeled, open and with a stubby blade. Scapes distally ancipital, 3–4 mm wide, with 2 smooth costae making edges, surfaces yellow-green, striate, smooth. Spikes ovoid, 2–3 cm long, acute, of very many firm, tightly spirally imbricate bracts, these brown with conspicuous paler dorsal areas; sterile bracts many, the lowest much smaller than the fertile bracts, triangular-ovate, keeled, grading into fertile bracts, these oblong to obovate, ecarinate, 10–15 mm long, apically narrowly rounded and subentire. Lateral sepals free, subequilateral, linear-oblanceolate, 10–11 mm long, acute, the wide keel above middle finely lacerate and/or villosulous, aging subentire. Petal blades broadly oblong-elliptic, 1–1.2 cm long, yellow, the broadly rounded apex erose. Anthers oblong-linear, ca. 3.5 mm long, deeply bifid and sagittate, on filaments ca. 1.5 mm long. Staminodia multibrachiate, the slender branches densely plumose with long, penicillate hairs. Capsule narrowly ellipsoid, 8–10 mm long, the massive placenta basal, the valves dehiscing to reveal deep septa at base. Seeds several on short, bulbous funicles, linear, ca. 3 mm long, including an apical coma of pale, narrow, erect squamellae ca. 1 mm long, the narrow, pale brown seed body with a few strongly raised, pale, short-squamellate ribs.

Distribution. Wet, low savanna in SE Colombia, SW Venezuela, and contiguous Amazonas, Brazil.

This is one of the most distinctive species of *Xyris*, particularly noticeable in the low savannas along the upper Río Orinoco. Its slender, long-comose seeds are the longest known for the genus; its lovely pale yellow petal blades, unfolding in midday, form the largest known flower in *Xyris*.

17. Xyris lomatophylla C. Martius, Flora 24(2): 57. 1841. TYPE: Colombia. Amazonas: "In campis, Arara Coará, *Martius*" (lectotype, M; phototype, GH). Figure 17.

Robust, stiff, hard-based, solitary to cespitose perennial 5–7 dm high, the stems contracted. Leaves spreading flabellately, 0.5–3 dm long; sheaths eciliate, cartilaginous-keeled, fully the length of the blades, abruptly dilated at very base, dark brown or castaneous, shading distally to brown, narrowing gradually upward into blade, there with a short, narrowly triangular, erect ligule; blades flattened, twisted, ensiform, mostly 3–5 mm wide, narrowly acute or abruptly narrowly rounded, with a pale-cartilaginous-thickened, smooth or (frequently) ciliolate border, the surface smooth, finely nerved, dark green. Scape sheaths slightly shorter than leaves, twisted, proximally dark red-brown, keeled, with a cartilaginous costa, distally with a strong, short blade like that of leaves. Scape twisted, straight or flexuous, distally terete or oval in cross section, 1–1.5 mm wide, ecostate, smooth, longitudinally striate. Spikes dull brown, ovoid to cylindrical, 1–3 cm long, blunt, base attenuate or broadly rounded, with many spirally imbricate bracts with large, deep brown, apically broadened dorsal areas and broad, wooly-villous margins; sterile bracts many, the lowest much smaller than the fertile bracts,

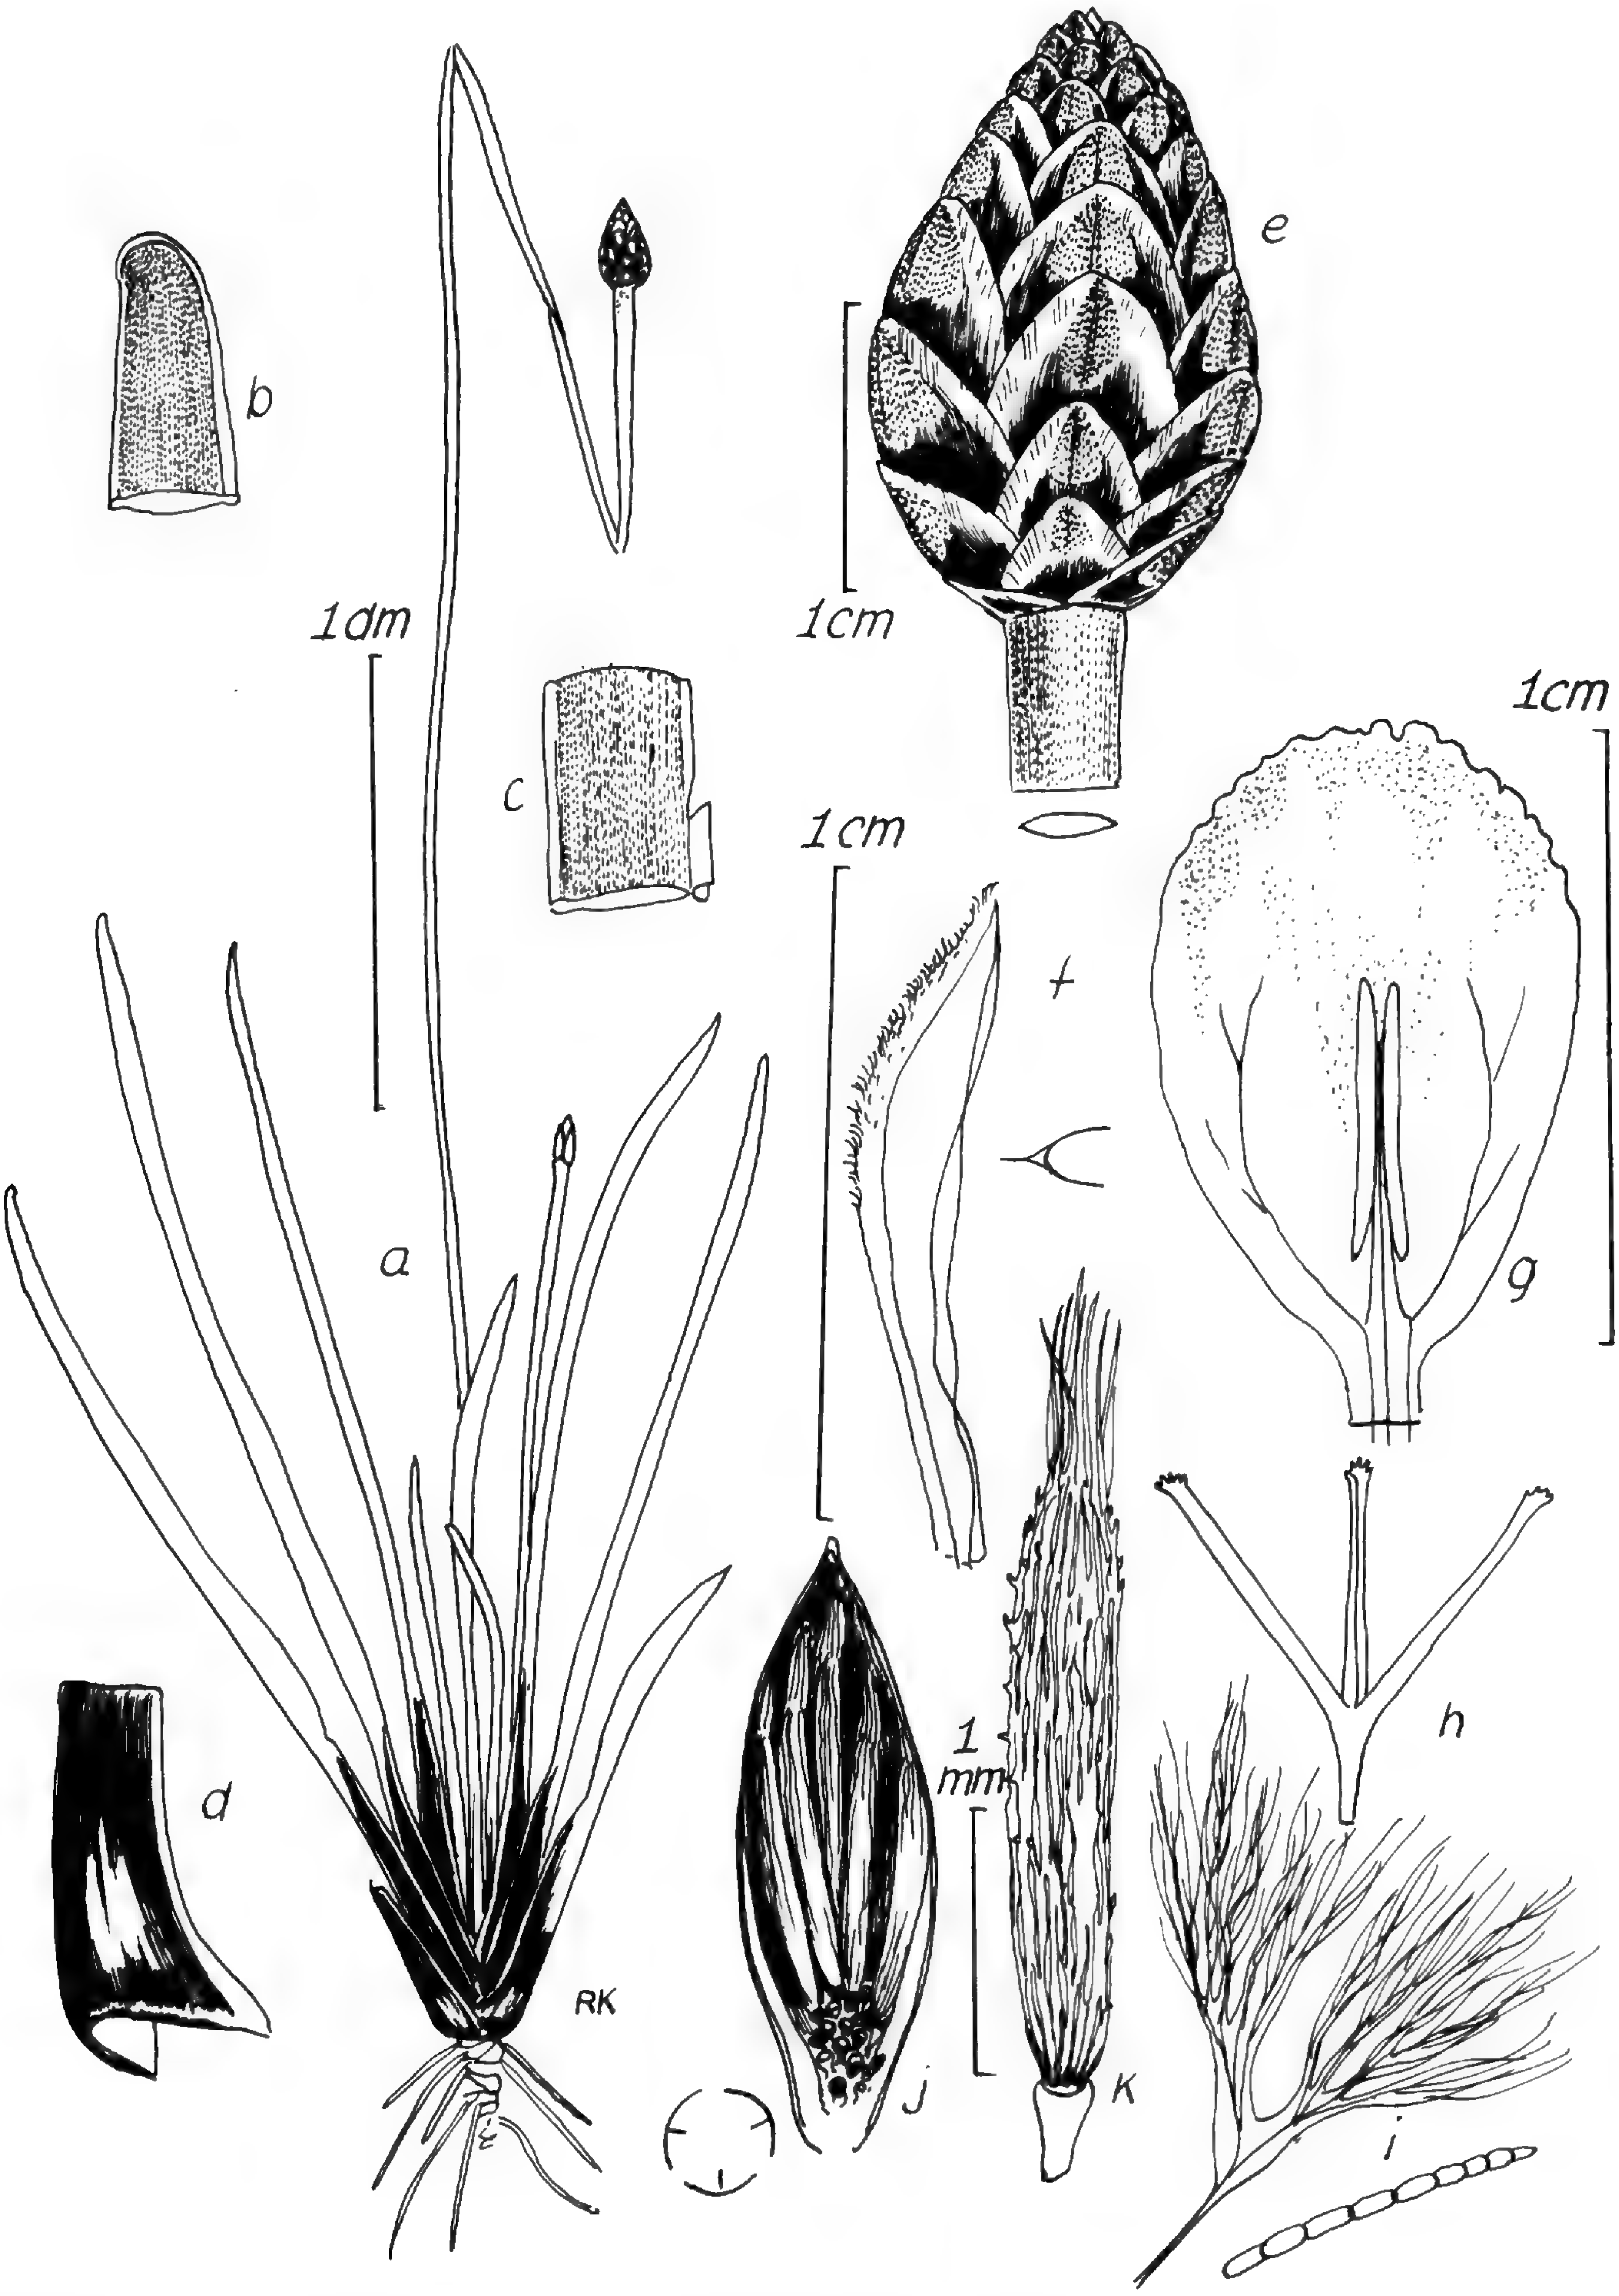

FIGURE 16. Xyris teinosperma (Kral & Huber 70708).—*a. Habit sketch.—b. Leaf tip.—c. Leaf blade-sheath junction.—d. Leaf base.—e. Spike.—f. Lateral sepal.—g. Petal blade, stamen.—h. Stylar apex.—i. Staminode, enlarged tip of beard hair.—j. Capsule, one valve removed to show placentation.—k. Seed.*

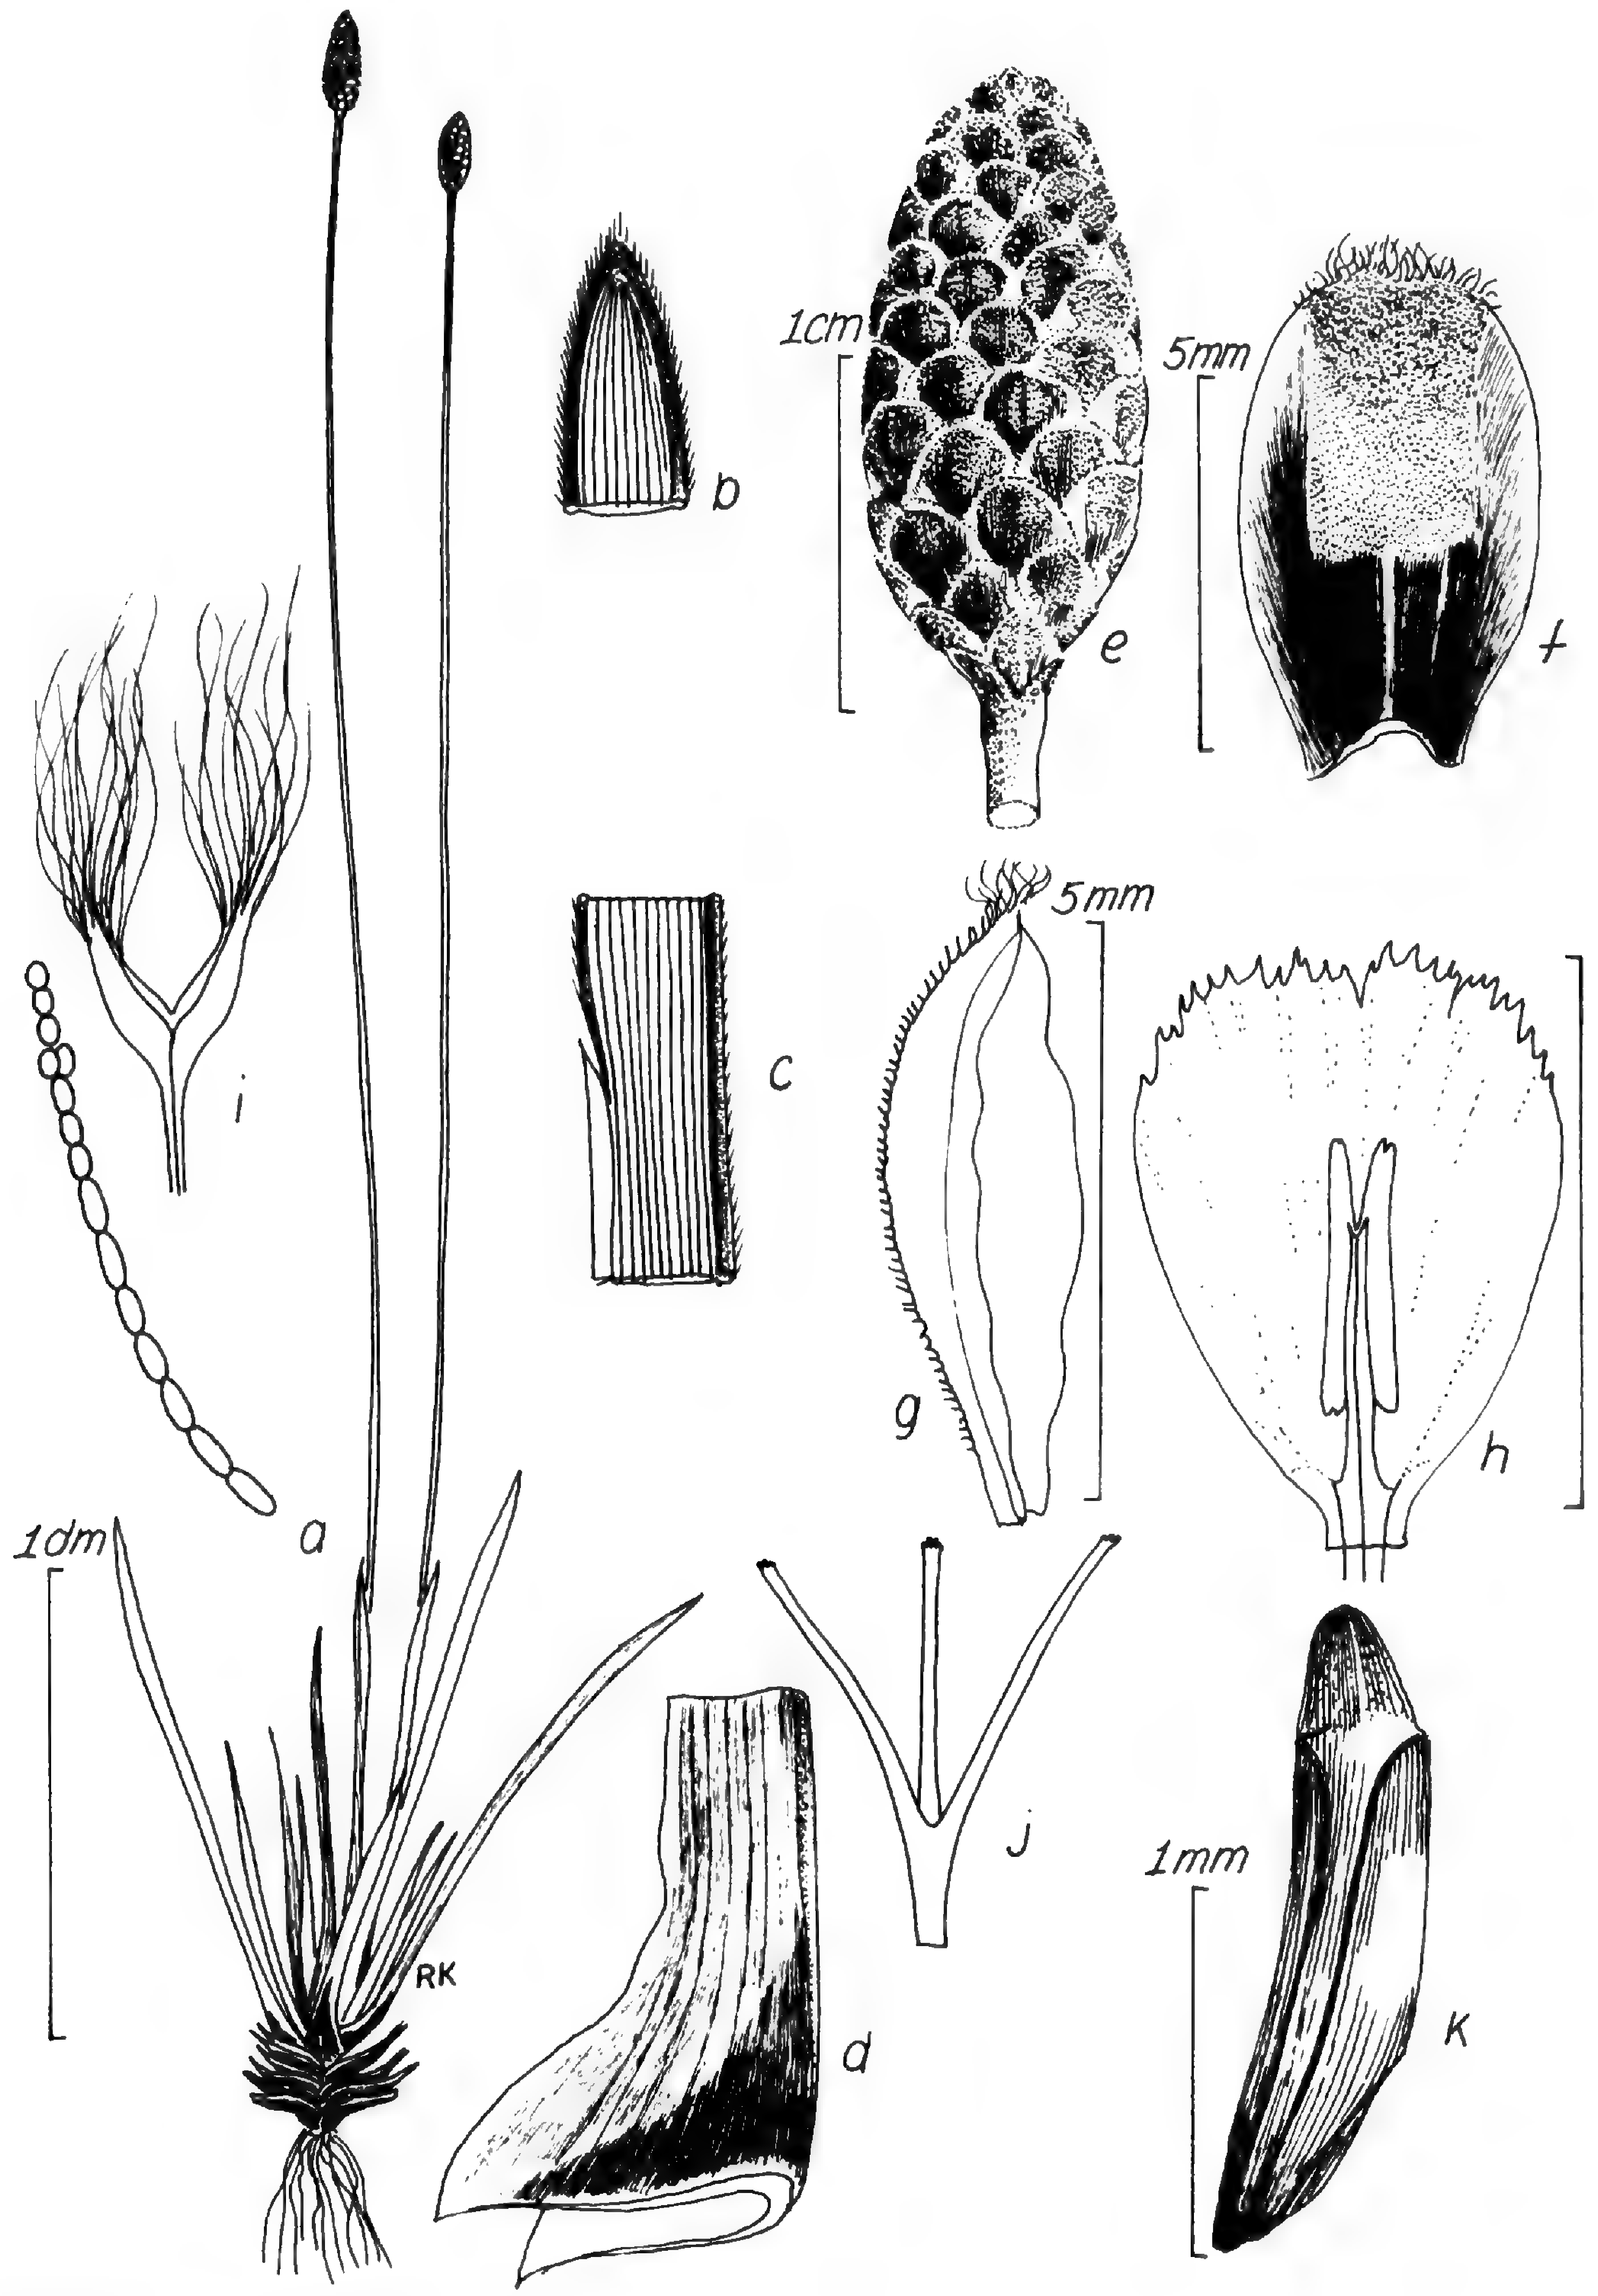

FIGURE 17. Xyris lomatophylla (Huber & Tillett 3058).—*a. Habit sketch.—b. Leaf apex.—c. Leaf sheath-blade junction.—d. Leaf base.—e. Spike.—f. Fertile bract.—g. Lateral sepal.—h. Petal blade, stamen.—i. Staminode.—j. Stylar apex.—k. Seed.*

ovate, slightly keeled, grading gradually larger to fertile bracts, these obovate or broadly elliptic, 7–7.5 mm long, ecarinate. Lateral sepals free, very inequilateral, oblong-curvate, ca. 6 mm long, blunt, lustrous-brown, thin, the wide, firm keel increasingly densely brown-ciliate from near base to tip, there frequently villous-fimbriate. Petal blades broadly obovate, yellow, to nearly suborbicular, ca. 5 mm long, the broadly rounded apex lacerate. Staminodia bibrachiate, the flat, narrowly triangular branches tipped with a dense tuft of penicillate hairs. Anthers lance-oblong, ca. 2.5 mm long, deeply bifid and sagittate, on filaments 0.5 mm long. Capsule ellipsoid, planoconvex, ca. 3–4 mm long, the placentation basal, the valves without septa. Seeds few, cylindrical, 2–2.5 mm long including a white, conic apiculus ca. 0.5 mm long, pale amber, longitudinally finely lined, coarsely overlain by a few prominent dark ribs.

Distribution. Low, wet, sandy savanna, Amazonian southeastern Colombia through the savannas along the upper Río Orinoco and the Río Negro, T. F. Amazonas, Venezuela, southeastward into Pará, Brazil.

Additional specimens examined. BRAZIL. PARÁ: campo inundavel, Missão Velha, Rio Cururu, Alto Tapajós, 19 July 1959, *Egler & Raimundo 952* (US). "*Xyris lomatophylla* Mart. Brasilia prov. Río Negro, Legit *Martius*, Herbar. reg. Monacense Duplum 1864," attributed to Brazil but according to Dr. L. B. Smith, actually Colombian.

In spike character this species most resembles *X. globosa* but differs in its (usually) more elongate spikes; broader, flatter, cartilaginous-bordered leaves; and longer, narrower seeds. In the Venezuelan savanna along the upper Río Orinoco it may be the dominant species.

18. Xyris contracta Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 33. 1963. TYPE: Venezuela. T. F. Amazonas: Cerro de La Neblina, Río Yatua, summit, 1,200–1,300 m, flowers yellow; infrequent in stream bed, upper Cañon Grande, 1,900 m, 11 Dec. 1957, *B. Maguire, J. J. Wurdack & C. K. Maguire 42359* (holotype, NY; isotypes, US, VEN). Figure 18.

Cespitose, thick-based, smooth perennial 2–3(–5.5) dm high, the stem short, to ca. 3 cm long. Leaves ascending, 1–2(–3) dm long; sheaths entire, less than ½ as long as blades, lustrous at base, deep red-brown, dorsally rounded-convex, firm, narrowing gradually and keeled to blade and with a prominent, erect, broadly oblong, blunt ligule 2.5–3 mm long; blade narrowly linear, ca. 1(–3) mm wide, flat, acute at apex, the margins without border, entire, surfaces finely nerved, green. Scape sheath slightly to much shorter than leaves, proximally maroon or castaneous, opening distally, green, producing a strong blade. Scapes linear, straight, distally terete, ca. 1 mm thick, ecostate or with 1–2 very low, smooth costae, or flattened and 2-edged, to 2 mm wide. Spikes ellipsoid, ca. 1.5 cm long, acute, dull red-brown with numerous bracts in several subvertical ranks. Sterile bracts several, lowest keeled, slightly smaller than the fertile bracts and grading into them; fertile bracts oblong, 7–8 mm long, strongly rounded-folded, ecarinate, subentire, apically rounded-emarginate, when young frequently villose-ciliate apically, all with pale, subapical, somewhat indistinct, elliptic dorsal areas. Lateral sepals free, subequilateral, oblanceolate-linear, 7–8 mm long, straight, pale red-brown, the wide, thin keel ciliolate or papillate from middle to apex, or at apex also sparsely red-villosulous. Petal blades broadly obovate or reniform, ca. 7–8 mm long, yellow, the broadly rounded apex lacerate. Staminodia bibrachiate, the branches long-penicillate. Anthers ca. 2.5 mm long, oblong, on filaments ca. 1 mm long. Capsule ellipsoid, 4–4.5 mm long, septa lacking, the placentation basal. Seeds numerous, ellipsoid-fusiform, ca. 2 mm long, including a narrowly conic, pale apiculus ca. 0.4 mm long, the body dark, translucent, longitudinally prominently several-ribbed, with occasional cross-ribs.

Distribution. So far known only from the type area, re-collected there by Steyermark (*104018*, US, VEN) and on the Bra-

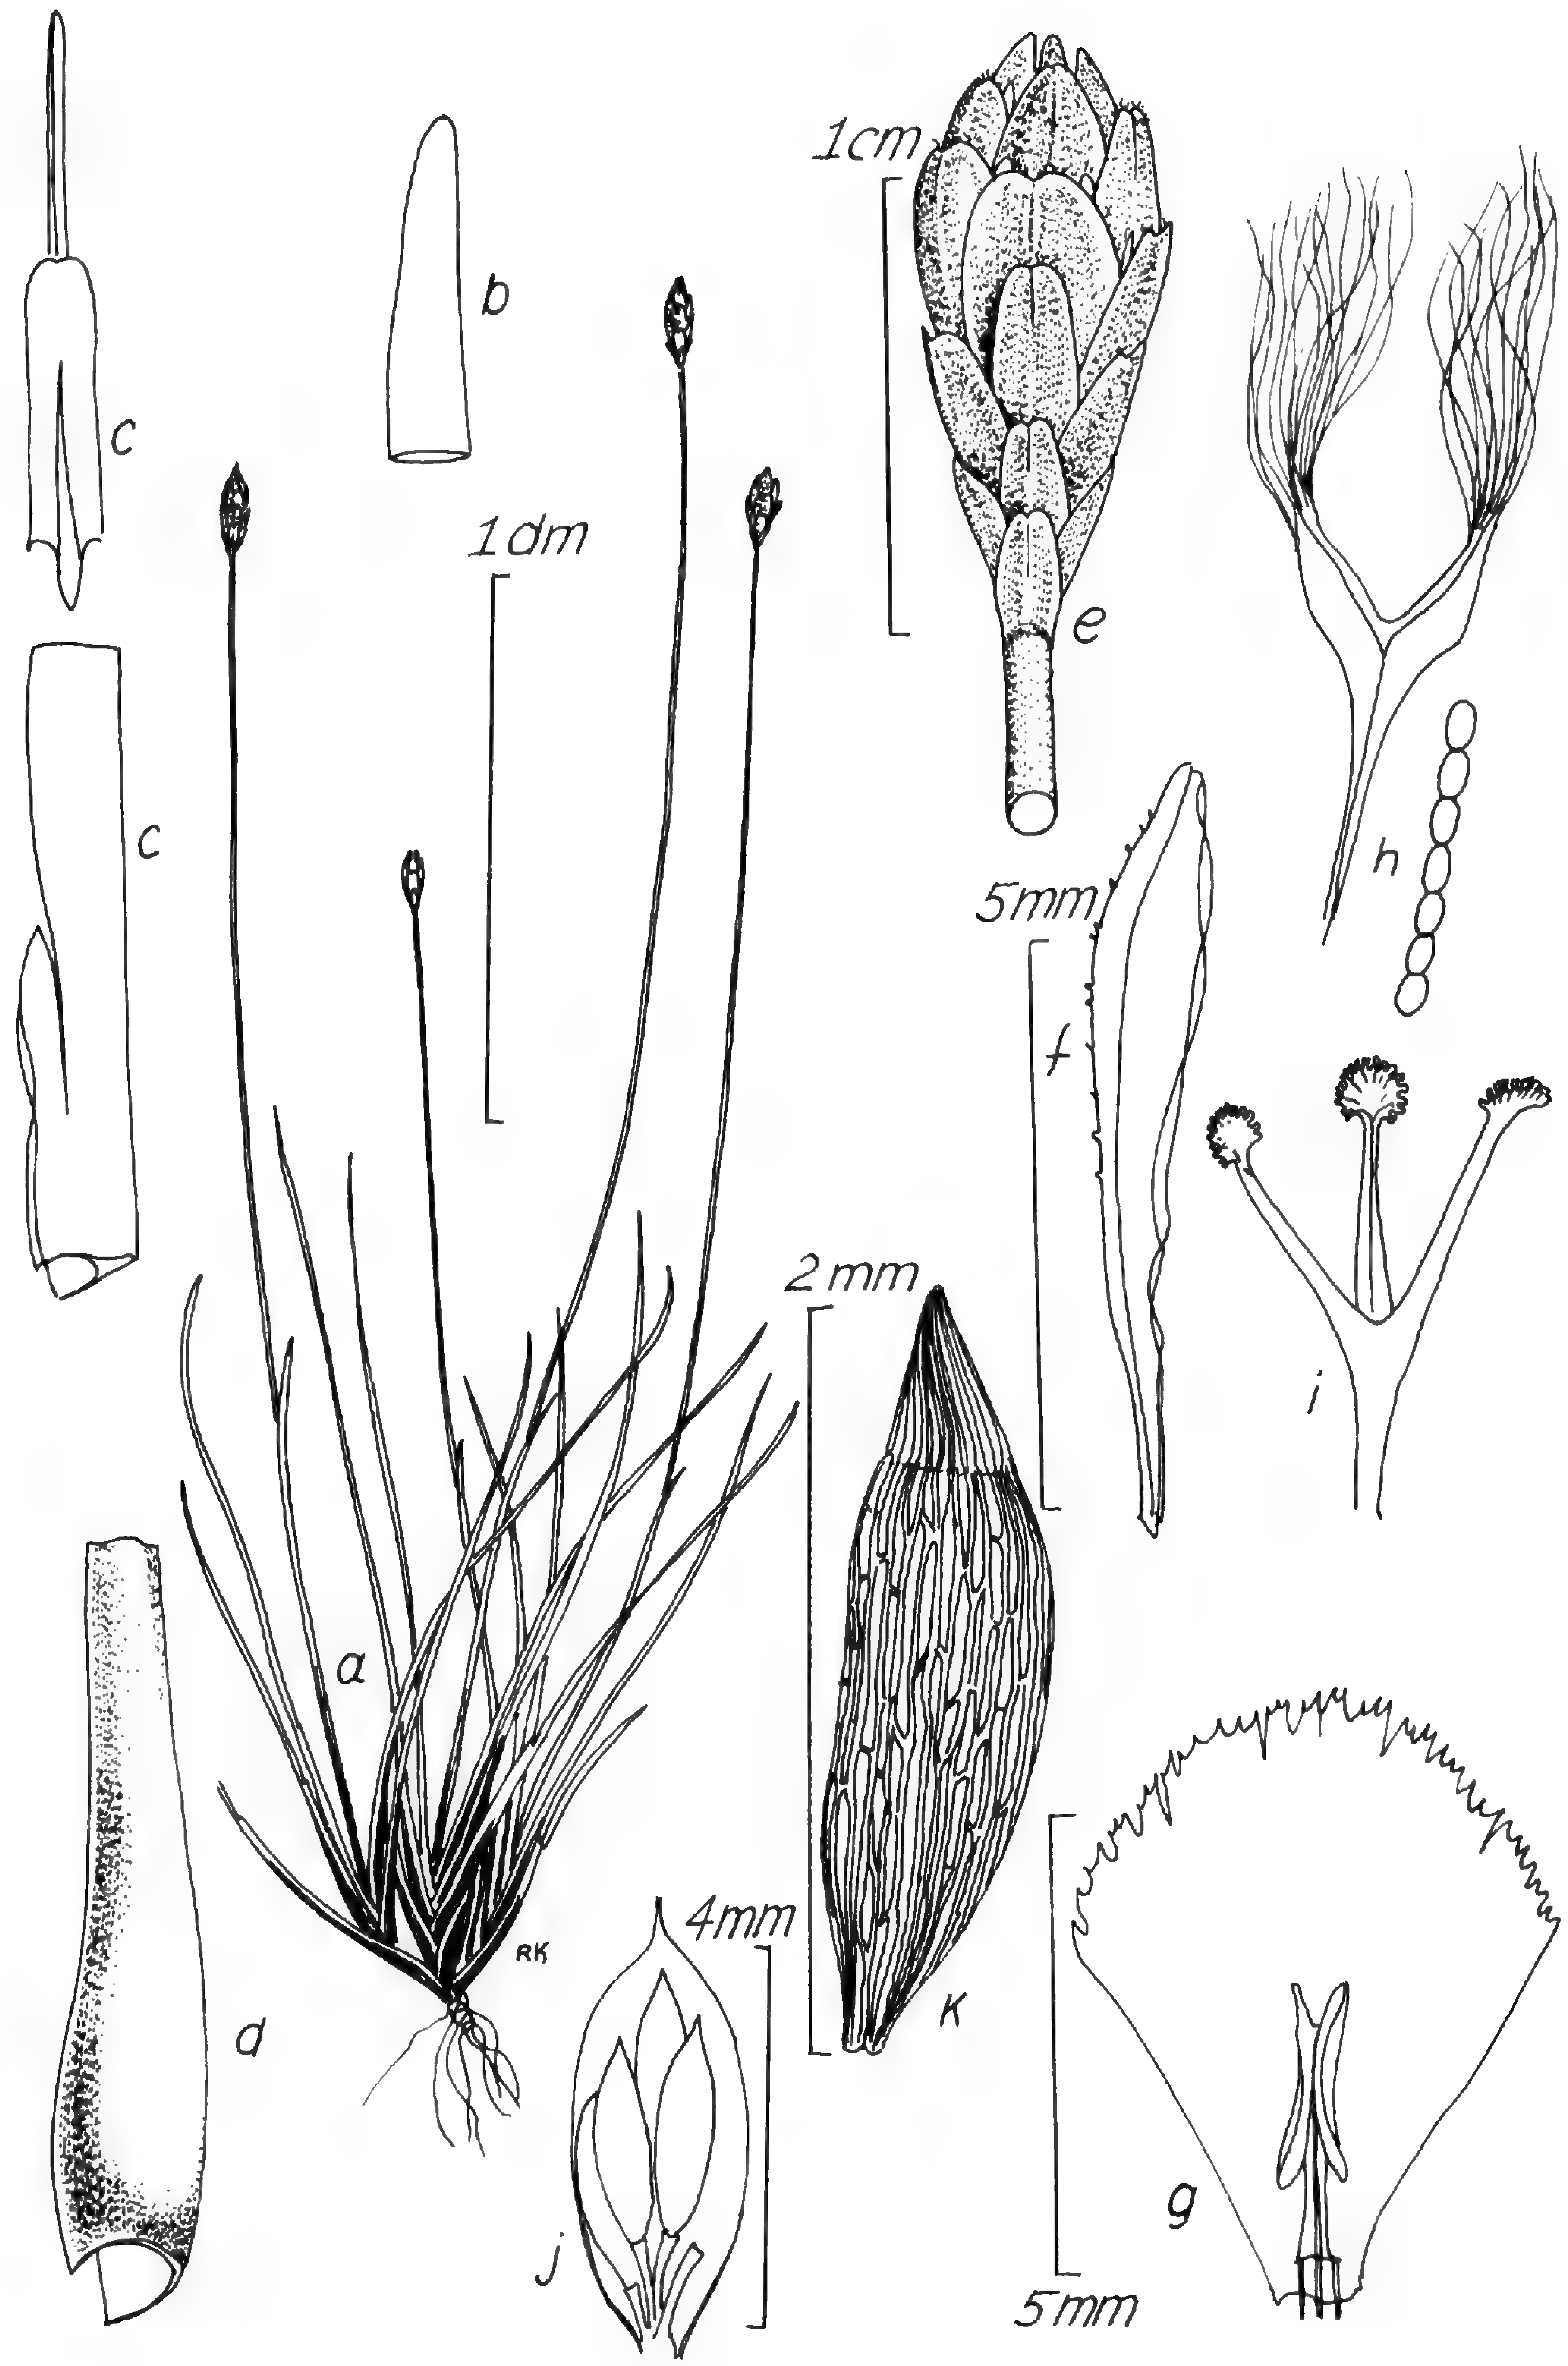

FIGURE 18. Xyris contracta *(from the type).—a. Habit sketch.—b. Leaf tip.—c. Adaxial (inside) view of leaf–sheath junction and side view of same.—d. Leaf base.—e. Spike.—f. Lateral sepal.—g. zilian side of the Neblina crest (Rio Cauaburi, Brazil, *Maguire et al. 60483*, NY).

This rare plant is very distinctive in its combination of narrow, smooth leaves, dark, lustrous, ribless sheath bases, contracted leaf blade base, large ellipsoid spikes, and distinctive seeds. The only exceptional material is that collected by Steyermark which, while definitely this species, is a longer- and wider-leaved extreme with scapes distally flattened and 2-edged, much wider than in the type. I have not seen any further collections of this among many recent collections made by the Neblina workers.

19. Xyris seubertii Nilsson, Sv. Vet. Akad. Handl. 24(14): 51, pl. 4. 1892. TYPE: Guyana: "British Guiana, Rich. *Schomburgk n. 897*" (phototype, US). Figure 19.

X. calcarata Heimerl, Ann. Naturhist. Hofmus. Wien 21: 68, pl. 4, f. 1–3. 1906. TYPE: Brazil: *Tamberlik s.n.* (W—lost; phototype, F).

Slender, solitary to cespitose, hard-based, smooth and glaucous perennial 2–7 dm high, the stems contracted. Leaves spreading flabellately, 0.5–2.5 dm long; sheaths eciliate, at very base abruptly dilated, castaneous to dull, dark brown, above pink or pale purple, sharply keeled, narrowing gradually to blades, often ½ or more as long as blades, at apex producing a narrowly triangular, erect or spreading ligule or tapering directly into blade; blades linear-ensiform, flattened, straight or slightly twisted, 1.5–3.5 mm wide, narrowing above middle gradually into an incurved-acute or acuminate tip, the margins thin, entire to papillose, tuberculate, or scabridulous-ciliolate, the surfaces green, smooth, finely multinerved. Scape sheaths often as long as leaves, tubular and multicostate toward base, often rose or purple, ribbed, above open, keeled, with short, flat blades similar to those of leaves. Scapes straight or flexuous, twisted, subterete toward apex, 0.5–0.7 mm thick, ecostate or with 1 or more costae and striate, mostly smooth. Spikes ovoid, broadly ellipsoid or suborbicular, 0.8–1.2 cm long, pale brown, of many spirally imbricate bracts with distinct though narrow dorsal areas, the sterile bracts few, broadly rounded, slightly shorter and narrower than the fertile bracts but with 1 or 2 of the lowest often with dorsal areas prolonged as cusps or short blades equaling or exceeding spike; fertile bracts strongly convex-backed, obovate, 5–6 mm long, broadly rounded at apex, sometimes with apical, red-villosulous tuft. Lateral sepals ca. ⅕–⅓ connate, inequilateral, lanceolate, 6–6.5 mm long, blunt, slightly exserted, thin, the tan, firm keel above middle to apex increasingly densely reddish villous. Petal blades broadly obovate to reniform, ca. 6–7 mm long, yellow, the very broadly rounded apex wavy-erose. Staminodia bibrachiate, the branches long-penicillate. Anthers narrowly oblong, ca. 2 mm long, deeply bifid, deeply sagittate, on filaments ca. 1 mm long. Capsule obovoid, ca. 3 mm long, placentation free-central, the valves without septa. Seeds numerous, broadly ellipsoid to ovoid, ca. 0.3–0.4 mm long, apiculate, amber, finely striate-reticulate.

Distribution. Abundant and widespread from the Gran Sabana of Estado Bolívar, Venezuela, eastward into Guyana, increasingly abundant south of the Amazon Basin in the Brazilian planalto southward to São Paulo.

This species is distinctly weedy, often a pioneer in mechanically disturbed, eroded, or burned savanna. Its glaucous foliage and rather pale yellow flowers, which unfold in late morning, make it particularly handsome.

20. Xyris huberi Kral & Lyman B. Smith, nom. nov. TYPE: Venezuela. T. F. Amazonas: Cerro Yapacana, en la sabana grande entre el Caño Cotua y el pie del cerro, 3°45′N, 66°45′W, 125 m, 7 May 1970, *J. A. Steyermark & G. Bunting 103241* (holotype, US; isotype, VEN). Figure 20.

roots slender. Leaves ensiform-linear, (7–)8–15(–16) cm long, spreading flabellately, longer than the scape sheaths; sheaths entire, carinate, the carinae ciliate-scabrid, the sides deep brown, narrowing from the dilated, castaneous base gradually to the blade, there the edges converging to form a triangular, linear-acute, slightly spreading ligule 1.5–2 mm long; blades equal to or twice as long as sheaths, flat or somewhat twisted, strongly compressed, 1.5–2 mm wide, the surfaces green, tinged with brown or rusty brown, punctate (stomata depressed), longitudinally multinerved; apices narrowly acute, erect or incurved, slightly thickened; margins thickened, yellowish, densely pale ciliate with antrorse hairs. Sheaths of scapes multicostate, twisted, carinate, the carinae ciliate, the blades short, similar to leaf blades. Scapes 1.5–2.5 dm high, straight or somewhat flexuous, slightly twisted, distally 1–1.5 mm wide, punctate, bicostate, brownish, ancipital, the edges antrorsely long-ciliate. Spikes obovoid, 6–7 mm long, obtuse, few-flowered, bracts loosely imbricate, subdecussate, with scarious, reddish brown, revolute, ciliate borders and large, pale brown dorsal areas; sterile bracts 2–4, the lower pair oblong-triangular, 4–5 mm long, strongly carinate, the inner pair absent or ovate-triangular, ecarinate, the backs low-rounded, 1-nerved; fertile bracts narrowly ovate, narrowly rounded-folded, ca. 5 mm long, toward apex subcuculate, strongly papillose. Lateral sepals free, equilateral, somewhat curved toward base, lance-linear, ca. 4 mm long, narrowly rounded, acute or bidentate at apex; keel firm, entire toward base, ciliate from middle to apex. Petal blades obovate, ca. 5 mm long, pale yellow, the broadly rounded apex lacerate. Staminodia bibrachiate, the branches long-penicillate apically. Anthers linear-lanceolate, ca. 1.5 mm long, deeply bifid and sagittate on filaments ca. 1 mm long. Capsule narrowly obovoid, 2.5 mm long, the valves eseptate, the placentation basal. Seeds cylindric-fusiform, amber, 1.3–1.4 mm long, longitudinally spirally anastomosing-lined, with a few stronger, darker ribs.

Distribution. Confined to low-elevation savanna along the upper Río Orinoco and tributaries, T. F. Amazonas, Venezuela.

Additional specimens examined. VENEZUELA. T. F. AMAZONAS: Dept. Atabapo, Cerro Yapacana, 3 June 1978, *Huber 2030* (VEN); ca. 1 km a E del Caserio de Guarinuma, 23 Feb. 1979, *Huber 3356* (VEN); Cerro Yapacana, 28 Feb. 1980, *Huber 4815, 4829* (US, VEN); Dept. Casiquiare, 2–3 km al SE del bajo Guasacavi, 10 Mar. 1980, *Huber 5114* (US, VEN).

This species is distinguished by a combination of flattened, prominently thick-edged and ciliate leaves; ancipital and ciliate scapes; and hooded-tipped and reddish-margined, ciliate bracts. The margins of the leaf sheath, while thin, are firm and terminate in a long, narrow, sharp ligule. The large pale dorsal areas and surfaces of leaf blades and scapes are all strongly punctate.

21. **Xyris graniticola** Kral, sp. nov. TYPE: Venezuela: Amazonas. Dept. Atures, vegetación de laja (VL) sobre afloramiento granítico en raudal "pereza" en el Río Autana, 9 Nov. 1984, *F. Guánchez & E. Melgueiro 3425* (holotype, VEN; isotypes, TFAV, VDB). Figure 21.

Planta perennis, densicaespitosa, glabra; radices graciles. Caules breves vel usque ad 3 cm longis. Folia principalia erecta vel leviter flabellate expansa, 10–25 cm longa, scapos circa aequantes, vaginis scaporum longiora; vaginae integrae, carinatae, nitidae, pallide brunneolae, laminis 1–2-plo breviores, ad basin gradatim dilatatae, in laminas gradatim decrescentes, ad apicem ligulatae, ligula rigida, erecta, linearotriangulata, usque ad 1.5 mm longa; laminae anguste lineares, tortae, leviter complanatae, 0.5–0.7 mm latae, longitudine inconspicue paucinervatae, margine ad basin truncato-incrassatae, hispidulae, ferrugineae; apices peranguste conicae, ad apicem dorsaliter scabridae. Vaginae scaporum prope basin brunneolae, nitidae, apicem versus apertae, laminis brevis. Scapi leviter torti, teretes, vel in sectio transversali elliptici, ca. 0.5 mm lati, ecostati, olivacei. Spicae pauciflorae, anguste vel late turbinatae, ca. 4–5 mm longae; bracteae leviter expansae, integrae, decussatae, infimae 4 steriles, par inferiora lanceolata, ca. 4 mm longa, carinata, area dorsali lineari, par intima late triangulata, ca. 3.5 mm longa, area dorsali triangulata, leviter nervata; bracteae fertiles oblongae, 4–4.5 mm longae, anguste obtusae, subconduplicatae, anguste rotundatae, inconspicue unicostatae, dorsum ad basin castaneo, ad apicem area dorsali ovata, viridi. Sepala lateralia libera, aequilateralia, ca. 4 mm longa, obtusa, leviter curvata, ala carinali angusta, integra vel remote papillosa. Laminae petalorum obtriangulatae, luteolae, ca. 2–2.5 mm longae, apice subtruncatae, irregulariter dentatae. Staminodia bibrachiata, brachiis lon-

gipenicillatis. Antherae oblongae, profunde bifidae et sagittatae, ca. 1 mm longae, filiis ca. 0.5 mm longis. Capsula matura ca. 3 mm longa, obovoidea; placenta basalis. Semina ovoidea, ca. 0.5 mm longa, translucentia, atroferruginea vel fusca, subtiliter longitudine multicostata.

The plant perennial, densely cespitose, smooth; the roots slender-fibrous. Stems short or up to 3 cm long. Principal leaves erect to slightly flabellately spreading, 10–25 cm long, about as long as the scapes, longer than the scape sheaths; sheaths entire, carinate, shining, pale brown, ½ or more the length of the blades, gradually dilated toward base, gradually narrowing into the blades, ligulate at apex, the ligule erect, rigid, linear-triangular, up to 1.5 mm long; blades narrowly linear, twisted, somewhat flattened, 0.5–0.7 mm wide, inconspicuously few-nerved, the margin toward the base beveled-incrassate, reddish, hispidulous; tips narrowly conic, dorsally scabrid at apex. Scape sheaths brownish toward base, shining, open, short-bladed toward apex. Scapes somewhat twisted, terete or elliptic in cross section, ca. 0.5 mm wide, ecostate, olivaceous. Spikes few-flowered, narrowly to broadly turbinate, ca. 4–5 mm long; bracts slightly spreading, entire, decussate, with conspicuous dorsal areas, the lowest 4 sterile, the lowermost pair lanceolate, ca. 4 mm long, carinate, the dorsal area linear, the inner pair broadly triangular, ca. 3.5 mm long, the dorsal area triangular, lightly nervose; fertile bracts oblong, 4–4.5 mm long, narrowly obtuse, subconduplicate, narrowly rounded, inconspicuously unicostate, the back castaneous toward base, with an ovate green dorsal area toward apex. Lateral sepals free, equilateral, ca. 4 mm long, oblong, obtuse, slightly curvate, the keel narrow, entire to remotely papillate. Petal blades obtriangular, yellow, ca. 2–2.5 mm long, the apex subtruncate, irregularly dentate. Staminodes bibrachiate, the branches long-penicillate. Anthers oblong, deeply bifid and sagittate, ca. 1 mm long, on filaments ca. 0.5 mm long. Mature capsule obovoid, ca. 3 mm long, the placenta basal. Seeds ovoid or ellipsoid, ca. 0.5 mm long, translucent, deep reddish brown or brown, finely longitudinally many-lined.

Distribution. A "laja" plant known only from the type locality.

This species comes, in treatments of Venezuelan *Xyris*, nearest those perennials with discernably leafy stems, distinct dorsal areas, and comparatively low stature, such as *X. frondosa* Mag. & Sm. However, the few-flowered spikes, in their turbinate outline and broad dorsal areas, are strikingly similar to those of *X. guianensis* Steud., here differing primarily in the nearly entire-keeled, less curvate lateral sepal. The latter plant is also shorter-stemmed, its leaves wiry-bordered.

22. Xyris frondosa Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 33, fig. 18A–E. 1963. TYPE: Venezuela. Bolívar: frequent in scrub forest near Summit Camp, 1,925 m, Central Section, Chimantá Massif, 2 Feb. 1955, *J. A. Steyermark & J. J. Wurdack 346* (holotype, NY; isotypes, F, US, VEN). Figure 22.

Moderately low, slender, densely cespitose perennial 2–3 dm high, the stems ascending, elongate, and forming frondlike plates of leaves. Leaves flabellately spreading, mostly 15–20 cm long; sheaths firm, entire, up to ½ as long as blades, deep reddish brown, papillate, tapering evenly to blade, often ciliate-carinate, at blade junction with an erect, narrowly triangular ligule to 1 mm long or eligulate; blades flat, often twisted, linear, 1.5–2.5 mm wide, tapering evenly to an acute-incurved, densely pale-ciliate apex, the margins ascending-ciliate with pale narrow hairs, submarginally with a deep reddish brown border, the surfaces green or maroon, finely multinerved, mostly smooth. Scape sheaths shorter than leaves, loosely carinate, keel ciliate, open at apex, short-bladed. Scapes slenderly linear, straight or slightly flexuous, slightly twisted, distally terete or slightly compressed, ecostate or low-bicostate, smooth. Spikes ellipsoid, 6–7 mm long, reddish brown, several-flowered, the bracts tightly spirally imbricate and with distinct reddish brown dorsal areas,

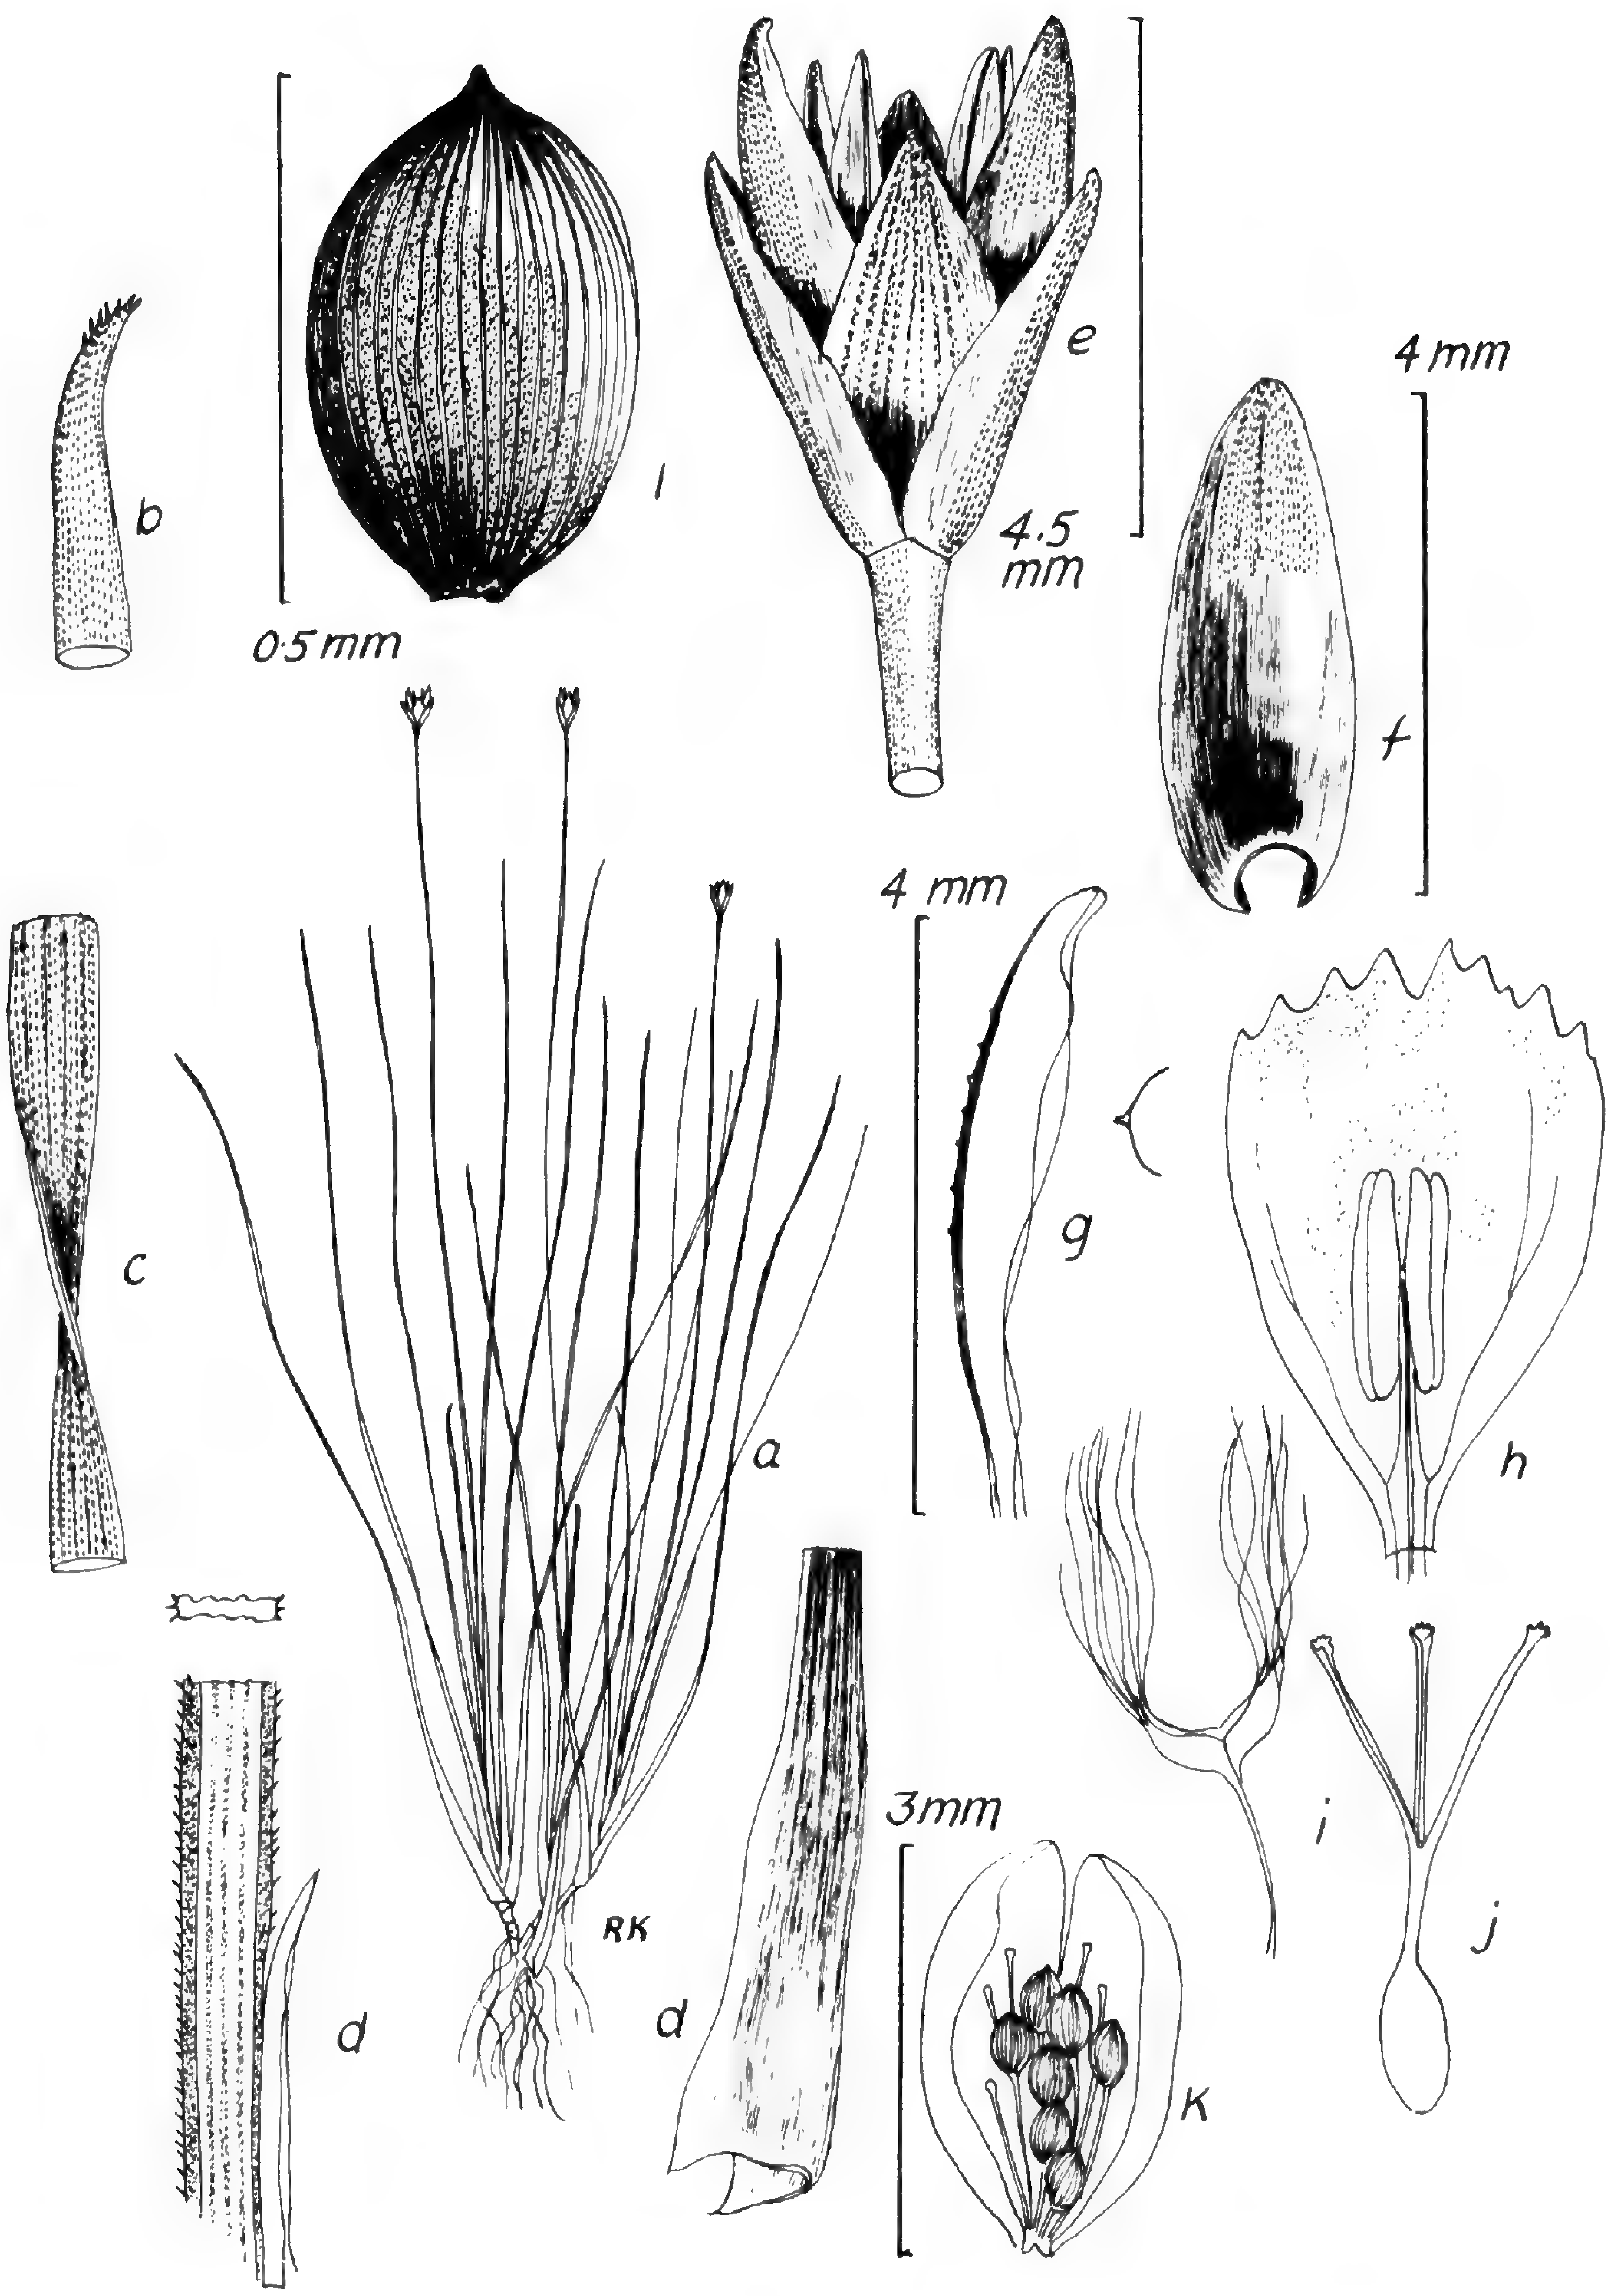

FIGURE 21. Xyris graniticola *(from the isotype)*.—*a. Habit sketch.—b. Leaf apex.—c. Sector of midblade.— d. Leaf sheath–blade junction (at left); leaf base (at right).—e. Spike.—f. Fertile bract.—g. Lateral sepal.— h. Petal blade, stamen.—i. Staminode.—j. Ovary, style branches.—k. Capsule, one valve removed.—l. Seed.*

apically often white-villosulous-ciliate; sterile bracts smallest, grading into the fertile bracts, triangular or ovate, acute, keeled, the fertile bracts obovate, ecarinate, 4.5–5 mm long, subentire, broadly rounded apically, backs convexly rounded, the dorsal areas bisected by a low but distinct rib. Lateral sepals oblong, curvate, free, inequilateral, ca. 4.5 mm long,

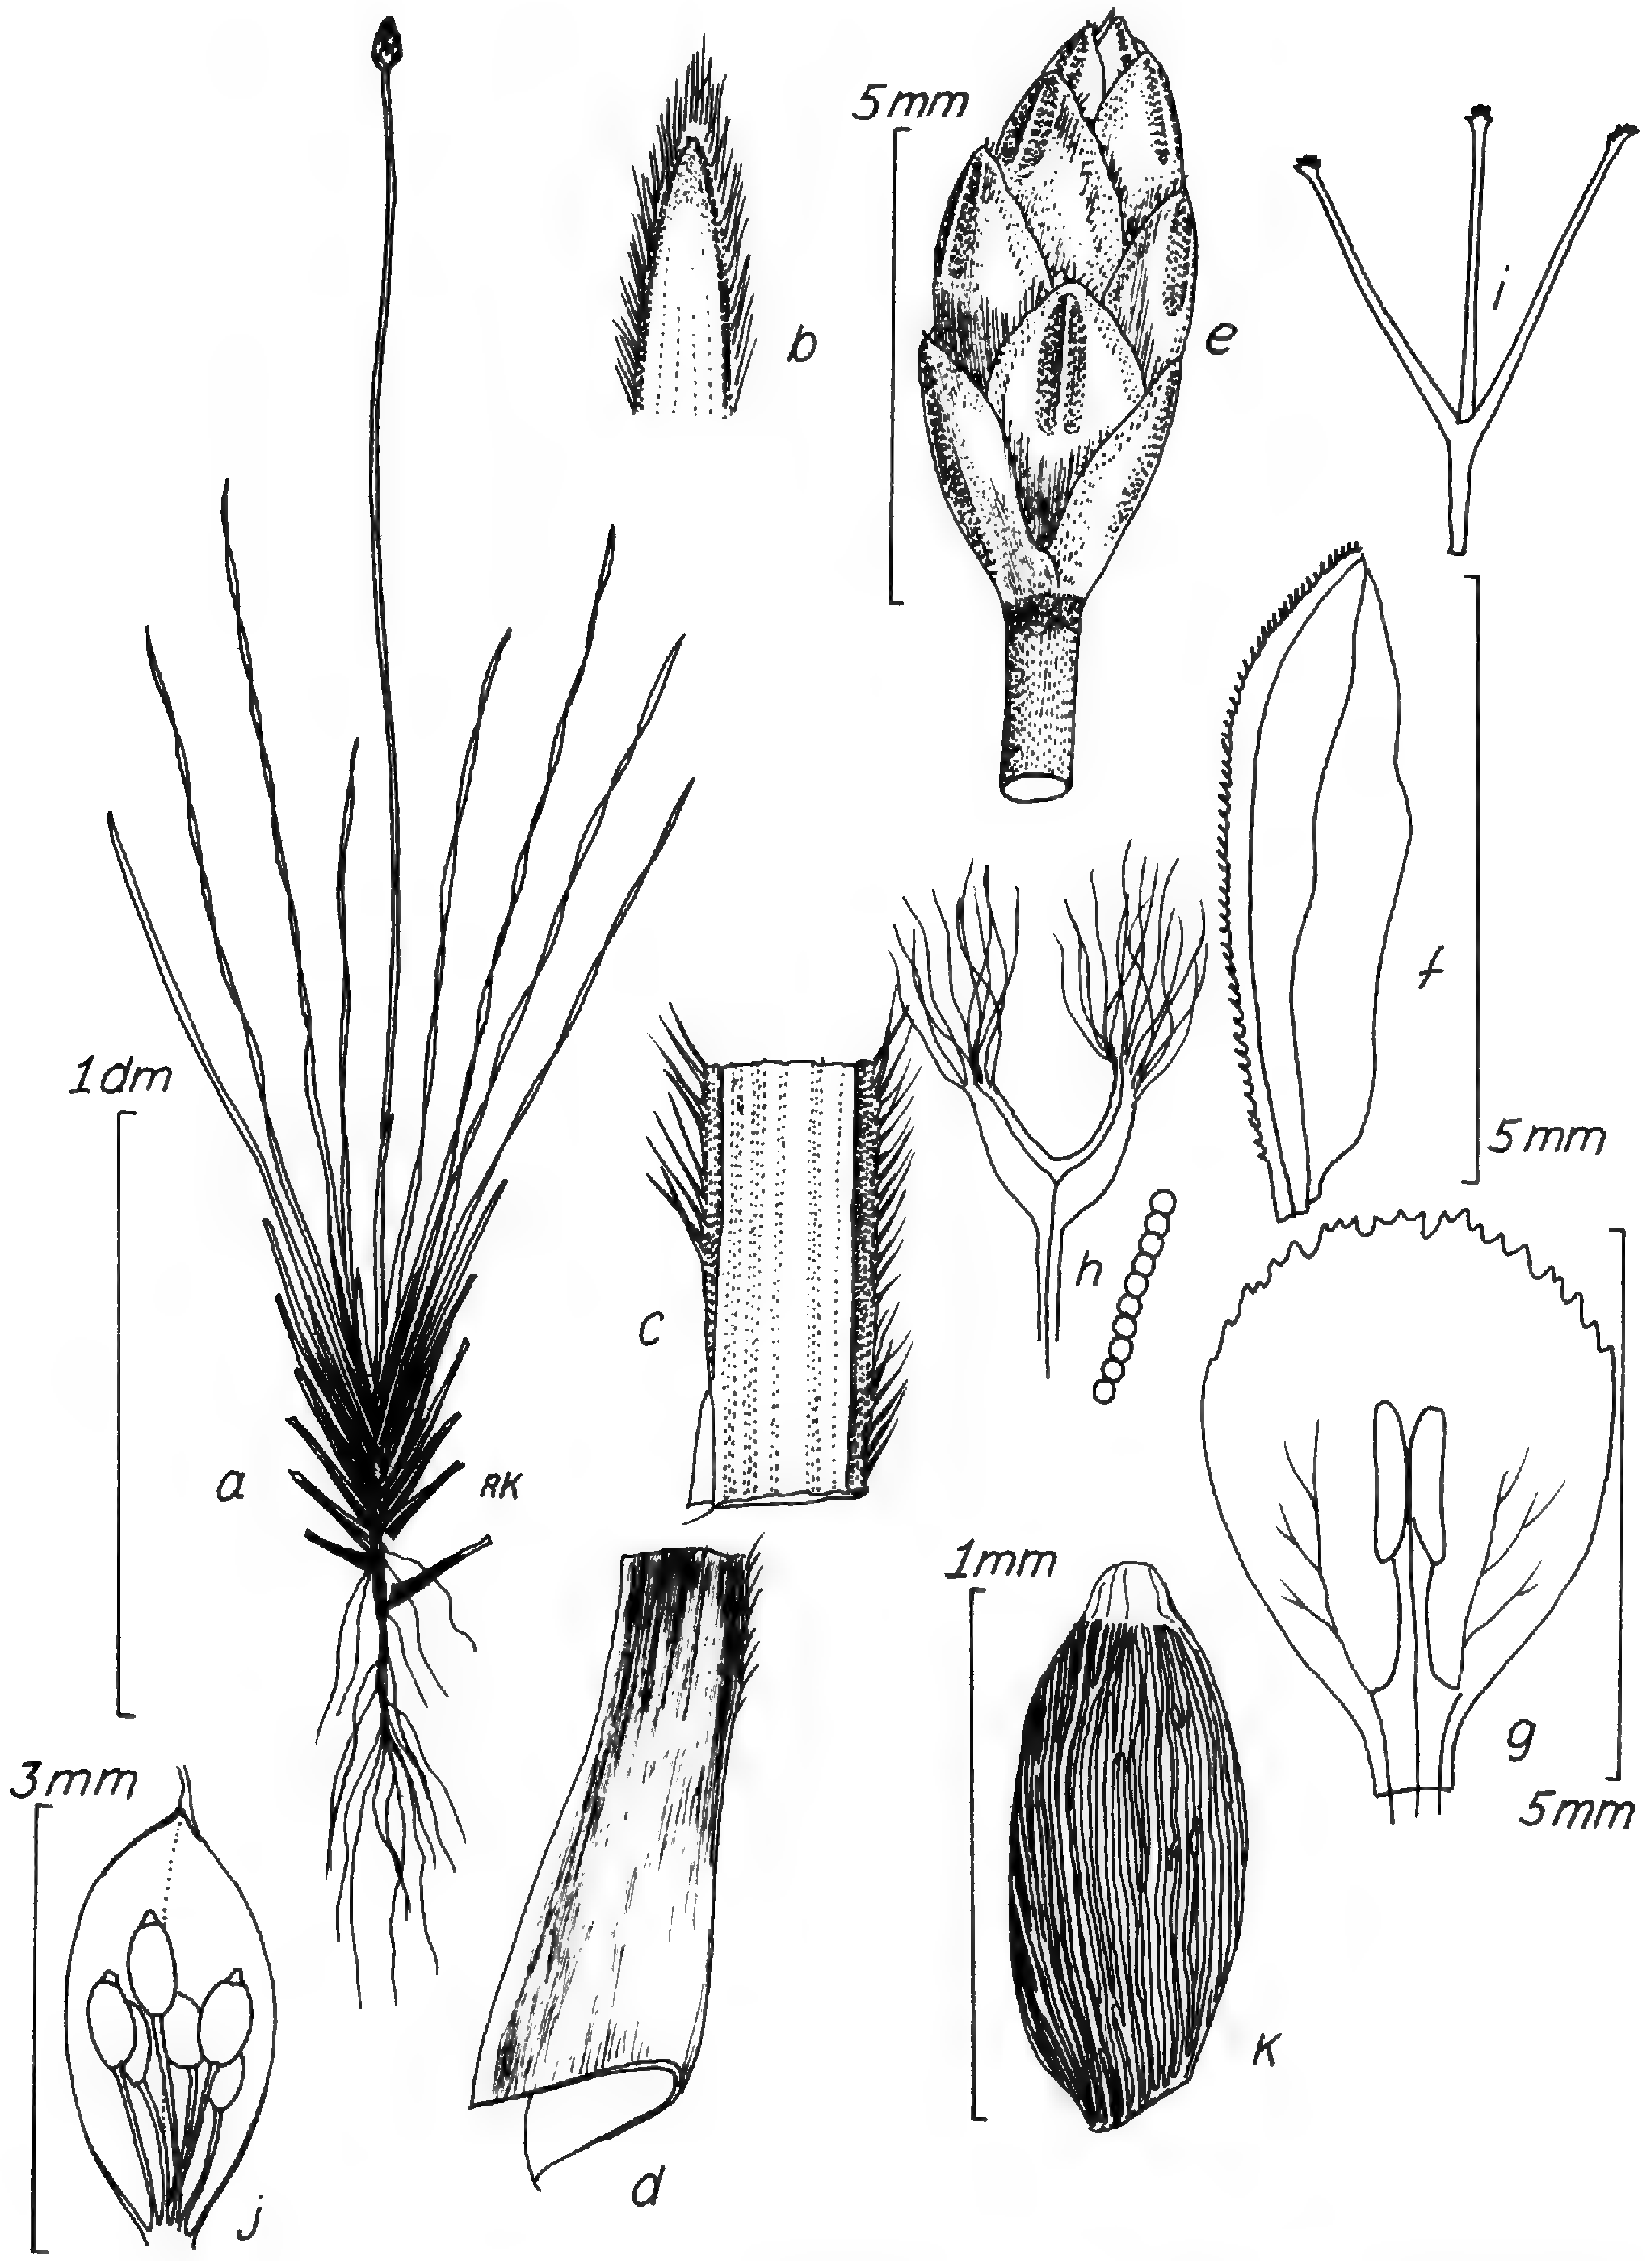

FIGURE 22. Xyris frondosa *(from the type).—a. Habit sketch.—b. Leaf apex.—c. Leaf blade–sheath junction.—d. Leaf base.—e. Spike.—f. Lateral sepal.—g. Petal, stamen.—h. Staminode.—i. Stylar apex.—j. Capsule, one valve removed, showing basal placentation.—k. Seed.*

blunt, pale reddish brown with a dark, firm, irregularly tuberculate-ciliate or ciliolate keel from base to apex. Petal blades broadly obovate to suborbicular, yellow, ca. 5 mm long, the apical margin lacerate-dentate. Staminodia bibrachiate, the broad, flat branches densely penicillate at tip. Anthers oblong, ca. 1 mm long, bifid, auriculate, on flattened filaments ca. 1 mm long. Capsule ellipsoid or narrowly obovoid, ca. 3 mm long, the placentation basal, the valves without evident septa. Seeds several, on long funiculi, ellipsoid to oblong-cylindrical, ca. 1 mm long, translucently deep amber, pale apiculate, with fine, longitudinal, anastomosing ribs.

Distribution. Abundant in wet, high savanna, the Chimantá Massif and associated systems, usually above 1,500 meters, Estado Bolívar, Venezuela.

Additional collections examined (since those published by Maguire & Smith (1963)). VENEZUELA. BOLÍVAR: Macizo del Chimantá, *Huber & Steyermark 6907* (VDB, VEN); Chimantá, Apacará-tepui, *Huber & Steyermark 6961* (VDB, VEN); sección oriental del Chimantá-tepui, *Huber & Steyermark 7161* (VDB, VEN); Auyan-tepui, *Huber & Medina 8538* (NY, VEN); Apacará-tepui, *Huber & Colella 8727* (NY), *8736*, *8774* (NY, VDB, VEN); Churi-tepui, *Huber & Colella 9000* (NY, VDB, VEN); Acopan tepui, *Huber et al. 9069* (NY); ca. 25 km al SE de Canaima, *Huber 9730* (MYF, VDB); Murey-tepui, *Huber 11586* (MYF, VDB, VEN); Abacapá tepui, *Huber 11471* (MYF, VDB, VEN); Meseta de Jaua, Cerro Jaua, *Steyermark 98124* (MO, NY, VEN); Auyan-tepui, *Steyermark 93505* (NY, US, VEN), *93697* (F, NY, US, VEN), *93757* (NY, US, VDB, VEN), *93992* (L, NY, US, VEN); Cerro Jaua, *Steyermark 98055* (F, VEN), *109387* (NY, VEN); Cerro Guanacoco, *Steyermark et al. 109731* (US, VEN), *109734* (US, VEN); Cerro Jaua, *Steyermark 109426* (US, VDB, VEN), *109460* (K, MO, US, VEN), *109610* (US, VDB, VEN); Cerro Guaiquinima, *Steyermark & Dunsterville 113173* (F, US); Murey (Eruoda) tepui, *Steyermark et al. 115839* (F, MO, US, VEN).

This low-growing species with its long-stemmed fronds of rusty-bordered, ciliate leaves and small spikes with distinct dorsal areas, has no near morphological neighbor within its narrow range.

23. Xyris chimantae Kral & Lyman B. Smith, Phytologia 53: 432–433, fig. 1a–h. 1983. TYPE: Venezuela. Bolívar: Chimantá Massif, central section, swampy depression in wet savanna along east branch of headwaters of Río Tirica, 2,120 m, 12 Feb. 1955, *J. A. Steyermark & J. J. Wurdack 768* (holotype, VEN; isotypes, F, NY). Figure 23.

Cespitose perennial to 6 dm high, the stems either short or ascending through deep substrate and to 1 dm long, the bases mostly covered by scalelike old leaf bases. Roots slender, arising from lowermost nodes. Principal leaves stiff, spreading distichously, (1.8–)2–4(–4.8) dm long, longer than scape sheaths; blades narrowly linear, 3–4 times longer than the sheaths, slightly twisted, flattened, somewhat thickened and with thick margins, 2–2.5 mm wide, olivaceous to yellow-brown, finely papillose-rugulose; apices abruptly incurved-acute, thickened, entire to scabrociliate; margins slightly papillose to minutely scabro-ciliate; sheaths ecarinate, the broad bases firm, lustrous, castaneous to yellow-brown, entire, narrowing gradually into blades, eligulate. Scape sheaths proximally tubular, dark, multicostate, papillose, distally open, short-bladed. Scapes slenderly lineal, straight or slightly flexuous, slightly twisted, distally subterete to oval or elliptic in cross section, ecostate to narrowly bicostate, the costae papillose to scabrid. Spikes obovoid to obconic, ca. 1 cm long, many-flowered, the bracts loosely imbricate, subdecussate, ecarinate, without dorsal area, smooth, light to deep brown, strongly lacerate; sterile bracts several, ovate, shorter than the fertile bracts and grading into them; fertile bracts several, ovate, 7 mm long, narrowly rounded, reddish ciliate at apex when young, with the median nerve low but manifest. Lateral sepals free, subequilateral, oblanceolate, ca. 5.5 mm long, included to exserted at apex of spike, slightly curvate, acute; keel reddish fimbriociliate from middle to tip. Petal blades obovate-rhombic, ca. 6 mm long, yellow, apically narrowly rounded, erose. Staminodia bibrachiate, the branches long-penicillate. Anthers narrowly oblong, ca. 2 mm long, shallowly bifid, shallowly auriculate, on filaments ca. 1 mm long. Capsule cylindric-ellipsoid, ca. 5 mm long, the valves with septa from base to tip. Seeds narrowly ellipsoid-fusiform, ca. 2 mm long, including a terminal white, conic scale 0.6–0.7 mm long, the seed body reddish brown, translucent, conspicuously longitudinally multiribbed.

Distribution. Locally abundant in wet savanna at elevations over 1,900 meters, the

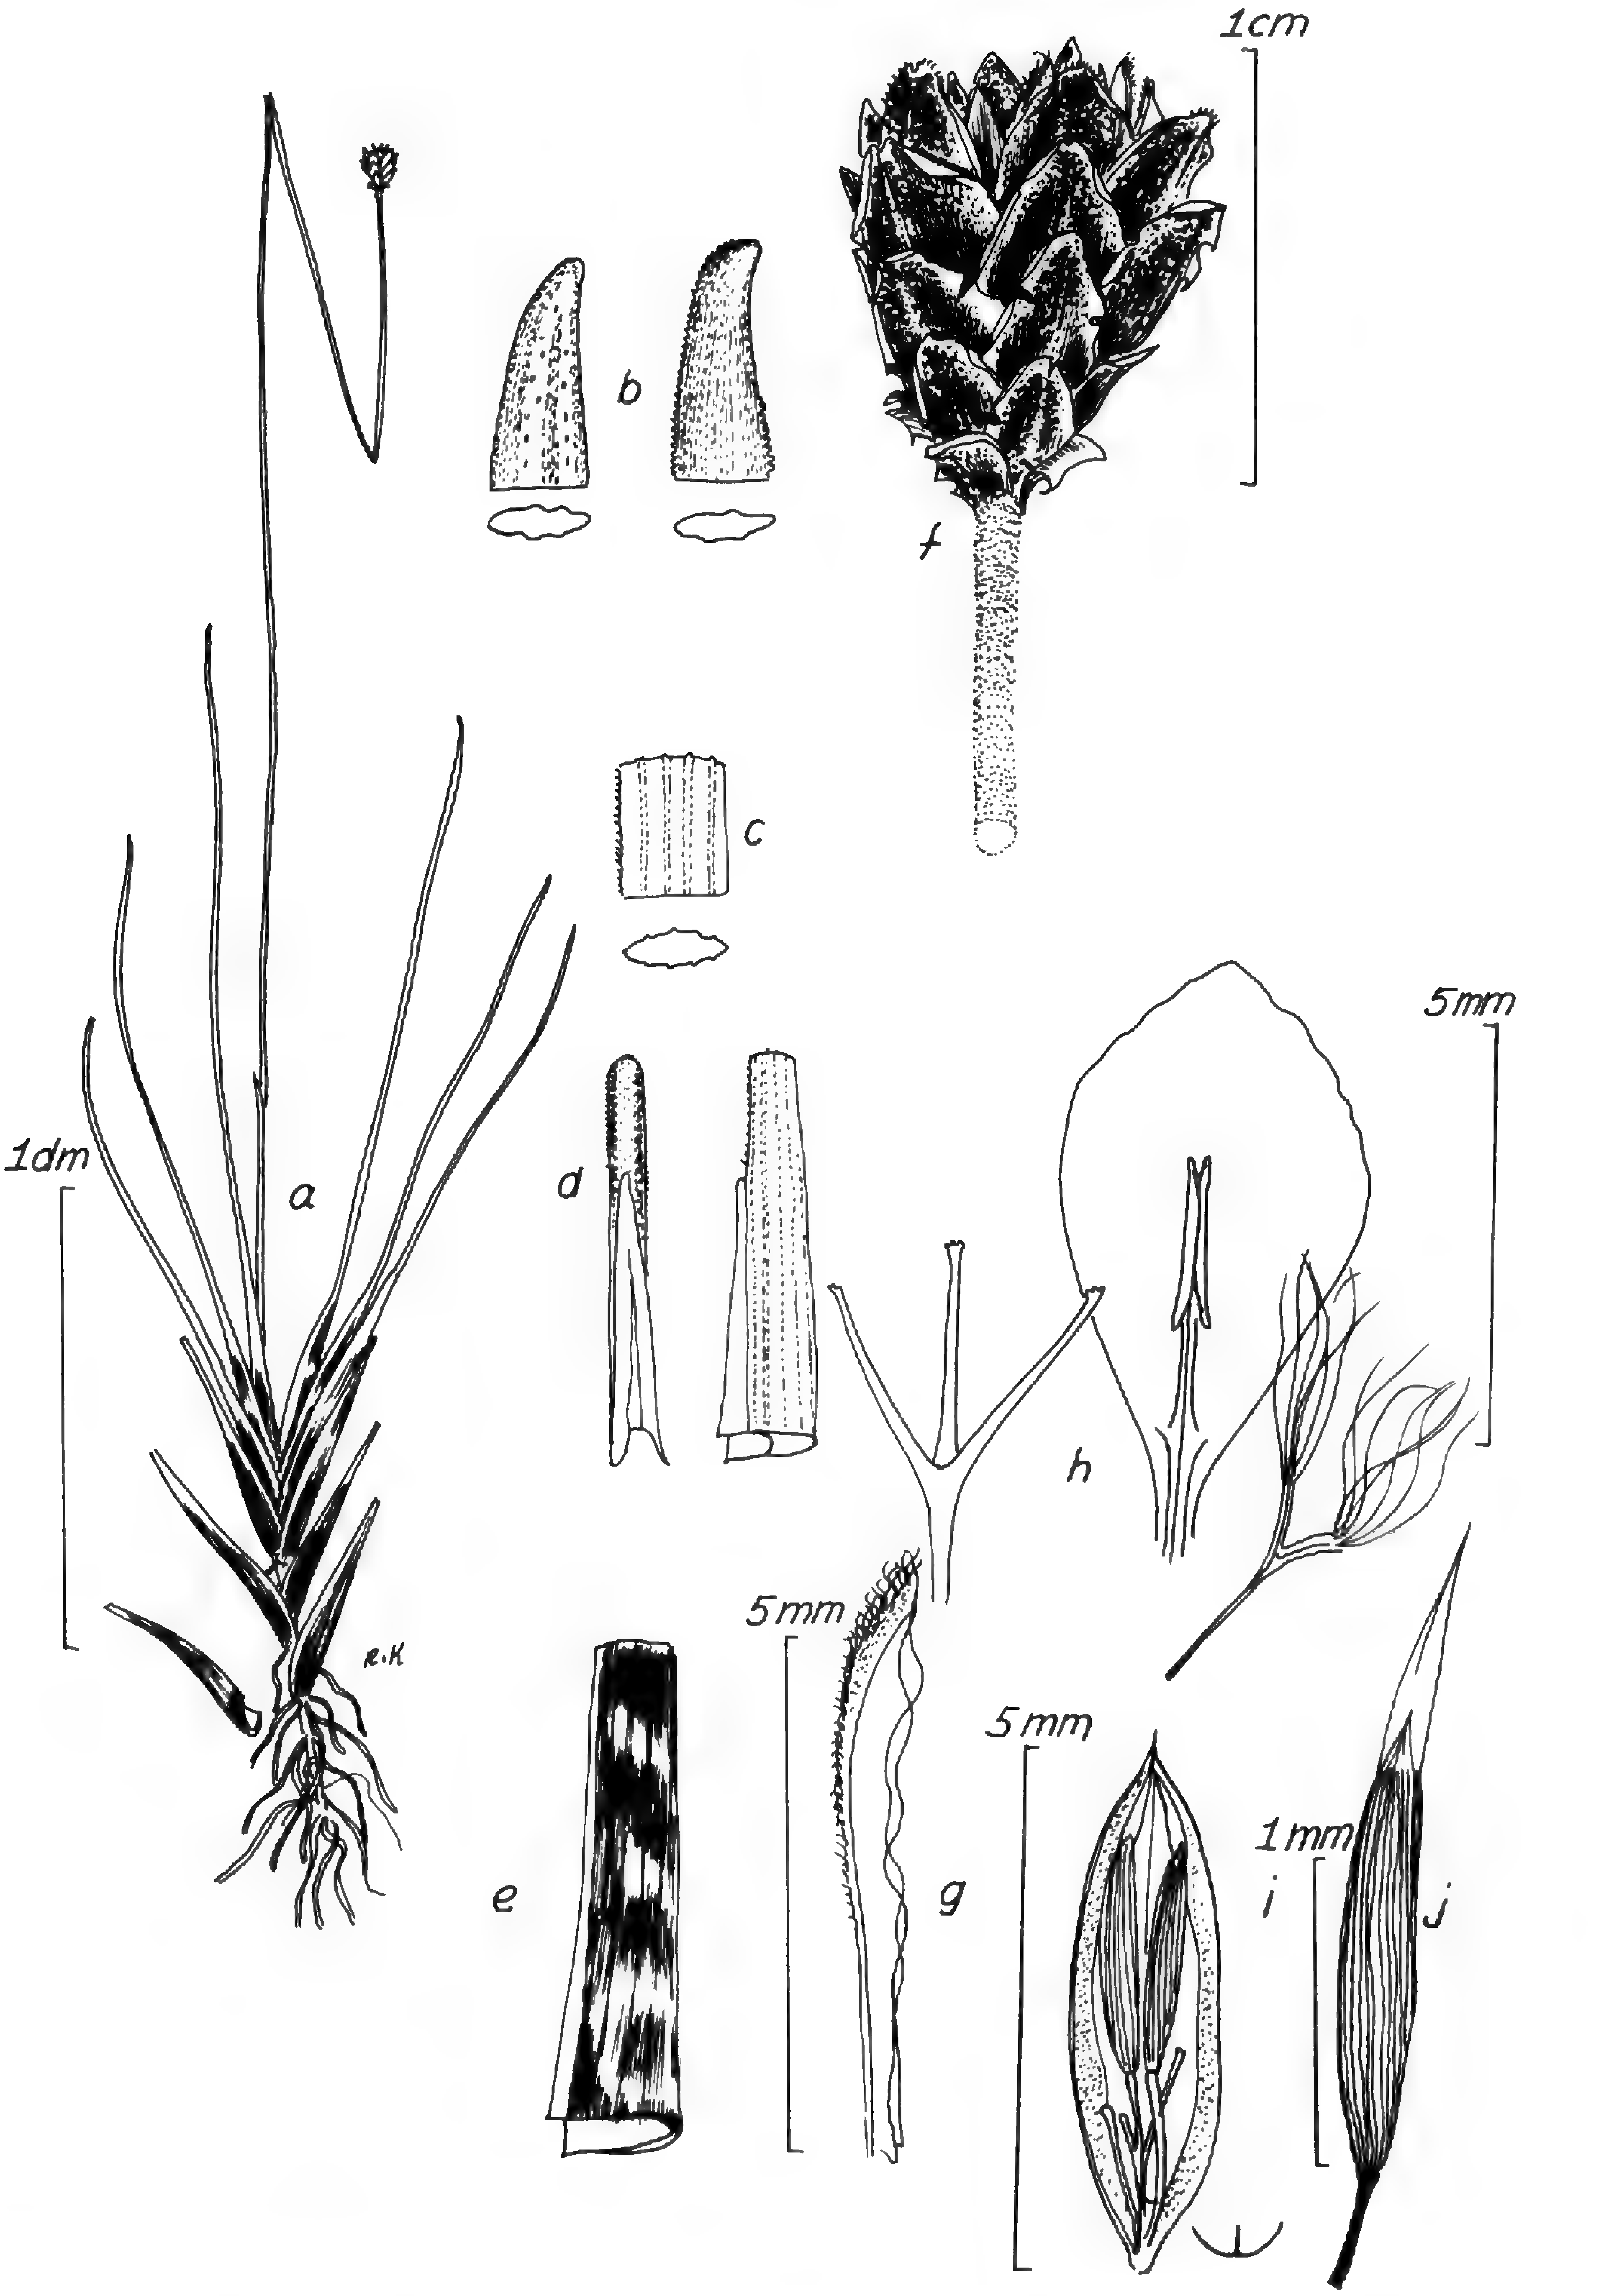

FIGURE 23. Xyris chimantae *(from the type).—a. Habit sketch.—b. Two leaf tips.—c. Leaf blade, sector at midblade.—d. Two views of leaf sheath–blade junction.—e. Leaf base.—f. Chimantá Massif in Estado Bolívar, Venezuela.

Additional specimens examined. VENEZUELA. BOLÍVAR: *Huber & Dezzeo 8592* (NY); *Huber & Colella 8735* (NY, VDB, VEN); *Huber et al. 10181* (MYF, VDB); *Steyermark & Wurdack 486* (F, NY, US, VEN); *Steyermark & Wurdack 1010* (F, NY, VEN); *Steyermark 75870* (F, NY, VEN); *Steyermark et al. 115835* (US, VEN); *Steyermark et al. 115922* (MO, US, VDB); *Steyermark et al. 128375 & 128380* (VDB, VEN).

This species is most similar to *X. lugubris* Malme but is overall more slender and has spikes of narrower outline and longer seeds.

24. Xyris stenophylloides Malme, Bull. Torrey Bot. Club 58: 323. 1931. TYPE: Venezuela. T. F. Amazonas: gorge of Caño Negro, Savanna Hills, growing in tussocks, Cerro Duida, 4,000 ft., *G. H. H. Tate 808* (lectotype, NY; paratype, "Savanna Hills, summit of Cerro Duida, 2 Sept. 1944, *Steyermark 58211*," F, NY, US, VEN). Figure 24.

Slender, densely cespitose, hard-based, smooth perennial 3–4 dm high, the stems contracted. Leaves erect or ascending, to 2.5 dm long; sheaths entire, much less than ½ as long as blades, the bases lustrous pale brown shading upward through yellow-brown to green, tapering from a slightly dilated base gradually to blade, there abruptly narrowed and producing an oblong, rounded or acute ligule to 1 mm long; blades narrowly linear, pale green, proximally and medially somewhat flattened, ca. 1 mm wide, narrowing gradually above middle to a narrowed, bluntly conic or flattened, thickened apex, the margins thick and rounded, smooth, the surfaces green, strongly 1–2-nerved, sometimes sulcate. Scape sheaths shorter than leaves, proximally tubular, striate, lustrous brown at base, open toward apex, there producing a short, erect, cusplike blade. Scapes straight or flexuous, twisted, distally subterete, 0.5–0.7 mm thick, with broad, low costae and shallowly sulcate, striate. Spikes broadly turbinate, 7–8 mm high, red-brown, of several loosely subdecussate bracts without dorsal areas, the sterile ones several, the lowest much smaller, ovate, narrowly rounded, slightly convex-carinate, grading gradually to fertile bracts, these oblong, 5.5–6 mm long, apically truncate or broadly rounded, erose or lacerate, ecarinate, slightly folded, low-papillose. Lateral sepals free, equilateral, elliptic-linear, broadly acute, ca. 5 mm long, tan, the firm narrow keel entire. Petal blades broadly obovate, ca. 4 mm long, the broadly rounded apex erose. Staminodia bibrachiate, the slender branches long-penicillate-pubescent. Anthers lance-oblong, ca. 1.5 mm long, deeply bifid and sagittate, on filaments ca. 1 mm long. Capsule obovoid, ca. 3 mm long, the central axis extending ⅔ the fruit length, the placentation appearing axile at least at fruit base, the valves with broad, thin septa. Mature seeds fusiform, ca. 1.5 mm long, pale brown, translucent, longitudinally multiribbed.

Distribution. Known only from the Cerro Duida area in rocky "open" seeps above 1,000 meters, very seldom collected, the only records other than types being the following.

Additional specimens examined. VENEZUELA. T. F. AMAZONAS: Jan.–Feb. 1969, *M. Farinas, J. Velasquez & E. Medina 406* (NY, VEN); vertiente norte del Tepuy Duida, 16 Nov. 1982, *F. Guanchez 2342* (TFAV, VDB, VEN); between Brocchinia Hills and Savanna Hills, 1,050–1,600 m, 2 Sep. 1944, *Steyermark 58211* (F, NY, US, VEN); topotype, *S. S. Tillett et al. 751-67* (MYF, VEN).

This species is in several characters closest to *X. scabridula* Steyerm. from the same massif; however, *X. scabridula* is harsher in foliage, has the leaves more thickened, and the lateral sepals broader and ciliate.

25. Xyris columbiana Malme, Ark. Bot. 13(3): 40. 1913. TYPE: Venezuela. Merida: "Jaji" (fide L. B. Smith, Caldesia 6(29): 22. 1954). The original label information is "*Xyris tortilis* Kl. Columbian. Moritz," the location given as "Taji," and was therefore interpreted by Malme as in Colombia (*Moritz 1202*, Herb. Berol. & *415*, BM; isolectotype, L). I have seen only the isolectotype and must also assume that the original material at B is lost, while that at BM remains to be designated lectotype. Figure 25.

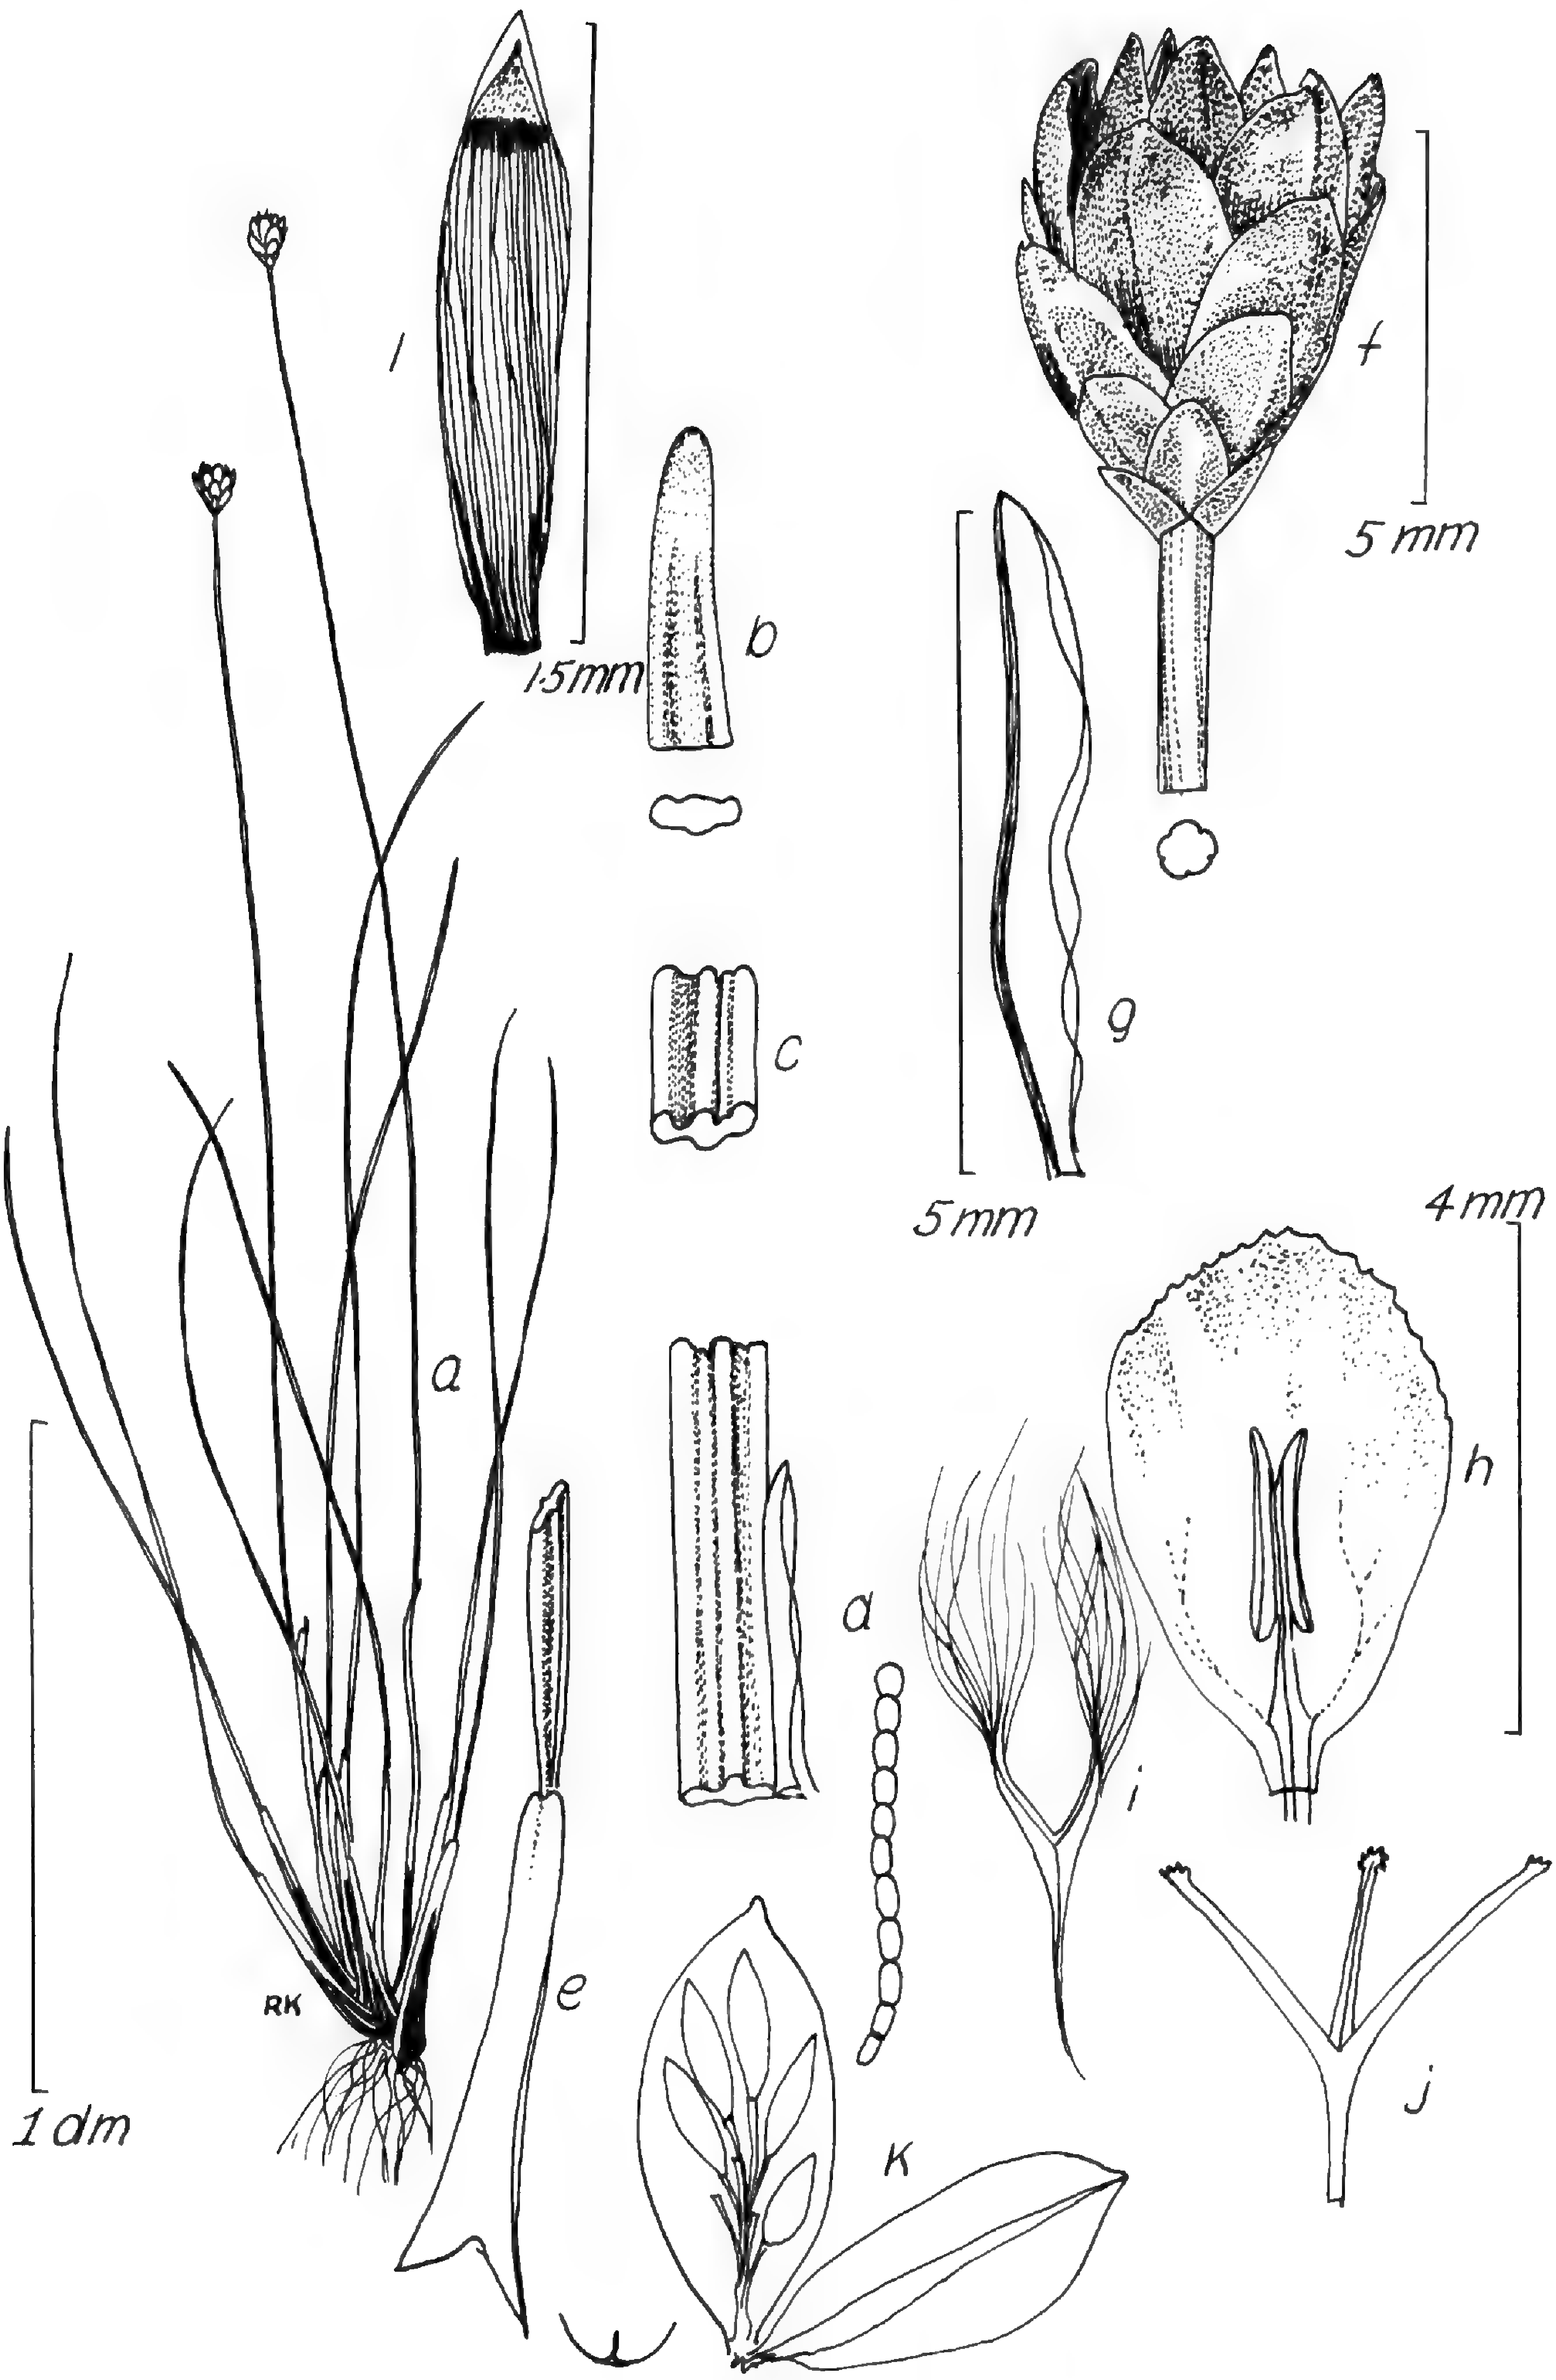

FIGURE 24. Xyris stenophylloides (Tate 808, Steyermark 58211).—*a. Habit sketch.—b. Leaf apex.—c. Sector from midblade.—d. Leaf at junction of sheath and blade.—e. Leaf base, inside view, showing orientation of blade base.—f. Spike and upper portion of scape.—g. Lateral sepal.—h. Petal blade.—i. Staminode.—j. Stylar apex.—k. Opened capsule showing two valves, placentation.—l. Seed.*

Cespitose, soft-based perennial to 6 dm high, the stems short. Leaves erect or ascending, mostly 2–3 dm long; sheaths entire, less than ½ as long as blades, narrowing gradually from the somewhat dilated, reddish green base to the blade, there producing a broadly oblong ligule 1–2 mm long; blades narrowly ensiform-linear, 0.5–1.5 mm wide, slightly twisted, flattened but round-edged, the apex narrowly acute, conic, the surfaces variously papillose-rugulose, dull green. Scape sheaths shorter than foliage leaves, the bases tubular, multicostate, the open apex producing a short, erect blade. Scapes straight or somewhat flexuous, narrowly lineal, terete or subterete distally, ca. 1 mm thick, unicostate, the costa low but strong, smooth or papillate. Spikes broadly obovoid to broadly ellipsoid or subglobose, 7–9 mm long, of several spirally imbricate, thin, castaneous bracts without dorsal areas, the sterile ones mostly 4–6, the lowest pair strongly keeled, ovate-triangular, 3.5–4 mm long, the inner slightly longer and broader, grading into the fertile bracts, these broadly obovate, ca. 5 mm long, broadly rounded apically, entire-margined, the backs slightly convex, ecarinate. Lateral sepals free, inequilateral, 5–6 mm long, strongly curvate, oblanceolate, pale brown with deep brown, firm keels, these ciliolate to villosulous-ciliate from ca. middle to apex. Petal blades ca. 6 mm long, elliptic, the broadly acute apex erose. Staminodia bibrachiate, the branches densely long-penicillate. Anthers oblong, ca. 2 mm long, the apex deeply bifid, the base sagittate, on filaments ca. 1 mm long. Capsule ellipsoid, 4–5 mm long; placentation free-central, the axis tending to separate into 3 branches distally, the ovules very numerous. Seeds ellipsoid, ca. 0.7 mm long, translucent, finely ribbed longitudinally.

Distribution. Andean paramos, apparently rare, Colombia and Venezuela.

Additional specimens examined. COLOMBIA. BOYACA: saturated sphagnum overlying sand, La Cumbre, valley of Río Pomera, 8,000 ft., 20 Aug. 1944, *N. C. Fassett 25631* (US); Cordillera Oriental, al NE de Arcabuco, linea divioria entre Boyaca y Santander del Sur, 2,600 m, 7 May 1972, *H. García-Barriga & R. Jaramillo M. 20267* (GH). ANTIOQUIA: a 1 km al sur de Hoyo Rico, ca. 2,600 m, 26 Sep. 1948, *F. A. Barkley 18A. 150* (US). VENEZUELA. MERIDA: Hoya del Río Capaz, bosque de San Eusebio: La Pinuela, bosque y pantamo, 2,600 m, 22 Oct. 1969, *J. Cuatrecasas et al. 28152* (US).

This has definite affinities with *X. subulata* Ruíz Lopez & Pavón but differs in having somewhat larger habit, larger, broader spikes which produce more florets, and more conspicuous indumentum of the lateral sepal keels.

26. Xyris subulata Ruíz Lopez & Pavón, Fl. Peruv. I: 46, pl. 71. 1798. TYPE: Peru. Huanuco: Pachitea, Pillao, 1787, *Ruíz Lopez & Pavón* (lectotype, MA; isolectotype, presumably at F).

Schizmaxon distichioides Steud., Bot. Zeitung (Berlin) 14: 391. 1856.

Densely cespitose, dwarf or to 5 dm high, the stems abbreviated to quite elongate and frondlike, to 1 dm long, the leaves erect to spreading flabellately, shorter than scapes or surpassing them, the sheaths entire or ciliate, mostly firm and lustrous, equaling blades in length or less than ½ as long, the blades mostly narrowly linear, the tips incurved-acute to blunt, the margins thin or incrassate, entire to papillate-scabrid or ciliolate, the surfaces usually dark green, smooth to (toward base) papillose-rugulose. Scape sheaths tubular proximally, open and carinate distally, the blades short to much elongated as in leaves. Scapes straight or flexuous, twisted, narrowly lineal to filiform, terete to somewhat compressed toward apex, ecostate to bicostate, smooth or papillate or ciliolate-scabrid along costae. Spikes mostly narrowly oblong to ovoid, mostly blunt, 0.5–1 cm long, the bracts decussate, thin, carinate to ecarinate, entire, deep olive brown, reddish brown or (mostly) near black, the sterile bracts usually 4, the lowest pair keeled, ca. ½ length of spike or less, the inner pair broader, slightly longer and ecostate, the fertile bracts mostly 2–4, broadly ovate, apically narrowly or broadly rounded, the backs papillose to smooth, folded-rounded. Lateral sepals mostly oblong-linear, free, subequilateral, mostly navicular, 3.5–6 mm long, narrowly to broadly acute,

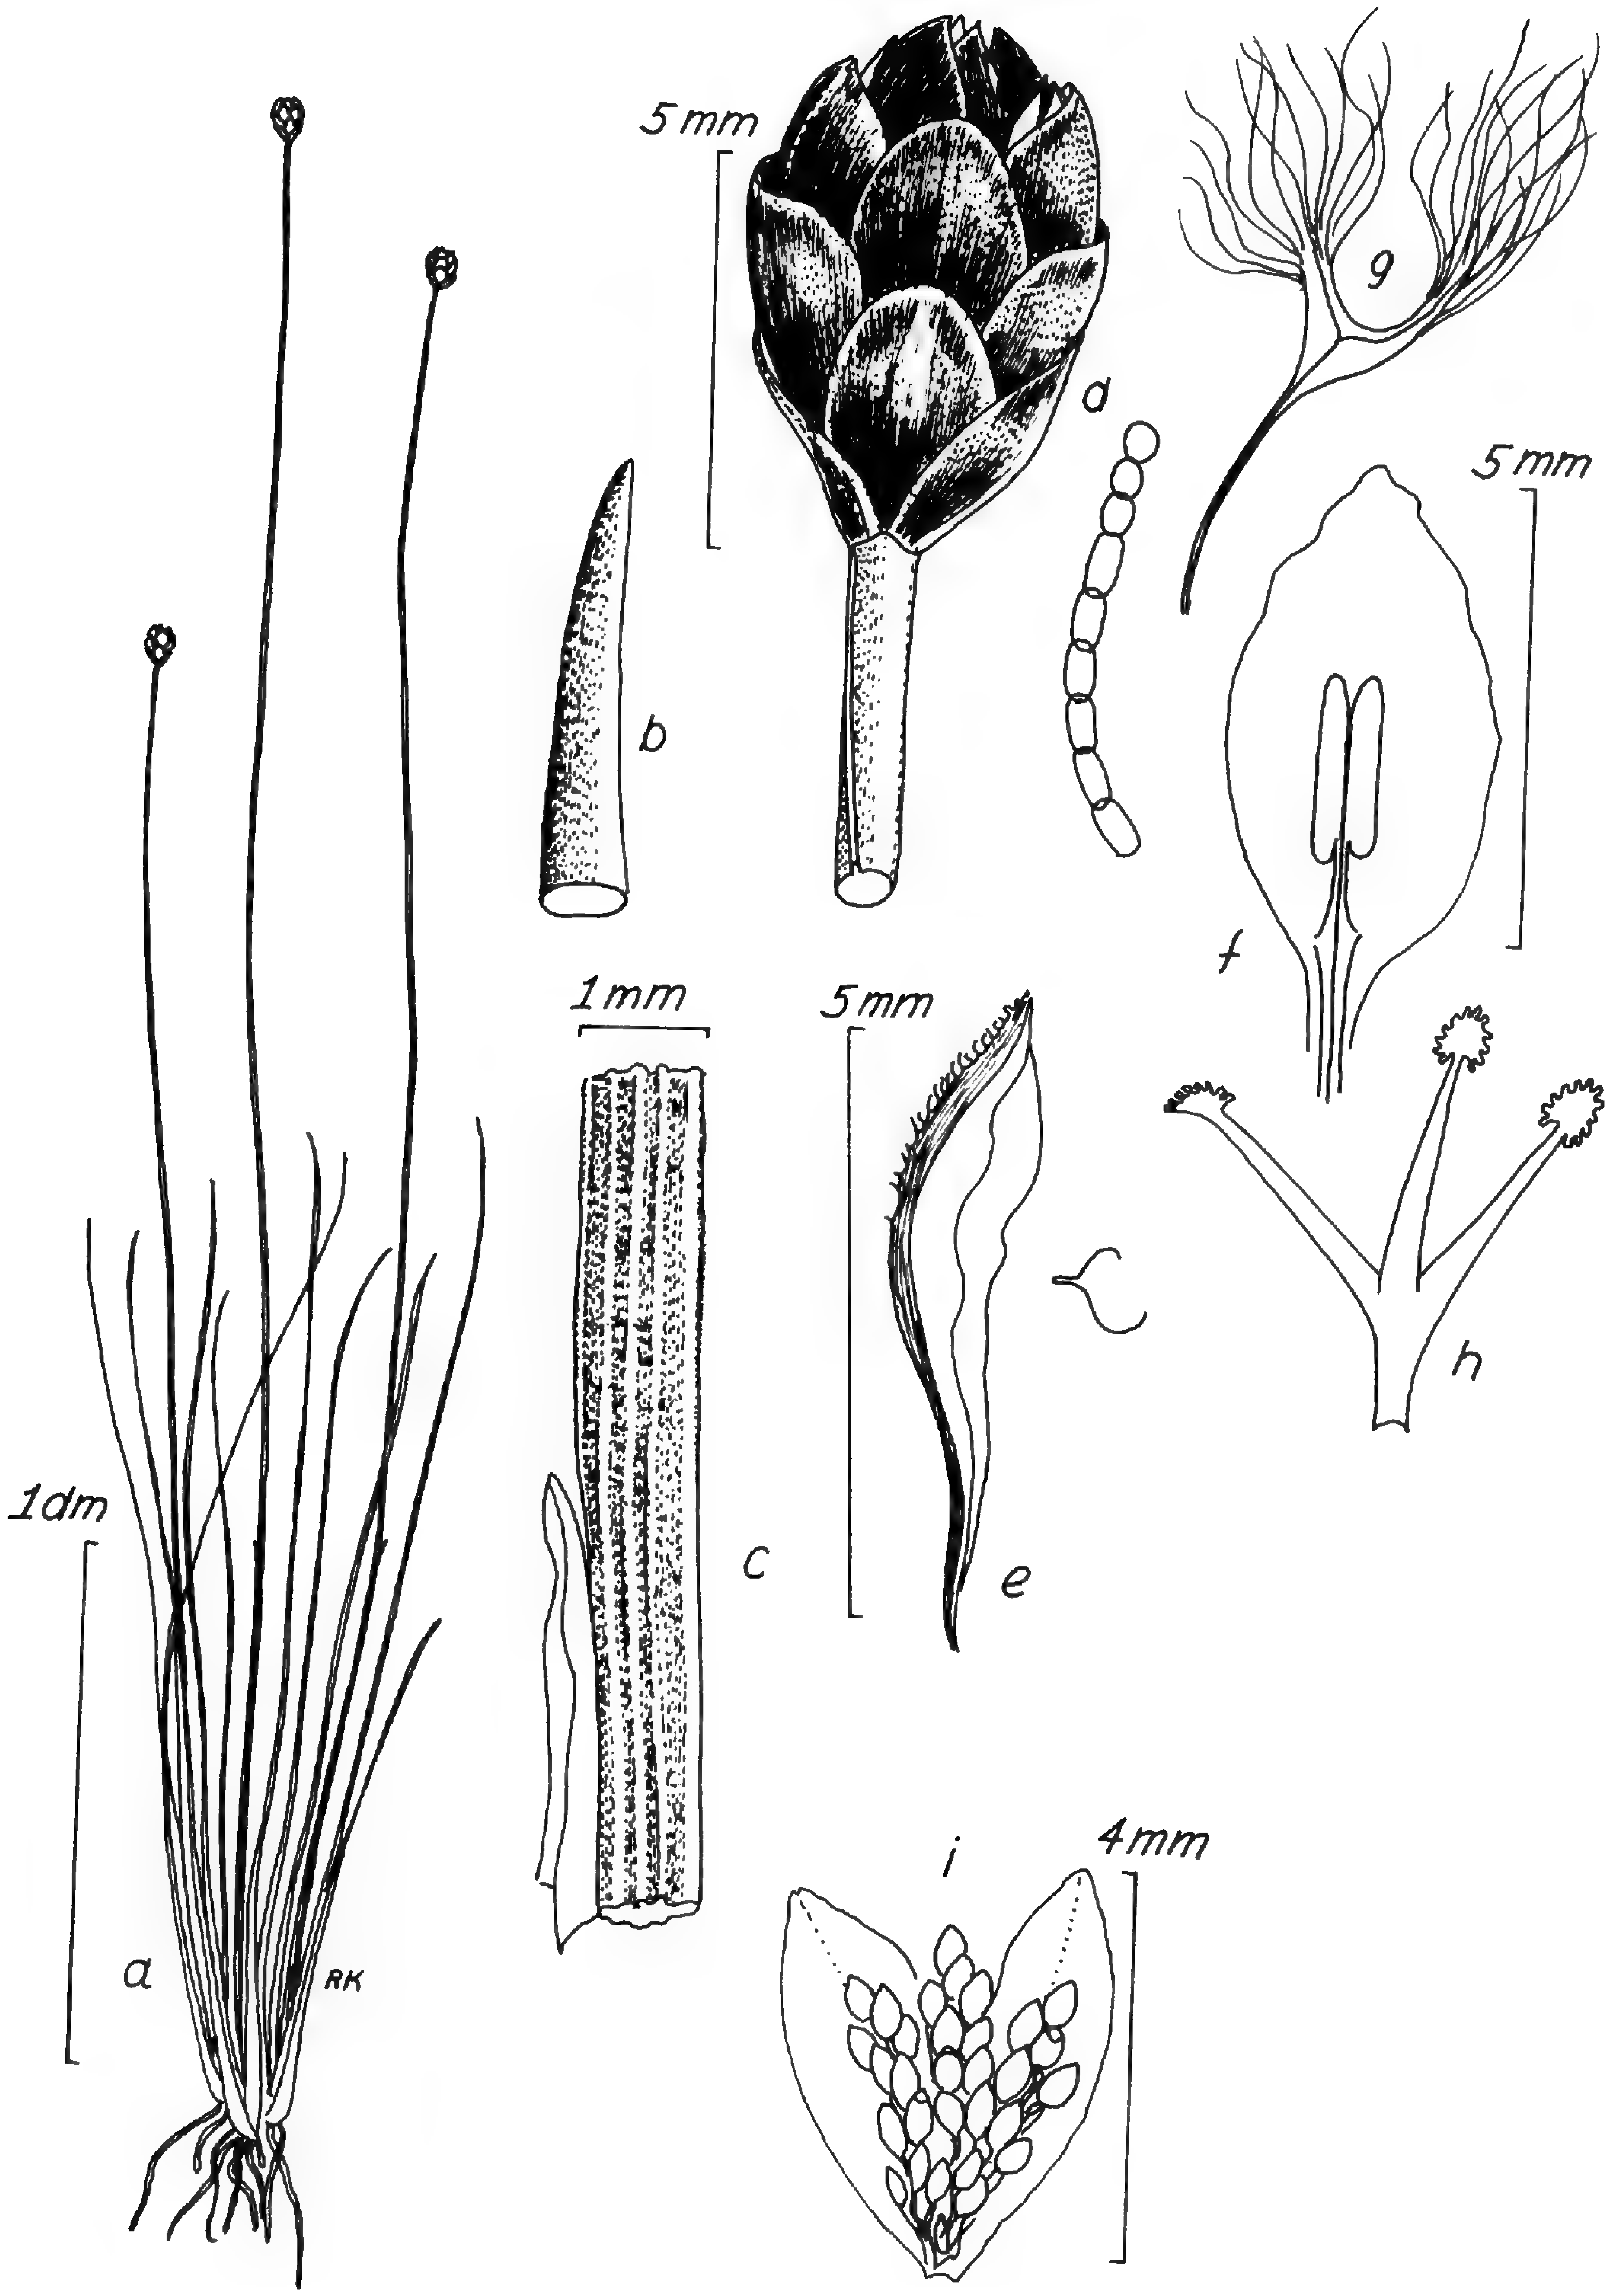

FIGURE 25. Xyris columbiana (Cuatrecasas et al. 28152).—*a. Habit sketch.—b. Leaf apex.—c. Leaf blade at junction with sheath.—d. Spike.—e. Lateral sepal.—f. Petal blade, stamen.—g. Staminode, enlarged sector of beard hair.—h. Stylar apex.—i. Capsule, one valve removed.*

with or without keel, entire to ciliolate or papillate along the crest or back medially. Petal blades broadly ovate to nearly orbicular, yellow, 3.5–5 mm long the broadly rounded apex erose or entire. Staminodia bibrachiate, branches long-penicillate. Anthers oblong, 0.6–2 mm long, the connective broad, on filaments 1–2 mm long. Capsule firm-valved, ellipsoid, 2–4 mm long, the placentation basal-central, the funicles elongate, the valves without septa or producing these at very base. Seeds ovoid to fusiform-cylindric, 0.5–1 mm long, prominently longitudinally ribbed or alveolate-reticulate.

This species has at least five marked varieties, the complex ranging widely along the "young" western cordilleras, from Costa Rica south to Chile, always in the high, cool to cold, "páramo." Only two of the varieties are known definitely to occur in the area of this treatment, but the key below includes the type variety which may yet be found there.

KEY TO SUBSPECIES OF *XYRIS SUBULATA*

1a. Edges of leaf sheaths variously ciliate; stems usually elongate.
    2a. The plants with leaves much shorter than scapes; seeds ca. 1 mm long; lateral sepals ca. 5 mm long .... 26A. *X. subulata* var. *subulata*
    2b. The plants dwarf, with leaves mostly equaling or exceeding scapes; seeds ca. 0.5 mm long; lateral sepals 3.5–4 mm long .... 26B. *X. subulata* var. *breviscapa*
1b. Edges of leaf sheaths entire; stems mostly contracted .... 26C. *X. subulata* var. *acutifolia*

26A. **Xyris subulata** Ruíz Lopez & Pavón var. **subulata.** Figure 26A.

Plants 10–30 cm high, the stems often elongate, with overlapping leaves forming fronds. Leaves flabellately ascending, loosely imbricate, ⅓–⅔ as long as scapes, the lustrous, pale red-brown sheaths ½ as long as the darker blades or longer, spreading arachnoid-ciliate, tapering gradually from the broad, clasping bases into blades, eligulate, the blades narrowly linear to filiform, mostly 0.5–1 mm wide, pale to deep green or red-green, compressed, flat to somewhat thickened, often terete toward apex, the tips terete, narrowly conic but blunt, the ventral edge a broad, papillose-rugulose band, the dorsal edge smooth or papillose, the surfaces papillose or smooth. Scape sheaths shorter than or slightly overtopping principal leaves, with strong, incurved-tipped blades similar to leaves. Scapes filiform, straight or flexuous, slightly twisted, terete below, subterete toward apex, or slightly compressed and bicostate, 0.3–0.5 mm wide, the surfaces mostly olive, smooth or (more often) tuberculate-papillose at least on costae. Spikes mostly ovoid to lance-ovoid, 2–4-flowered, 5–7 mm long, pale brown to near black, the bracts thin, loosely imbricate, decussate, entire or erose, without dorsal areas, the sterile pairs 2, the lowest pair shortest, ovate, carinate, the inner pair mostly broader, slightly longer, less carinate, the lowest pair of fertile bracts ecarinate but folded, much longer than the sterile bracts, ca. 4–5 mm long, entire, aging lacerate, dull or lustrous. Lateral sepals free, very thin, subequilateral, ca. 5 mm long, navicular, the midzone nearly without keel, entire. Petal blades broadly obovate to nearly suborbicular, ca. 5 mm long, yellow, broadly rounded, subentire. Anthers ca. 1 mm long, oblong, deeply bifid at apex, the filaments ca. 1.5 mm long. Staminodia bibrachiate, the flattened, narrow branches elongate, long-penicillate. Capsule firm-valved, brown, ellipsoid, ca. 3 mm long, placentation basal, funiculi elongate. Seeds fusiform-cylindric, ca. 1 mm long, caudate, red-brown, translucent, longitudinally irregularly multiribbed.

Distribution. South America, Andean paramos, rare in Colombia, increasingly frequent, Ecuador south through Peru. For Colombia I have only one certain record.

Additional specimen examined. COLOMBIA. ANTIOQUIA: Páramo Frontino Cerro de Campanas, *Espeletia* paramo, 3,650–4,290 m, clumps of ca. 20 plants, 28 Oct. 1976, *J. D. Boeke & J. B. McElroy 287* (U).

The long "stems" of this and related taxa may in part be a result of the deep humus deposits in which dense clumps of this sort of

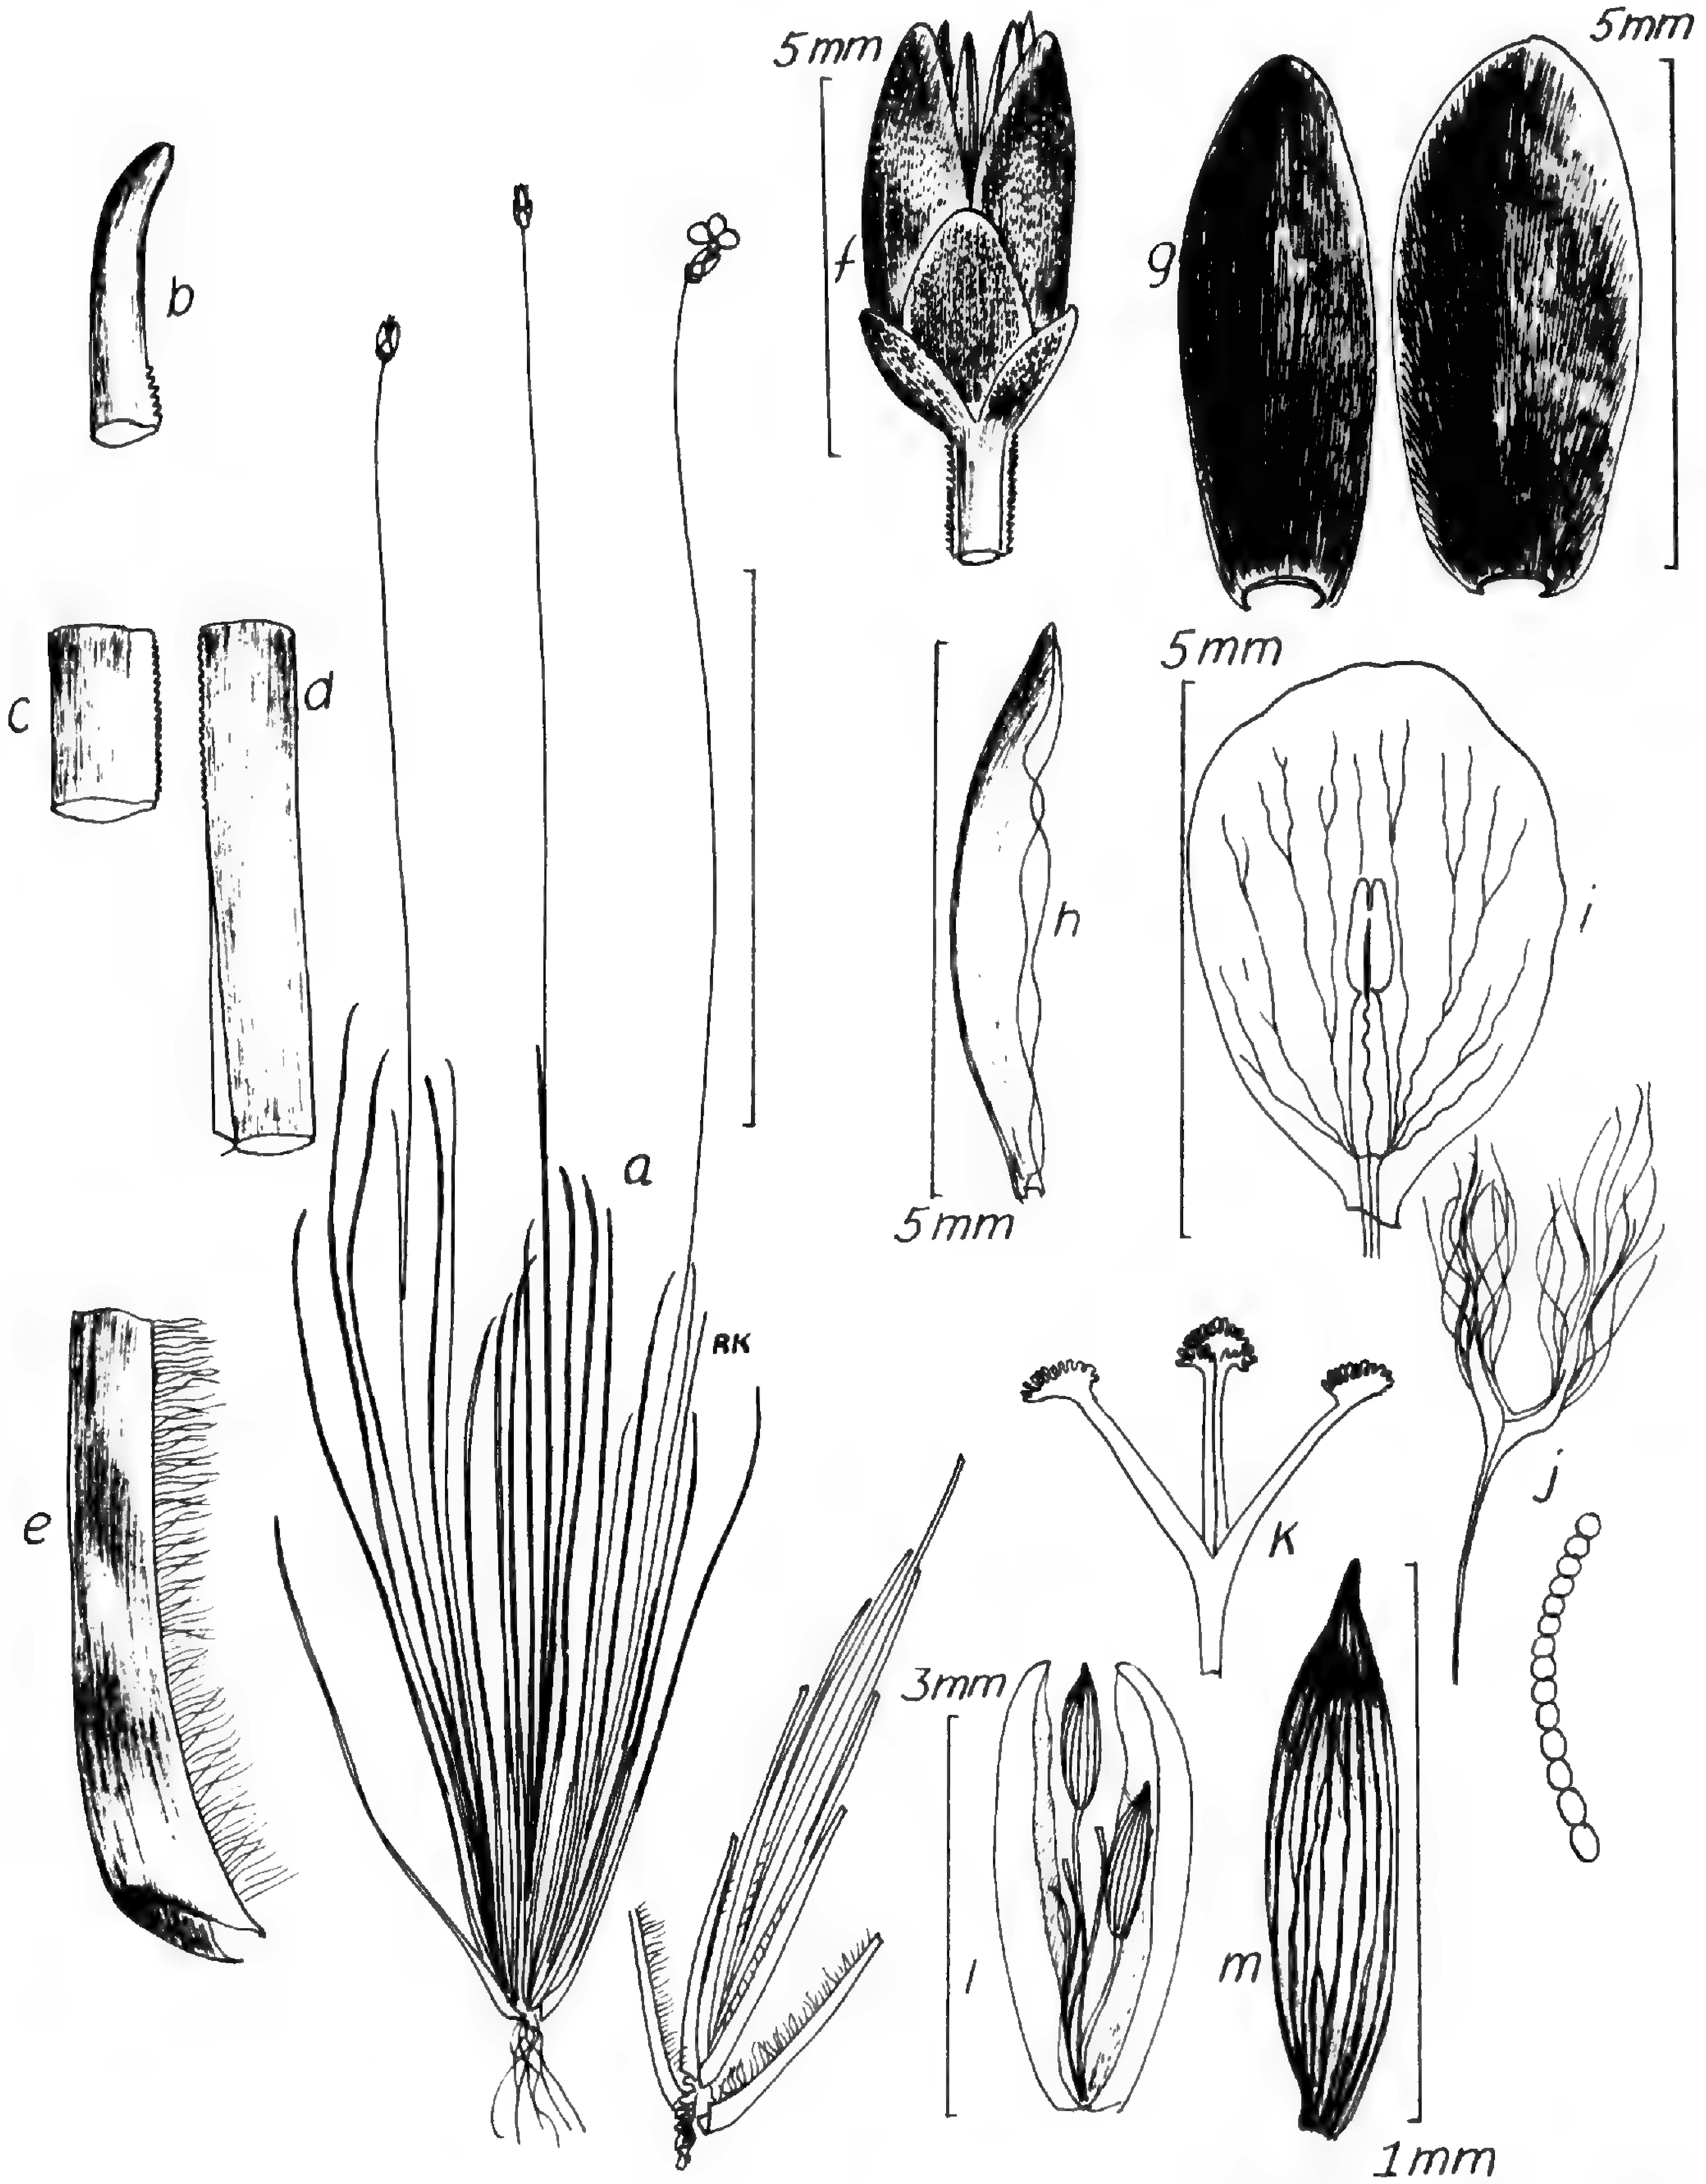

FIGURE 26A. Xyris subulata *var.* subulata *(drawn from several Peruvian examples)*.—*a. Habit sketch.*—*b. Leaf apex.*—*c. Short sector of leaf blade.*—*d. Leaf sheath–blade junction.*—*e. plant are rooted, this "burying" resulting in significant elongation of internodes comparable to that in *X. witsenioides* Oliv. and related species.

26B. Xyris subulata var. **breviscapa** Idrobo & Lyman B. Smith, Caldasia 6: 220, fig. 16. 1954. TYPE: Colombia. Putumayo: alta cuenca del Río Putumayo, filo de la Cordillera entre El Encano y Sibundoy, paramo de San Antonio de Bordencillo, 3,250 m, 4 Jan. 1941, *J. Cuatrecasas 11744* (holotype, US; isotype, COL). Figure 26B.

Densely cespitose perennial, tufted as in moss, to 1 dm high, usually much lower, the stems ascending from fascicled rhizomes, forming frondlike plates of leaves and leaf bases. Leaves 2.5–10 cm long, loosely imbricate, ascending-flabellate, the sheaths as long as blades or slightly longer, lustrous pale brown, smooth-keeled, low-costate, tapering gradually from broad, clasping bases into the blades, eligulate, the blades filiform to narrowly linear, flattened, ca. 0.5 mm wide, the apex subterete, slender-incurved, smooth, the ventral margin slightly thickened, pale, papillose-rugulose, the surface olive, with a few low nerves, usually smooth. Scape sheaths slightly longer than or slightly shorter than principal leaves, with elongate, incurved blades as in leaves. Scapes to 1 dm high, overtopping leaves or overtopped by leaves, filiform, 0.3–0.4 mm thick distally, there terete or slightly flattened, usually bicostate, the costae scabridulous, the surfaces olivaceous, usually papillate. Spikes narrowly to broadly ovoid, pale brown to dark brown, 4–7 mm long, the bracts decussately arranged, loosely imbricate, thin, the sterile of 2 pairs, the lowest pair broadly ovate-triangular, keeled, ca. 2 mm long, the inner pair ovate, carinate only toward the apex, ca. 3 mm long, the fertile bracts 2(–4), oblong-ovate, 3.5–4 mm long, the apex entire or erose, scarious, folded or carinate. Lateral sepals free, subequilateral, oblong, 3.5–4 mm long, the apex obtuse, nearly without keel, this a darker thickening medially, entire. Petal blades broadly elliptic to broadly obovate, yellow, 3.5–4 mm long, subentire, apiculate, erose. Anthers oblong, 0.6–0.7 mm long, deeply bifid, on filaments ca. 1 mm long. Staminodia bibrachiate, long-penicillate. Capsule broadly ellipsoid or obovoid, brown, ca. 2 mm long, the placentation basal, the funiculi elongate. Seeds ca. 0.5 mm long, ovoid, short-apiculate, rather coarsely ridged and cross-ridged, this irregularly reticulate.

Distribution. High grassy paramos of the Andes, Colombia south into Peru and Bolivia.

Additional specimens examined. BOLIVIA: Cordillera Real, Cocopunco, 10,000 ft., 24–29 Mar. 1926, *G. H. H. Tate 321* (NY); Tolapampa, 25 Sep. 1902, 10,000 ft., *R. S. Williams 1638* (NY—a putative isotype of *X. cryptocarpum* Rusby, which appears to be a nom. nud.). COLOMBIA. ANTIOQUIA: Páramo Frontino, near Llano Grande, *Espeletia* páramo, 3,450 m, *Boeke & McElroy 262* (NY, U). AZUAY. Cordillera Oriental, alrededores del Páramo de Patococha entre Gualaceo y Limón, 6–7 Aug. 1969, 3,400–3,450 m, *Barclay & Juajibioy 8626* (NY). CAUCA: Macizo Colombiano, Valle de Las Papas, alrededores de Valencia, ca. 3 km from Casa, Los Andes, Sta. 10, ca. 3,150 m, 4 Oct. 1958, *Barclay & Juajibioy 5915* (NY); Cordillera Central, cabeceras del Río Palo, altos páramos entre Quebrada de San Paulino y Quebrada del Lopez: Lagunilla de Las Casitas, 3,700 m, 3 Dec. 1944, *Cuatrecasas 19006* (GH). HUILA-CAUCA: Macizo Colombiano, Páramo de Las Papas, El Boquerón, paramo abierto y bosque Filo de La Cuchilla que sierra por el sur La Laguna de La Magdalena, 3,450 m, 5 Sep. 1958, *Idrobo et al. 2967* (VEN). LOJA: Muletrack Amaluza–Palanda, western slope near pass (at Laguna Areviatadas Pilares), 3,350–3,450 m, 22 Sep. 1976, *Ollgaard & Balslev 9680, 9707* (NY). PERU. CUSCO: Paso de Tres Cruces, Cerro de Cusilluyoc, 3,800–3,900 m, 3 May 1925, *Pennell 13886* (F, NY).

This variety is distinguished from the others primarily by its low habit, seeding spikes often overtopped by leaves, and distinctly shorter, coarsely reticulate seeds.

26C. **Xyris subulata** var. **acutifolia** Heimerl, Ann. k. k. Naturh. Hofmus. Wien 21: 63. 1906. *X. acutifolia* (Heimerl) Malme, Ark. Bot. 13(3): 40. 1913. TYPE: Colombia: Depto. Cundimarca, "Bogotá, Goudot" (presumably at W). Figure 26C.

Cespitose glabrous perennial, the stems contracted to slightly elongated. Leaves erect or slightly spreading, to 2 dm long; sheaths mostly ½ as long as blades or less, the bases shining, pale brown to brown or tan, mostly narrowing gradually into blades, eligulate or with narrow, scarious ligules to 2 mm long, entire; blades filiform to narrowly linear, 0.5–2 mm wide, slightly to very flattened, often twisted, narrowly acute apically, incurved, the margins smooth to papillate-scaberulous or

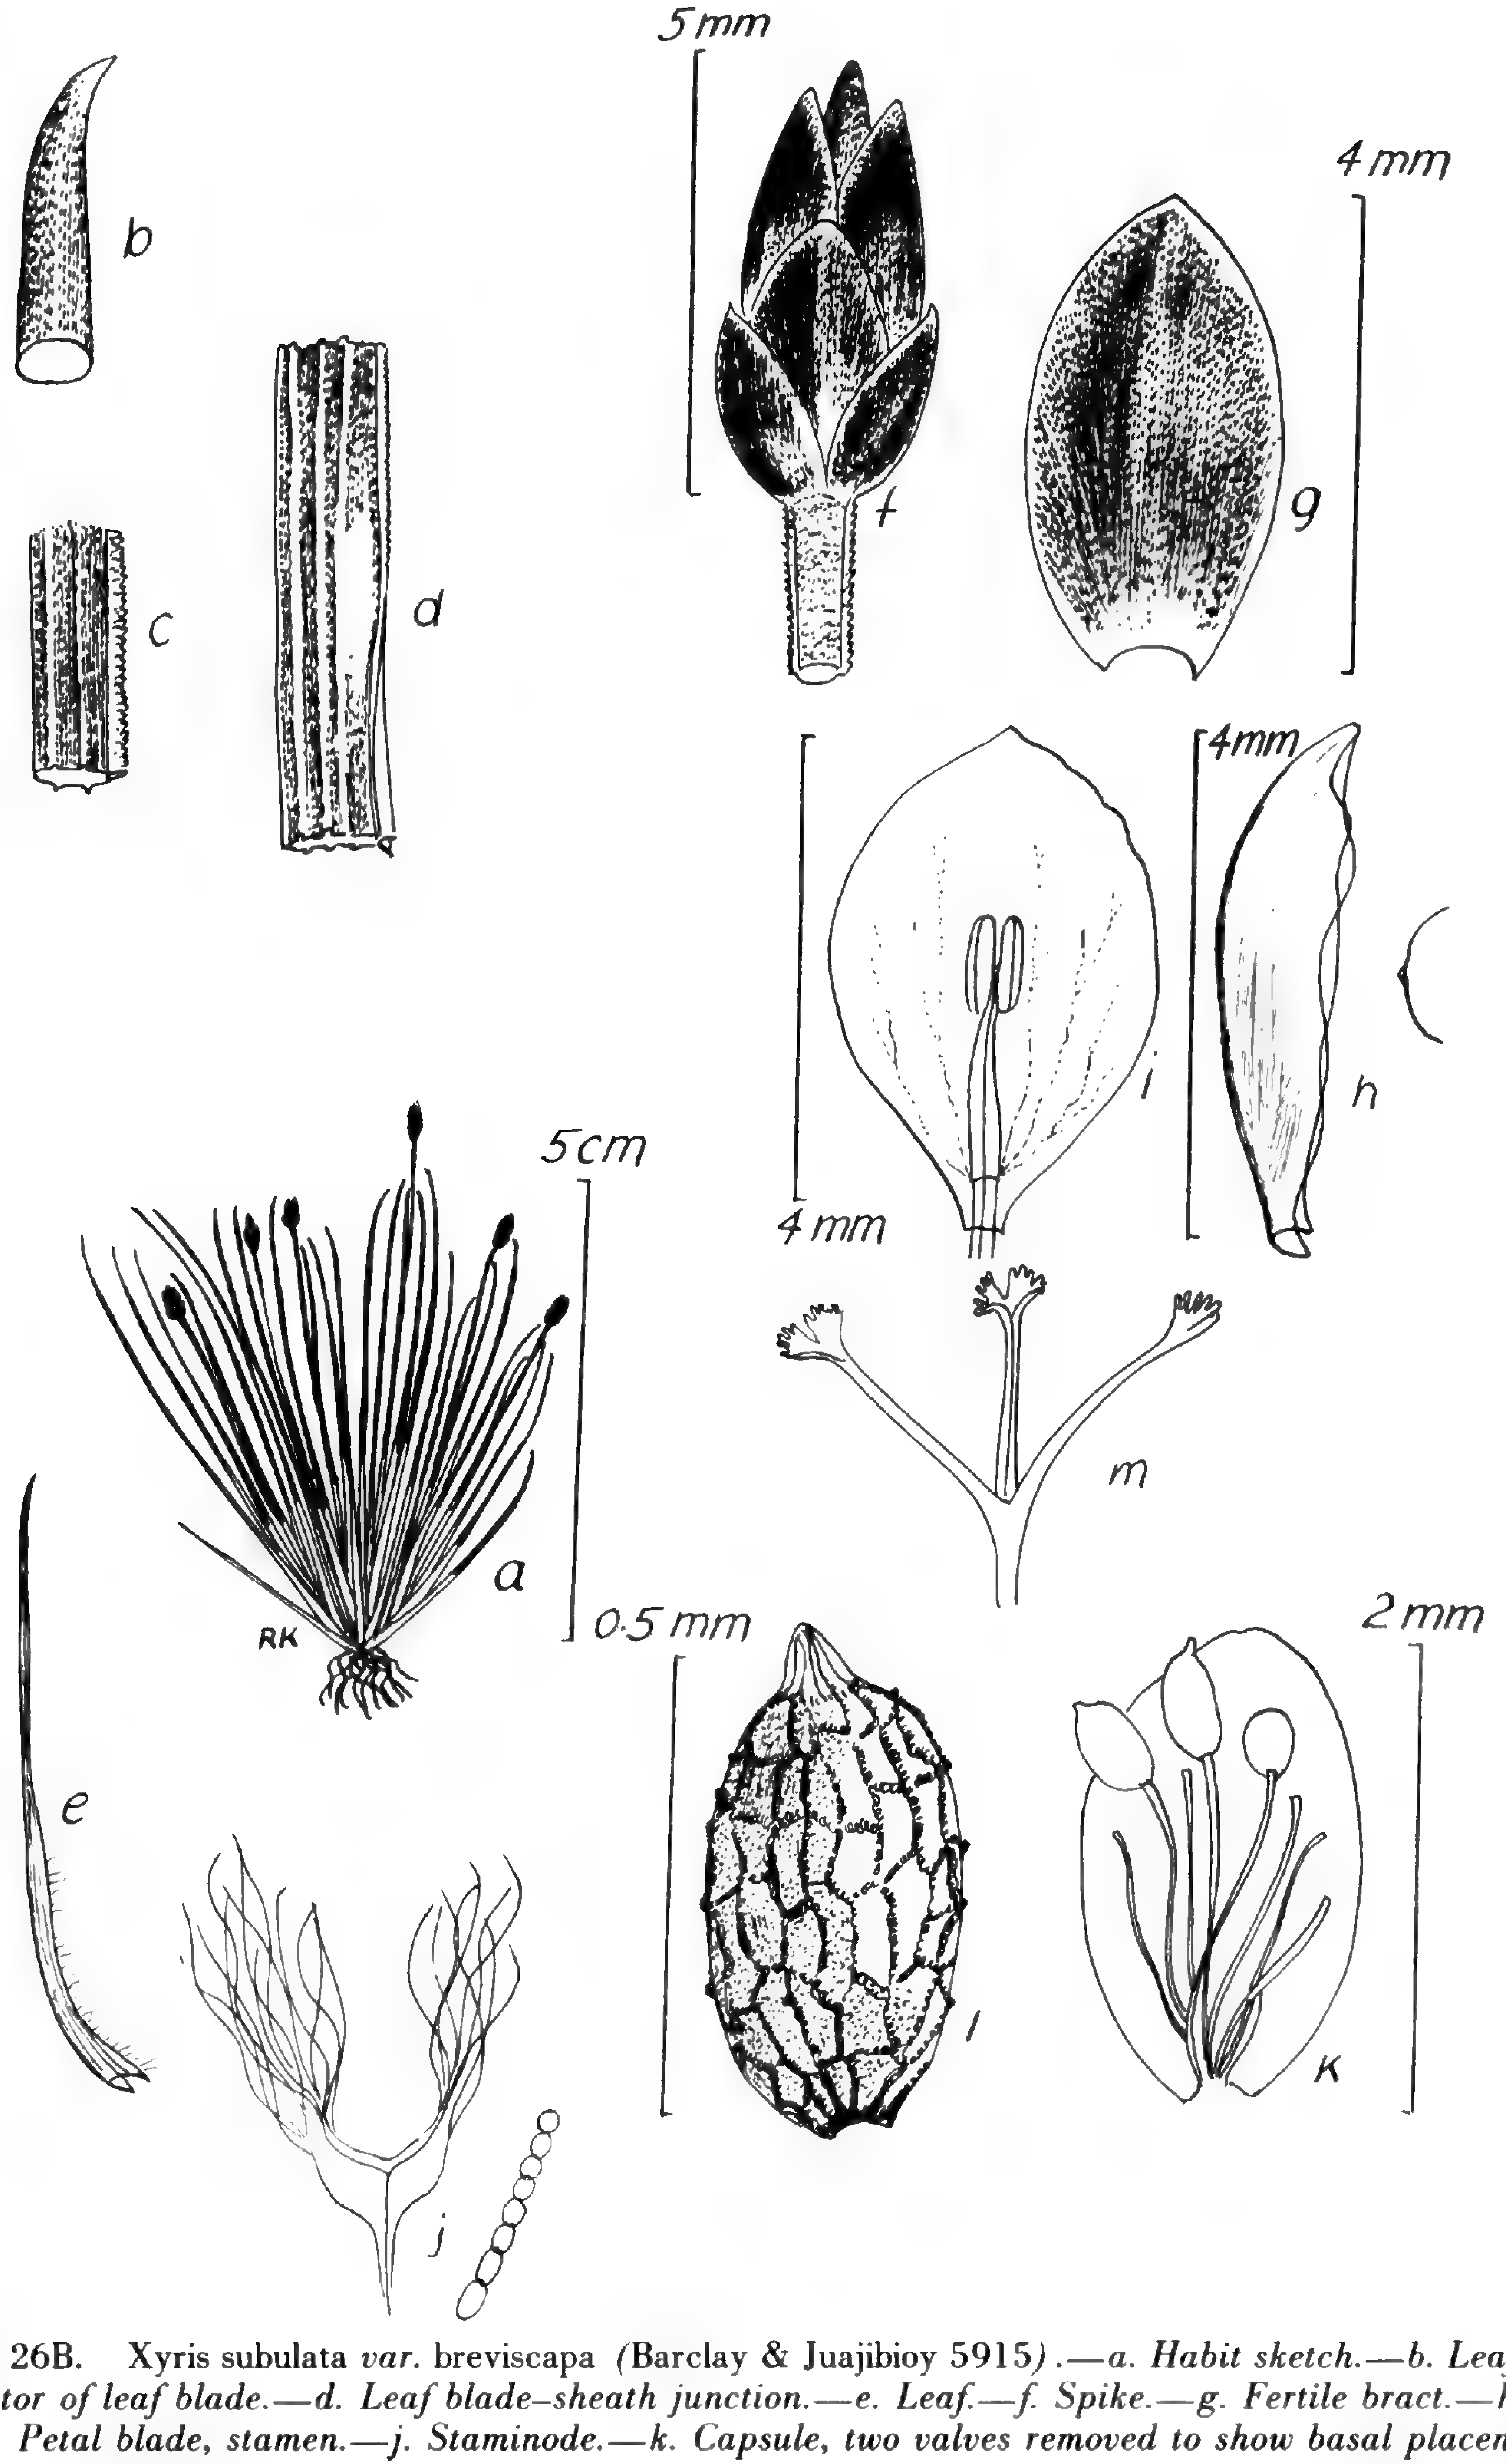

FIGURE 26B. Xyris subulata *var.* breviscapa *(*Barclay & Juajibioy 5915*).—a. Habit sketch.—b. Leaf apex.—c. Midsector of leaf blade.—d. Leaf blade–sheath junction.—e. Leaf.—f. Spike.—g. pale-ciliolate, the surfaces deep green, strongly or weakly nerved, smooth to papillose-rugulose, the latter particularly toward base. Scapes to 3 dm high, straight or flexuous, twisted, narrowly lineal, 0.5–1 mm thick, distally terete or oval, ecostate to commonly bicostate, the surfaces smooth to papillose-rugulose, the costae smooth to scabrid. Scape sheaths shorter than leaves, with short, erect blades. Spikes narrowly oblong to ovoid, mostly blunt, 0.5–1 cm long, the bracts decussate, thin, mostly ecostate, entire, deep olive brown, reddish brown or (mostly) near black, the sterile bracts usually 4, the lowest pair strongly keeled, ca. ½ spike length or less, the inner pair broader, slightly longer and ecostate, the fertile bracts 2–4, broadly ovate, narrowly or broadly rounded apically, the backs papillose to smooth, folded-rounded. Lateral sepals oblong-linear to elliptic-linear, free, subequilateral, mostly navicular, 4–6 mm long, narrowly to broadly acute, with or without keel, entire to ciliolate or papillate along the crest or back medially. Petal blades mostly ovate, 4–5 mm long, pale yellow, narrowly rounded apically, coarsely erose. Staminodia bibrachiate, with broad, flat branches apically multipenicillate. Anthers oblong, ca. 2 mm long, blunt, widely separated by broad connective on filaments ca. 2 mm long. Fruit ellipsoid, ca. 3–4 mm long, the placentation basal-central, the funicles elongate; capsule valves without septa or with septa only at base. Seeds ellipsoid-fusiform, ca. 0.7–1 mm long, deep amber, strongly longitudinally multiribbed.

Distribution. Páramos, high mountain bogs, western cordilleras, mostly over 2,000 meters high, Costa Rica south through the Andean chains to Peru, locally abundant.

Selected additional specimens examined. COLOMBIA. ANTIOQUIA: Páramo Frontino, Cerro de Campanas, *Boeke & McElroy 287* (NY). BOYACÁ: Sierra Nevada del Cocuy, Páramo Cóncavo, *Cleef 10004* (COL, U, US, VDB). CAUCA: Valle de Las Papas, near Valencia, *Core 999* (GH, NY); Cundimarca, páramo entre Cógua y San Cayetano, Laguna Verde y alrededores, 500 m al NW de La Laguna Verde, *Cleef 6240* (COL, U, VDB). META: Páramo de Sumapaz, Hoya de La Quebrada Sitiales, Vallecito Pantanoso 0.5 km SW de La Laguna La Primavera, *Cleef 1050* (U, US, VDB). HUILA: "Balsillas" on Río Balsillas, *Rusby & Pennell 775* (GH, NY); Norte de Santander, Páramo del Hatico, en route from Toledo to Pamplona, *Killip & Smith 20620* (GH, PH, NY). COSTA RICA. CARTAGO: bog in cloud forest along Pan Am. Highway near Cerro Las Vueltas, *Holm & Iltis 444* (F, GH, MO, NY, U, US). LIMÓN: Cordillera de Talamanca, Valle de Silencio, along Río Terbi 1.5 airline km W of Costa Rican–Panamanian border, 2,300 m, *Davidse et al. 28575* (MO, VDB, VEN). SAN JOSÉ: cloud forest area N of Cerro de La Muerte, Cordillera de Talamanca, *L. O. Williams et al. 24146* (F, NY, US). PERU. AMAZONAS: Chachapoyas, Jalca zone 3–6 km W of Molinopampa, *Wurdack 1405* (GH, NY, US). PASCO: Oxapampa, trail to summit of Cordillera Yanachaga via Río San Daniel, *D. N. Smith 7714* (MO, VDB). VENEZUELA. ANZOATEGUI: Cerro Peonia above Sta. Cruz, headwaters of Río Manantiales, E of Bergantin, *Steyermark 61697* (F, NY, US, VEN). LARA: trail from Hunocaro to Buenas Aires (Caserio) below Páramo Las Rosas, *Liesner et al. 8118* (MO, VDB). MERIDA: Páramo de Sto. Domingo, *A. Jahn 1102* (GH, MO, NY, US, VEN); San Raphael, *E. Reed 854* (US). SUCRE: Cerro Turumuquire, *Steyermark 62624* (F, MO, NY, US, VEN). TACHIRA: Páramo de Tama, cerca de la frontera Colombo–Venezolana, *Steyermark & Dunsterville 98625* (F, NY, US, VEN). TRUJILLO: Su-Oaramo y páramo de Guaramacal, *F. Ortega 2654* (MO, PORT, NY, VDB).

This is the most abundant variety, therefore the most collected, and is usually distinguished from the others by its generally shorter stems, paler brown sheaths, and particularly its entire (vs. long-ciliate) leaf-sheath margins.

27. Xyris valdeapiculata Kral, sp. nov. TYPE: Venezuela. T. F. Amazonas: Dpto. Río Negro, Valle de Titirico N of Pico Phelps in Cerro Neblina, ca. 0°56′N, 65°58′W, ca. 2,200 m; peat bog interspersed with shrub and low, rocky but wet ridges, 1 Dec. 1984, fls. open in A.M., *R. Kral 71919* (holotype, VEN; isotypes, F, MO, NY, US, VDB). Figure 27.

Planta perennis, caespitosa, glabra, gracilis. Radices graciles. Caules breves. Folia principalia leviter expansa vel flabellate expansa, 8–14 cm longa, vaginis scaporum longiora; vaginae integrae, basin versus ecarinatae, pallide brunneolae, nitidae, leviter dilatatae, multicostatae, in laminas gradatim decrescentes et carinatae, ad apicem breviligulatae; laminae anguste linearia, 2–3-plo vagines longiores, 1–2.5 mm latae, compressae, olivaceae, longitudine leviter multinervosae; apices incurvato-acuta, leviter incrassata; margine tenuis, retrorse scabrociliatae, pallidae. Scapi leviter torti vel recti, 20–35 cm alti, ca. 1 mm lati, ad apicem subteretes sed prominente bicostatae, costis dense pallide scabrociliatis. Spicae pauciflorae, brunneolae, anguste turbinatae (demum late turbinatae) ca. 10 mm longae; bracteae sine area dorsali, laxe

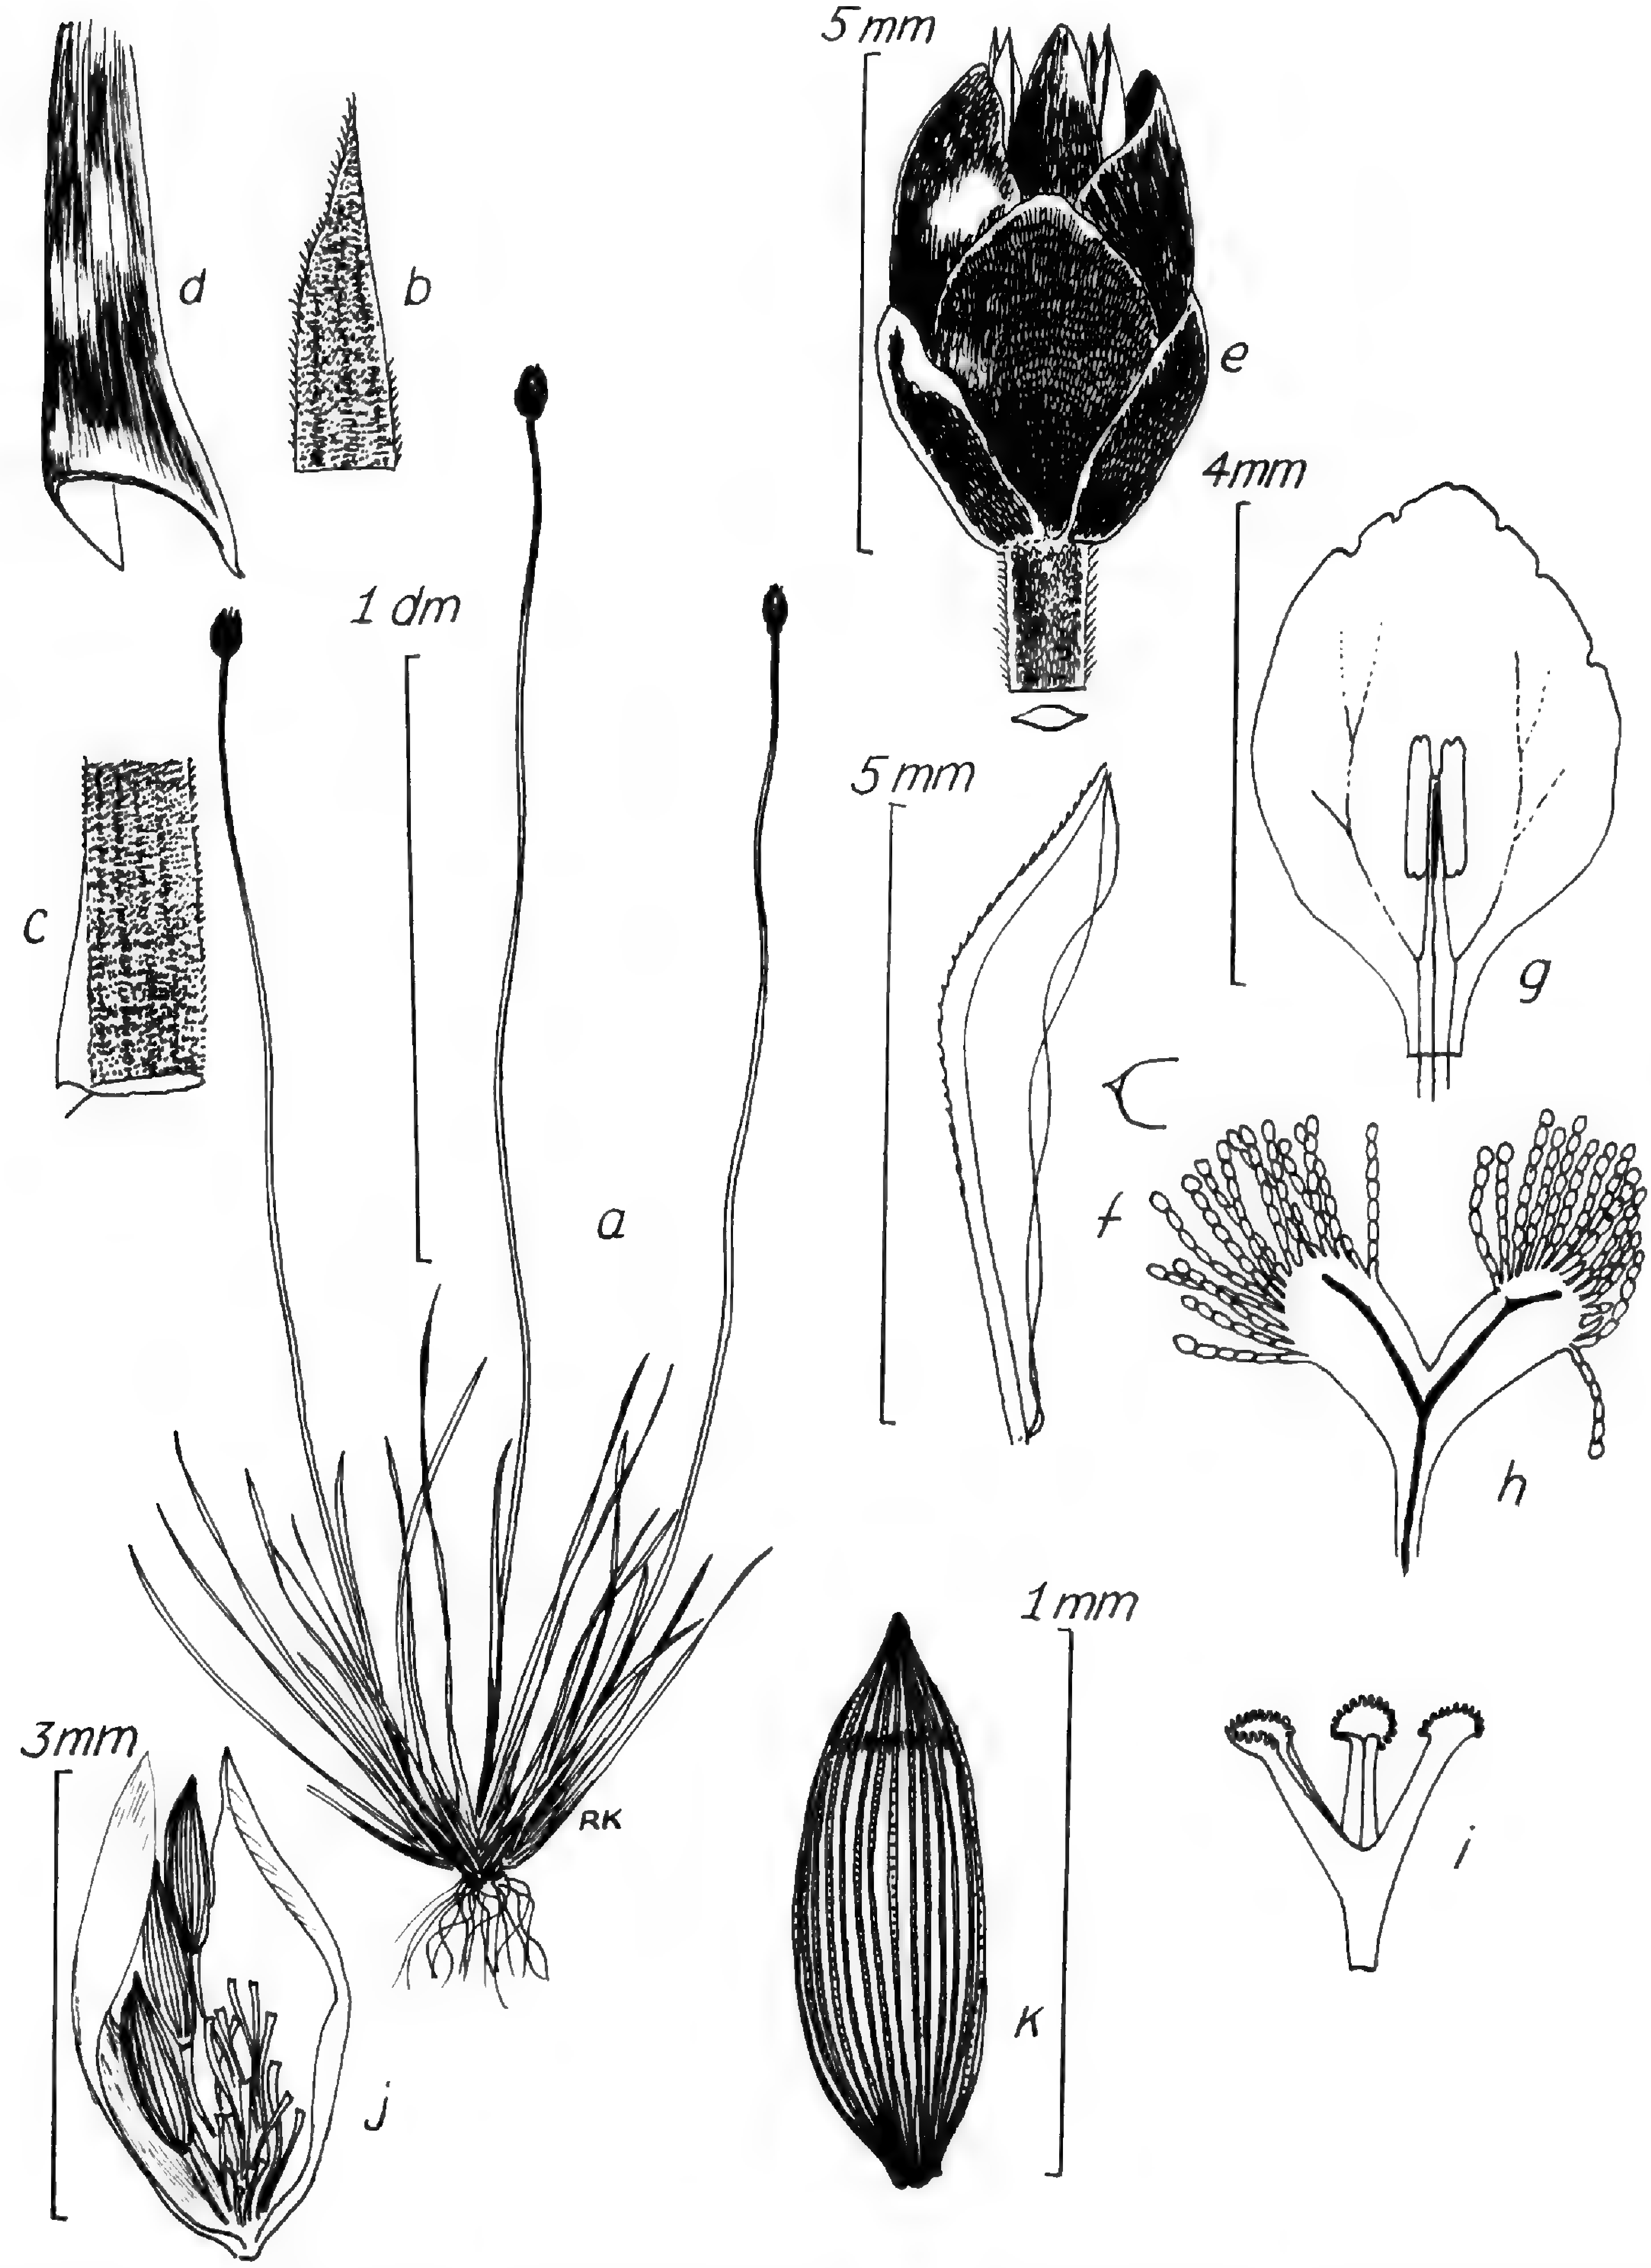

FIGURE 26C. Xyris subulata *var.* acutifolia *(*Steyermark & Dunsterville 101199*).—a. Habit sketch.—b. Leaf apex.—c. Leaf blade–sheath junction.—d. Leaf base.—e. Spike and upper scape.—f. Lateral sepal.—g. Petal blade, stamen.—h. Staminode.—i. Stylar apex.—j. Capsule, showing basal–central placentation.—k. Seed.*

spiraliter imbricatae, leviter expansae, integrae, infimae 5–6 steriles, par inferior anguste triangulata, ca. 4 mm longa, valde carinata, scabrociliata, 2–3-plo fertiles breviores, intimae leviter longiores, lanceolatae, carinatae, usque ad 5 mm longae, in fertiles abrupte transientes; bracteae fertiles late lanceolatae, usque ad 8 mm longae, a medio ad apicem valde carinatae, integrae (demum laceratae). Sepala lateralia libera, subaequilateralia, 7–8 mm longa, acuminata, leviter curvata, ala carinali angusta, incrassata, integra vel leviter scabrida. Laminae petalorum obtriangulatae, luteolae, ca. 5 mm longae, apice laceratae. Staminodia bibrachiata, brachiis disparibus, oblongis, penicillatis. Antherae oblongae, profunde bifidae et sagittatae, ca. 1 mm longae, filiis ca. 1 mm longis. Capsula matura anguste ellipsoidea, 4.5 mm longa, acuta, valvis basin versus septo habens; placenta centralis, funiculis crassis. Semina cylindrica (cum apicula) 2 mm longa, pallide brunneola, opaca, longitudine spiraliter multicostata, apiculo albosquamoso, ca. 0.5 mm longo.

Plants perennial, cespitose, smooth, slender, the roots slender-fibrous. Stems short. Leaves slightly to flabellately spreading, 8–14 cm long, longer than the scape sheaths; sheaths entire, ecarinate toward base, lustrous pale brown, slightly dilated, multicostate, gradually narrowing, carinate into the leaf blades, at apex short-ligulate; blades narrowly linear, 2–3 times longer than the sheaths, 1–2.5 mm wide, flat, olivaceous, finely multinerved; tips incurved-acute, slightly thickened; edges thin, retrorsely scabrociliolate, pale. Scapes slightly twisted or straight, 20–35 cm high, ca. 1 mm wide, subterete toward apex but prominently bicostate, the costae densely pale scabrociliate. Spikes few-flowered, brownish, narrowly turbinate, becoming broadly turbinate, ca. 10 mm long; bracts without dorsal area, laxly spirally imbricate, slightly spreading, entire, the lowest 5–6 sterile, the lowest pair narrowly triangular, ca. 4 mm long, strongly carinate, scabrociliate, 2–3 times shorter than the fertile bracts, the inner bracts slightly longer, lanceolate, carinate, up to 5 mm long, grading abruptly into the fertile bracts; these broadly lanceolate, up to 8 mm long, strongly carinate from middle to tip, entire (aging lacerate). Lateral sepals free, subequilateral, 7–8 mm long, acuminate, slightly curvate, the keel narrow, thick, entire to slightly scabrid. Petal blades obtriangular, yellow, ca. 5 mm long, apically lacerate. Staminodia bibranched, the branches unequal, oblong, penicillate at tips. Anthers oblong, deeply bifid and sagittate, ca. 1 mm long, on filaments ca. 1 mm long. Mature fruit narrowly ellipsoid, 4.5 mm long, acute, the valves with septa toward base; placenta free-central, with thickened funicles. Seed cylindric, 2 mm long including apiculus, pale brown, opaque, longitudinally spirally ribbed, the apiculus a pale scale ca. 0.5 mm long.

Distribution. Known only from the type locality.

In general dimensions and in strongly two-edged, ciliate scape, the new species resembles *X. bicostata* Maguire & Lyman B. Smith but lacks a dorsal area. Also, the lustrous brown leaf sheaths are entire rather than long-ciliate. In the locale, it is associated with an abundance of *X. xiphophylla* Maguire & Lyman B. Smith, *X. bicostata* Maguire & Lyman B. Smith, and *X. atriceps* Malme. Its petals unfold in late morning. As in several of the high-tepui endemics of the Guayana Highland, *X. valdeapiculata* has an elongated (2 mm) seed, the name for the species chosen to reflect the long, pale, thin apiculus.

28. Xyris tatei Malme, Bull. Torrey Bot. Club 58: 324, pl. 24, fig. 1A. 1931. TYPE: Venezuela. T. F. Amazonas: moist slopes of the Savanna Hills, summit of Mount Duida, 4,400 ft., *G. H. H. Tate 835* (lectotype, NY; phototypes, F, NY). Figure 28.

Robust, cespitose, hard-based perennial 6–9 dm high, the stem stout, contracted, or up to 9 cm long. Leaves spreading flabellately or ascending, 2.4–6 dm long; sheaths eciliate, usually ½ as long as blades, or shorter, broad at very base, lustrous deep red-brown or castaneous, thence upward shading to pale green, narrowing gradually to blade, there with an erect, pale, triangular ligule 1–2 mm long; blades linear, flattened, 3–7 mm wide, narrowing gradually above middle, abruptly narrowed at apex, incurved-acute, the tip somewhat incrassate; margins slightly to very thickened, pale, smooth or papillose; surfaces green, multinerved, smooth. Scape sheaths

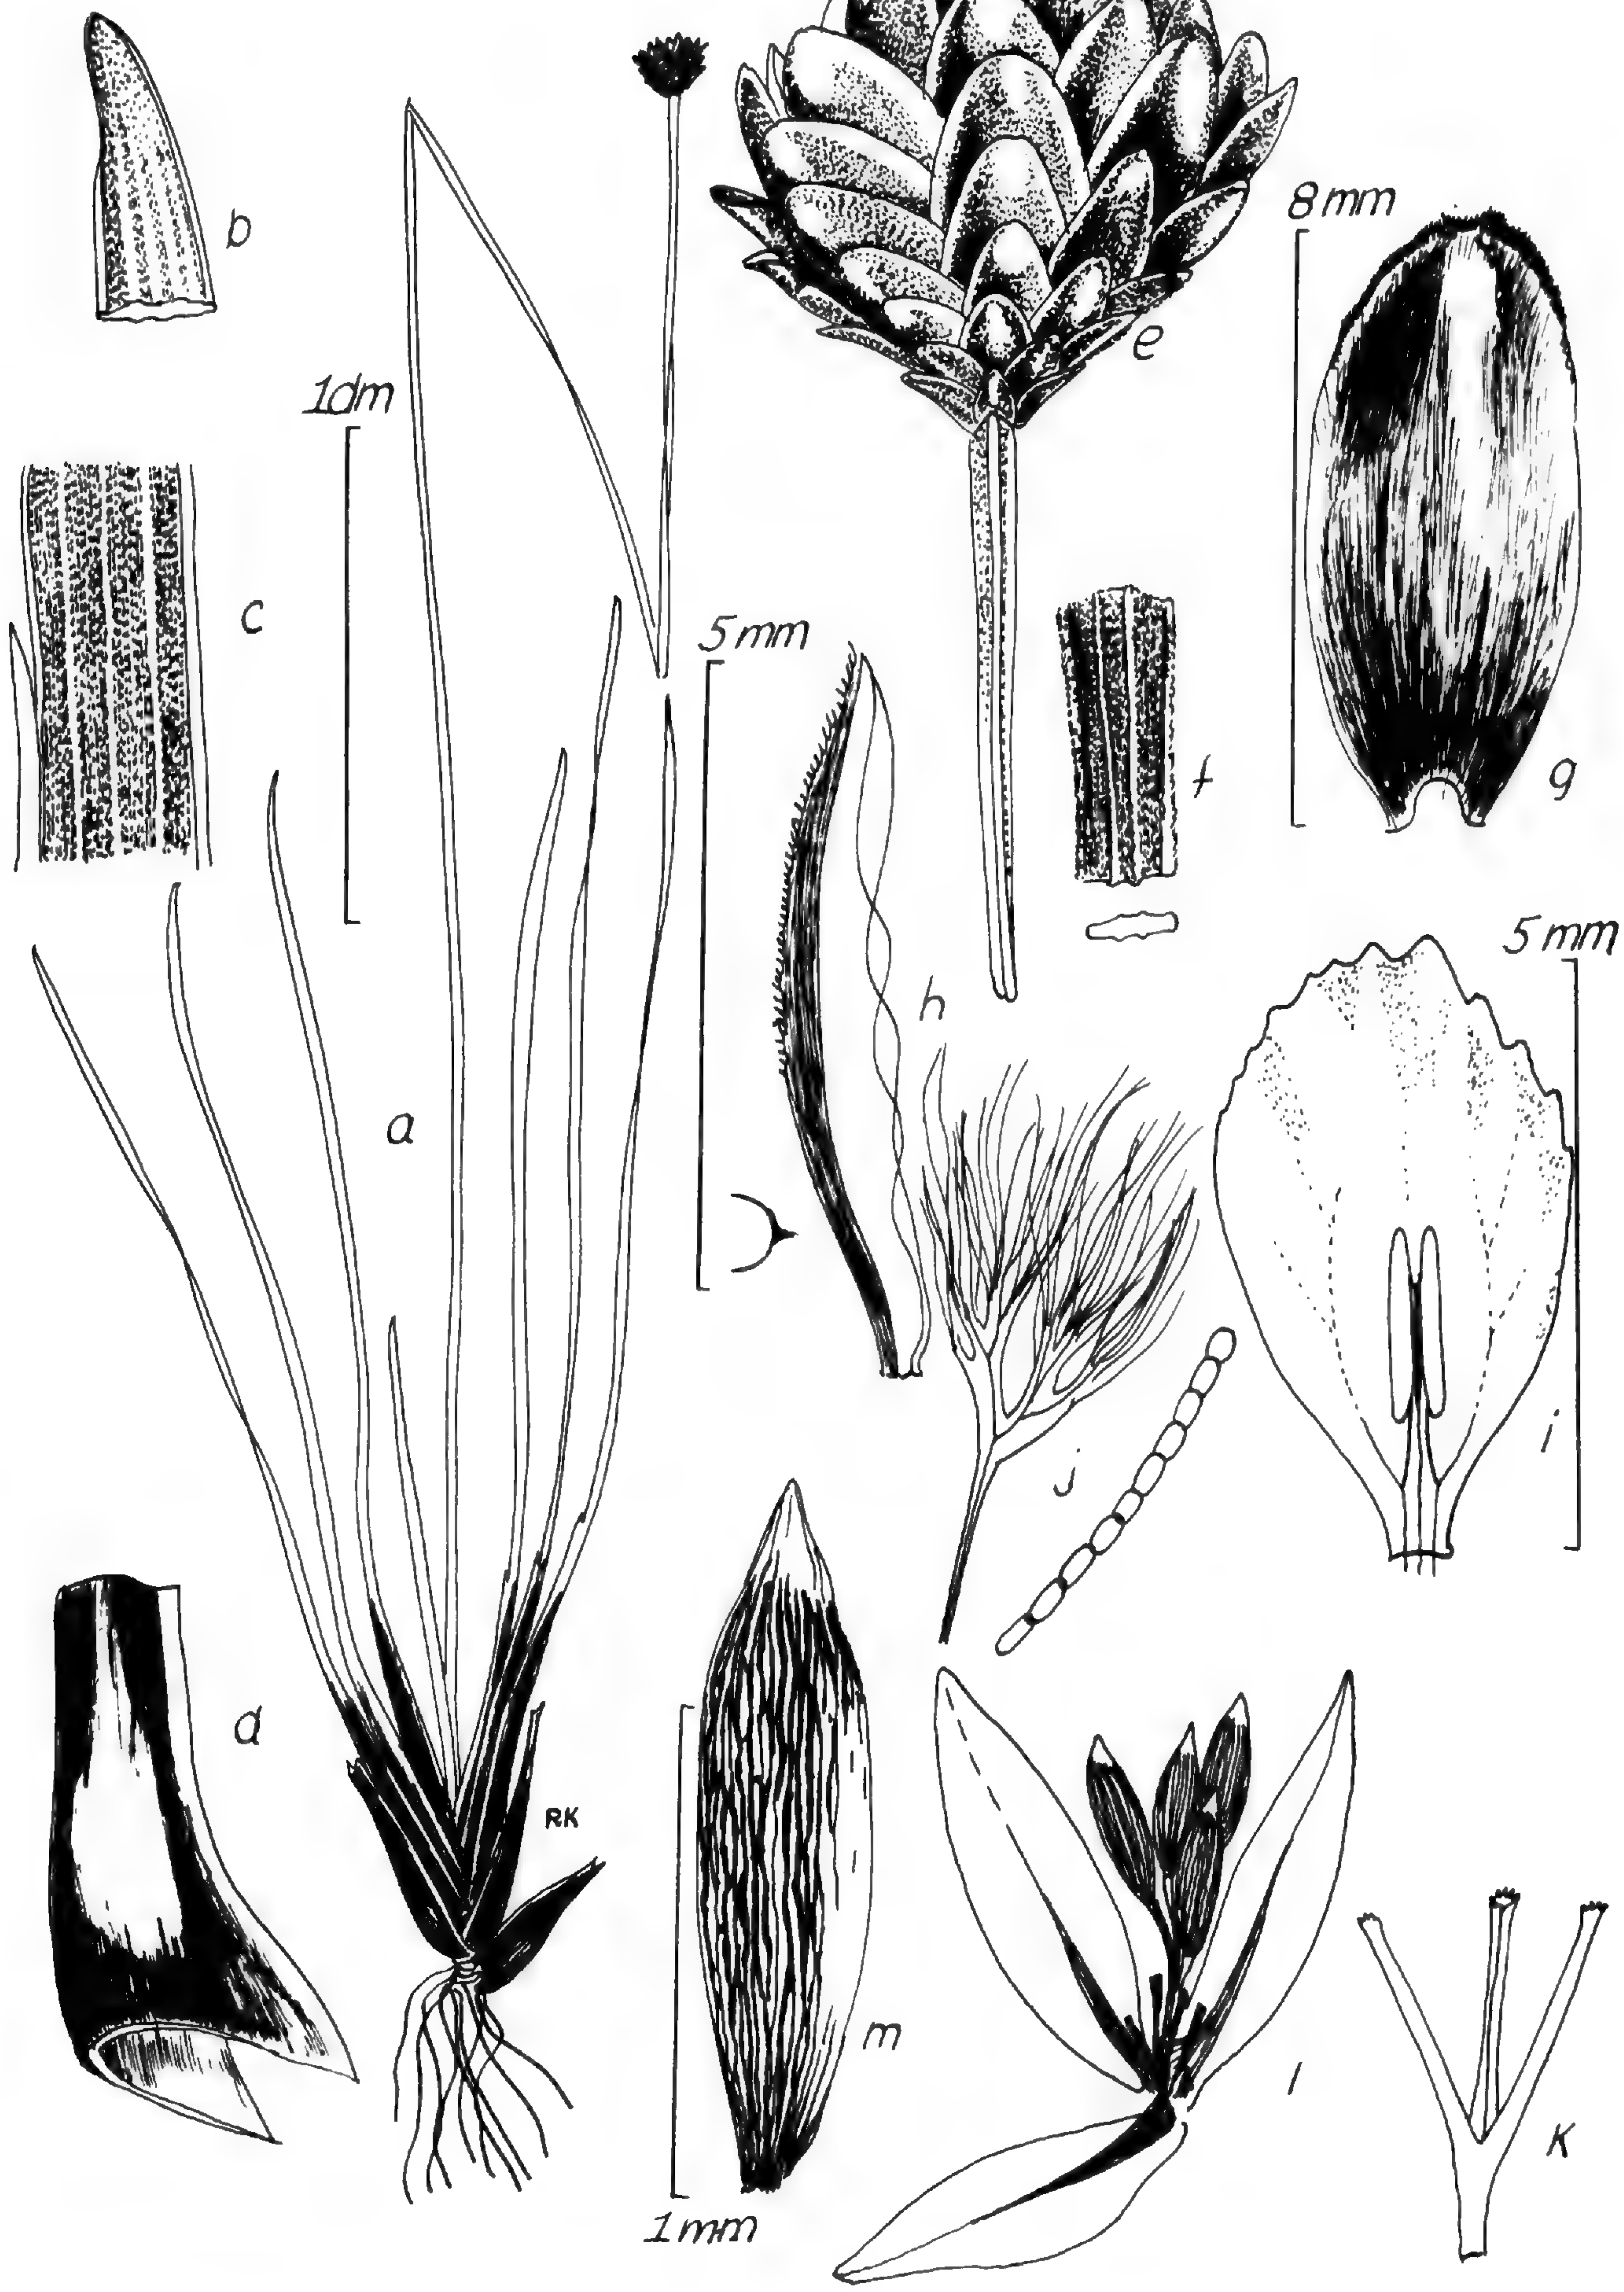

FIGURE 28. Xyris tatei (Tate 835).—*a. Habit sketch.—b. Leaf apex.—c. Leaf at blade-sheath junction.—d. Leaf base.—e. Spike.—f. Sector of upper part of scape.—g. Fertile bract.—h. Lateral sepal.—i. shorter than leaves, tubular and costate at base, keeled, open toward apex, producing a short, erect blade. Scapes flattened distally, 2–3 mm wide, the edges comprising 2 densely papillate pale costae, the sides sometimes with 1–2 more lower costae. Spikes globose to hemispherical or broadly turbinate, 1–1.5 cm high, the base attenuate, with many firm, lustrous brown, imbricate bracts in nearly vertical rows and without dorsal areas; fertile bracts numerous, the lowest bracts much smaller than the fertile bracts, ovate-triangular, carinate, grading into the fertile bracts, these broadly oblong to obovate, 6–8 mm long, broadly rounded at apex, with reddish scarious (rarely also reddish ciliolate) borders or subentire, the backs low-convex with a low, pale median nerve toward apex. Lateral sepals free, equilateral, narrowly oblong-elliptic, ca. 6–6.5 mm long, acute, reddish brown, the firm keel red-ciliolate from middle to apex. Petal blades obovate, ca. 5–5.5 mm long, the narrowly rounded apex and margins erose. Anthers oblong-lineal, 2–2.2 mm long, deeply bifid and shallowly auriculate, on erect filaments ca. 1 mm long. Staminodia with branches rebranched, the flattened ultimate branchlets long-penicillate. Capsule narrowly ellipsoid, acuminate, ca. 4–5 mm long, the placentation appearing basal-central, but each valve with a strong septum at base. Seeds few, cylindrical-fusiform, ca. 1.5–2 mm long, dark amber with apex conic and pale, the body finely and prominently longitudinally multiribbed.

Distribution. Known only from high, wet, rocky savanna, Cerro Duida, at elevations over 1,000 meters.

Additional specimens examined. VENEZUELA. T. F. AMAZONAS: Cerro Duida (all specimens): Río Cunucunuma, occasional in moist places in open scrub, basin of Caño Negro at 2,000 m, *Maguire, Cowan & Wurdack 29694* (NY); open places near summit of Culebra Peak, 1,800 m, *Maguire 29155* (NY, VEN); Río Cunucunuma, to 1 m high, occasional along Culebra Creek at 1,100 m, *Maguire, Cowan & Wurdack 29511* (NY); moist slopes of Savanna Hills, summit of Mt. Duida, 4,400 ft., *Tate 778* (NY).

This taxon resembles *X. albescens* Steyerm. superficially, but that species has its leaf-blade edges and its scape edges prominently ciliate with pale hairs, while its seeds are longer and much narrower.

29. Xyris melanovaginata Kral & Lyman B. Smith, sp. nov. TYPE: Venezuela. Bolívar: Dist. Piar, Macizo del Chimantá. Sección oriental del Chimantá-tepui, cabeceras del afluente derecho superior del Río Tirica ("Caño del Grillo"), 5°18′N, 62°3′W, ca. 2,450 m, 7–9 Feb. 1983, *O. Huber & J. A. Steyermark 7136* (holotype, VEN; isotype, VDB). Figure 29.

Planta robusta, perennis, caespitosa, 5–10 dm alta, basibus firmis, per bases persistentes veternas foliorum obtectis. Caules incrassati, varie elongati (basibus in substratio profunde elongati). Folia principalia rigida, disticha, flabellate expansa, 2–3 dm longa; vaginis scaporum longiora; vaginae integrae, vulgo laminis aut dimedio breviorae vel minus, lamprocastaneae, sursum in laminas gradatim contractae, ad apicem ligulatae, ligula anguste triangulata, ca. 2 mm longa; laminae planae, ensiformilineares, 4–6 mm latae, apices incurvati-acuti, incrassati; margines integri vel ciliolati aut pallide ciliatopilosi; paginae atrovirides, leviter multinervosae, glabrae. Vaginae scaporum foliis breviore, laxae, a basin castaneae, tubulosae, ad apicem carinatae et apertae, laminis brevibus, laminis foliorum similibus. Scapi recti vel aliquantum curvati, valde complanatae, ad apicem ancipiti, 2–4 mm lati, margine glabri vel varie pallide vel albociliatae. Spicae ovoideae vel ellipsoideae aut cylindricae, 1–3 cm longae, obtusae, atroporphyreae vel olivaceicastaneae, attenuatae, multiflorae; bracteae arcte spiraliter imbricatae, steriles multae, fertilibus breviores, latae ovatae vel obovatae, ecarinatae vel ad apicem leviter carinatae, fertiles gradatim profluentes, haec oblongae vel late obovatae, 5.5–7 mm longae, late rotundatae, integrae vel erosae, ecarinatae, leviter convexae, sine area dorsali. Sepala lateralia libera, subaequilatera, oblongo-linearia, ca. 5 mm longa, obtusa, vel acuta, pallide brunneola; ala carinali firma, super mediam ciliolata vel piloso ciliata. Laminae petalorum obovatae, ca. 6 mm longae, luteolae. Staminodia bibrachiata, brachiis longipenicillatis. Antherae latae oblongae, ca. 1 mm longae, filiis ca. 0.5 mm longis. Capsula anguste ellipsoidea vel obovoidea, 4–5 mm longa; placentae axiales. Semina pauca, ellipsoidea, apiculata, 1.3–1.5 mm longa, porphyrea, translucida, longitudine leviter multicostata.

Robust, cespitose perennial 5–10 dm high, the stems stout, contracted or elongated to 2 dm, producing frondlike plates of leaves. Leaves spreading flabellately, 2–3 dm long, sheaths entire, mostly ½ as long as blades or shorter, firm, castaneous, lustrous, tapering gradually from broad bases into blades, there

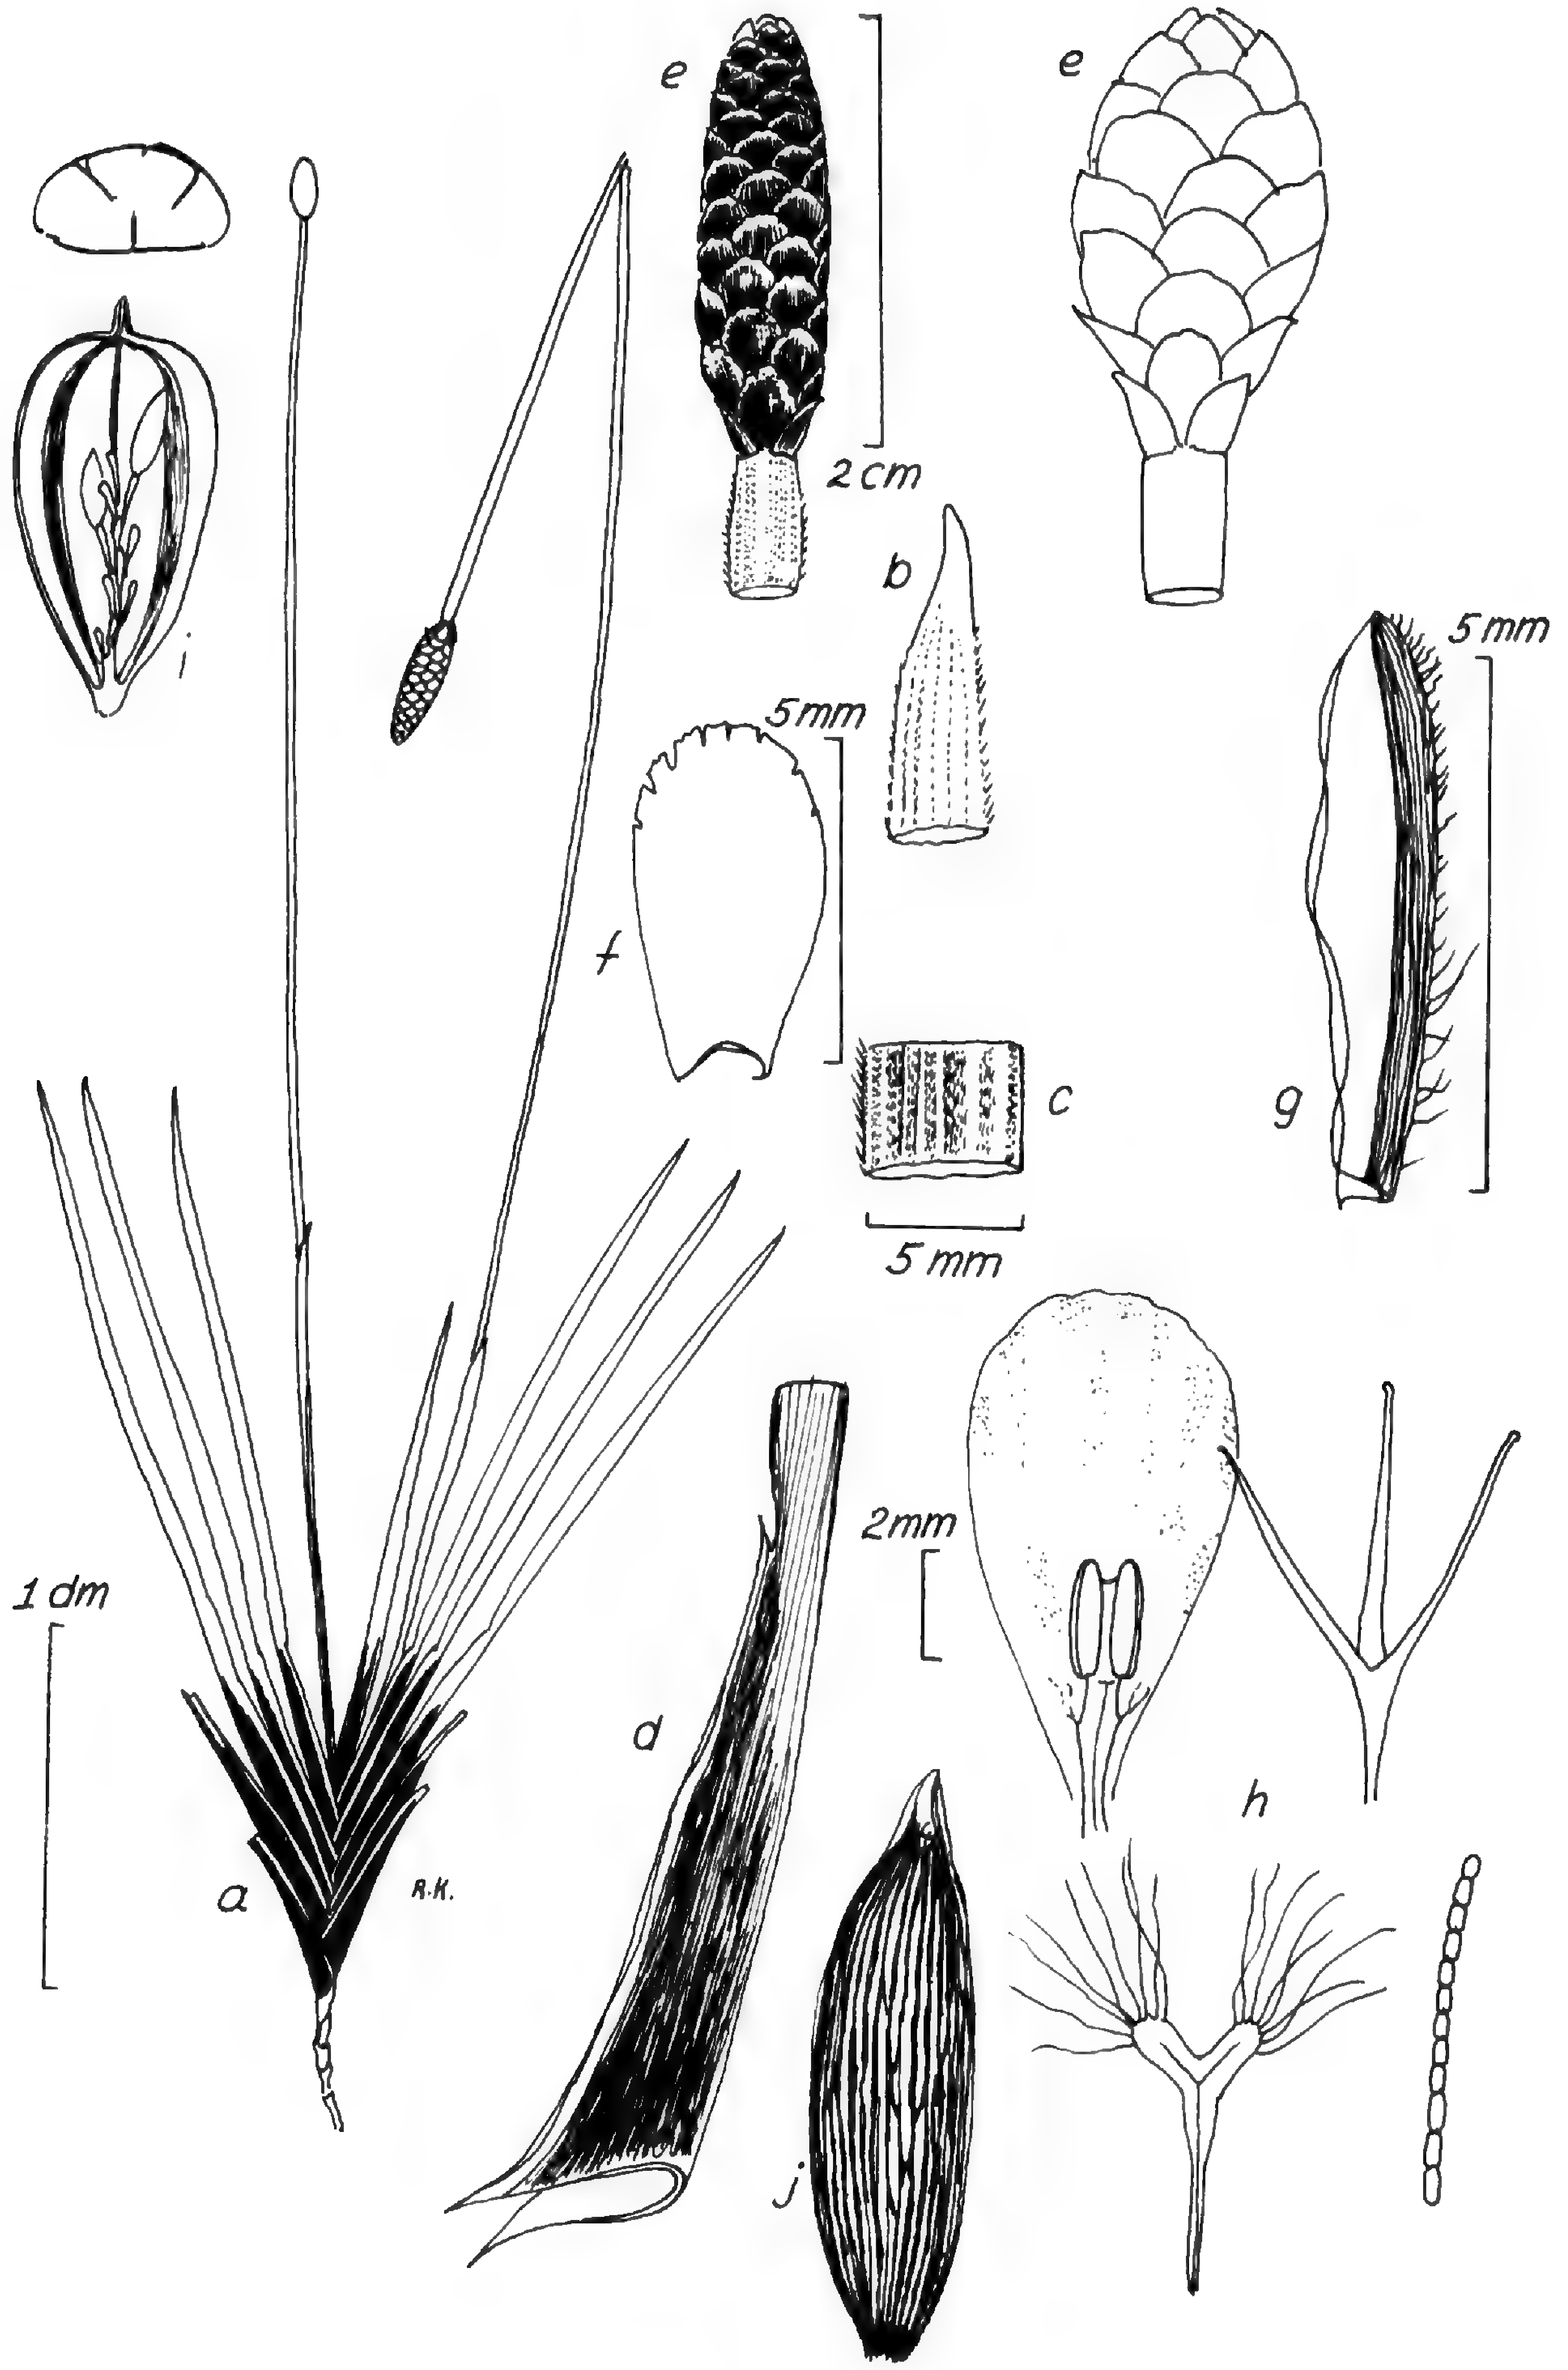

FIGURE 29. Xyris melanovaginata *(from the type)*.—*a. Habit sketch.—b. Leaf apex.—c. Leaf at ca. mid-blade.—d. Leaf base.—e. Two spikes.—f. Fertile bract.—g. Lateral sepal.—h. producing a scarious, narrowly triangular ligule ca. 2 mm long; blades flat, gladiate-linear, 4–6 mm wide, the apex incurved-acute, incrassate, the margins usually with submarginal narrow red-brown bands, the edges cartilaginous, smooth or ciliolate or pale-pilose-ciliate, the surfaces deep green, finely multinerved, smooth. Scape sheaths shorter than leaves, proximally castaneous and tubular, keeled and open above, producing a short, flat blade. Scapes strongly flattened, distally ancipital, 2–4 mm wide, the edges smooth to variously pale-ciliate. Spikes ovoid to ellipsoid or cylindric, 1–3 cm long, blunt, dark red-brown or olivaceous-castaneous, attenuate, of many spirally imbricate bracts, the sterile bracts many, broadly ovate to obovate, ecarinate or distally carinate, grading gradually larger into fertile bracts, these oblong to broadly obovate, 5.5–7 mm long, broadly rounded, entire or erose (lacerate in age), ecarinate and but slightly convex-backed, without dorsal area. Lateral sepals free, subequilateral, oblong-linear, blunt or acute, pale brown with firm ciliolate or pilose-ciliate keel. Petals with blades obovate, ca. 6 mm long, yellow, the broadly rounded apex erose. Staminodia bibrachiate, the branches at apex long-penicillate. Anthers broadly oblong, ca. 1 mm long, the connective broad, the filaments ca. 0.5 mm long. Capsule narrowly ellipsoid to obovoid, dorsiventrally compressed, 4–5 mm long, the placentae axile, the valves with prominent septa. Seeds ellipsoid, apiculate, 1.3–1.5 mm long, reddish brown, translucent, longitudinally finely anastomosing-ribbed.

Distribution. So far known only from the Chimantá Massif, there much collected in recent years.

Additional specimens examined. VENEZUELA. BOLÍVAR: sector centro-noreste, 26–29 Jan. 1983, *Huber & Steyermark 6950* (VDB, VEN); en ladera del Río Chimantá Superior, 1 Feb. 1983, *Huber & Steyermark 6983* (VDB, VEN); sector W del Acopan-tepui, 7–9 Feb. 1983, *Huber & Steyermark 7081* (MYF, VEN, VDB); sección oriental del Chimantá-tepui, *Huber & Steyermark 7136* (MYF, VDB); central section near Summit Camp, *Steyermark & Wurdack 347* (NY, US, VEN); island in Río Tirica above Middle Fall below Summit Camp, *Steyermark & Wurdack 487* (NY, US); upper shoulder of Apacará-tepui, SE facing upper shoulder, *Steyermark 75759* (F, NY, VEN); W part of Abacapá-tepui, 13 Apr. 1953, *Steyermark 74851* (F, NY, VEN); sector septentrional, Murey-tepui, 24 Feb. 1978, *Steyermark et al. 115769* (US, VEN), *115836* (MO, US, VEN); cumbre del Cerro Apacará, 8 June 1946, *F. Cardona 1586* (VEN); centro noreste sector, 26–29 Jan. 1983, *Steyermark et al. 128024, 128083, 128131, 128224* (VDB, VEN); Amuri-tepui, 2–5 Feb. 1983, *Steyermark et al. 128459*; same locality, 6 Feb. 1983, *Steyermark 128775* (VDB, VEN); sección oriental, 9 Feb. 1983, *Steyermark et al. 128883* (VDB, VEN); altiplanicie suroriental del Acopan-tepui, 14–16 Feb. 1984, *Steyermark et al. 129866* (MYF, VEN, VDB); Churi-tepui, 3 Feb. 1953, *Wurdack 34307* (NY, US).

This species, obviously abundant on the summits of the Chimantá Massif, and which has been in collections for many years, has been identified variously as *X. decussata* Gl., *X. albescens* Steyerm., *X. tatei* Malme, and otherwise. It is often very long-stemmed and is frequently a "plate" former like *X. witseniodes*, *X. ptariana*, *X. frondosa*, and other species. While it has ancipital scapes that are often ciliate as in *X. decussata*, it lacks the dense, continuous bands of reddish hairs of that species. Its elongate spikes are distinctive. While its scape and leaves are often pale-ciliate, its leaf blades are much longer than its leaf sheaths, its spikes are longer than in *X. albescens*, and its lateral sepals and seeds are shorter. Thus, more by a combination of characters held in part by different species, it is unique.

30. Xyris culmenicola Steyerm., Fieldiana, Bot. 28(1): 1951. TYPE: Venezuela. T. F. Amazonas: Brocchinia Hills, 1,700–1,980 m, Cerro Duida, 1 Sep. 1944, *J. Steyermark 58198* (holotype, F; isotypes, GH, NY, US). Figure 30.

Cespitose, robust, hard-based perennial 5–7 dm high, the stems contracted. Leaves erect to somewhat spreading, 2–3.5 dm long; sheaths entire, less than ½ as long as blades, deep, lustrous, reddish brown or castaneous at base, tapering gradually and keeled from broad base to blade, there essentially eligulate, the blades flat, linear, 2.4–5 mm wide, tapering very gradually from ca. midblade or

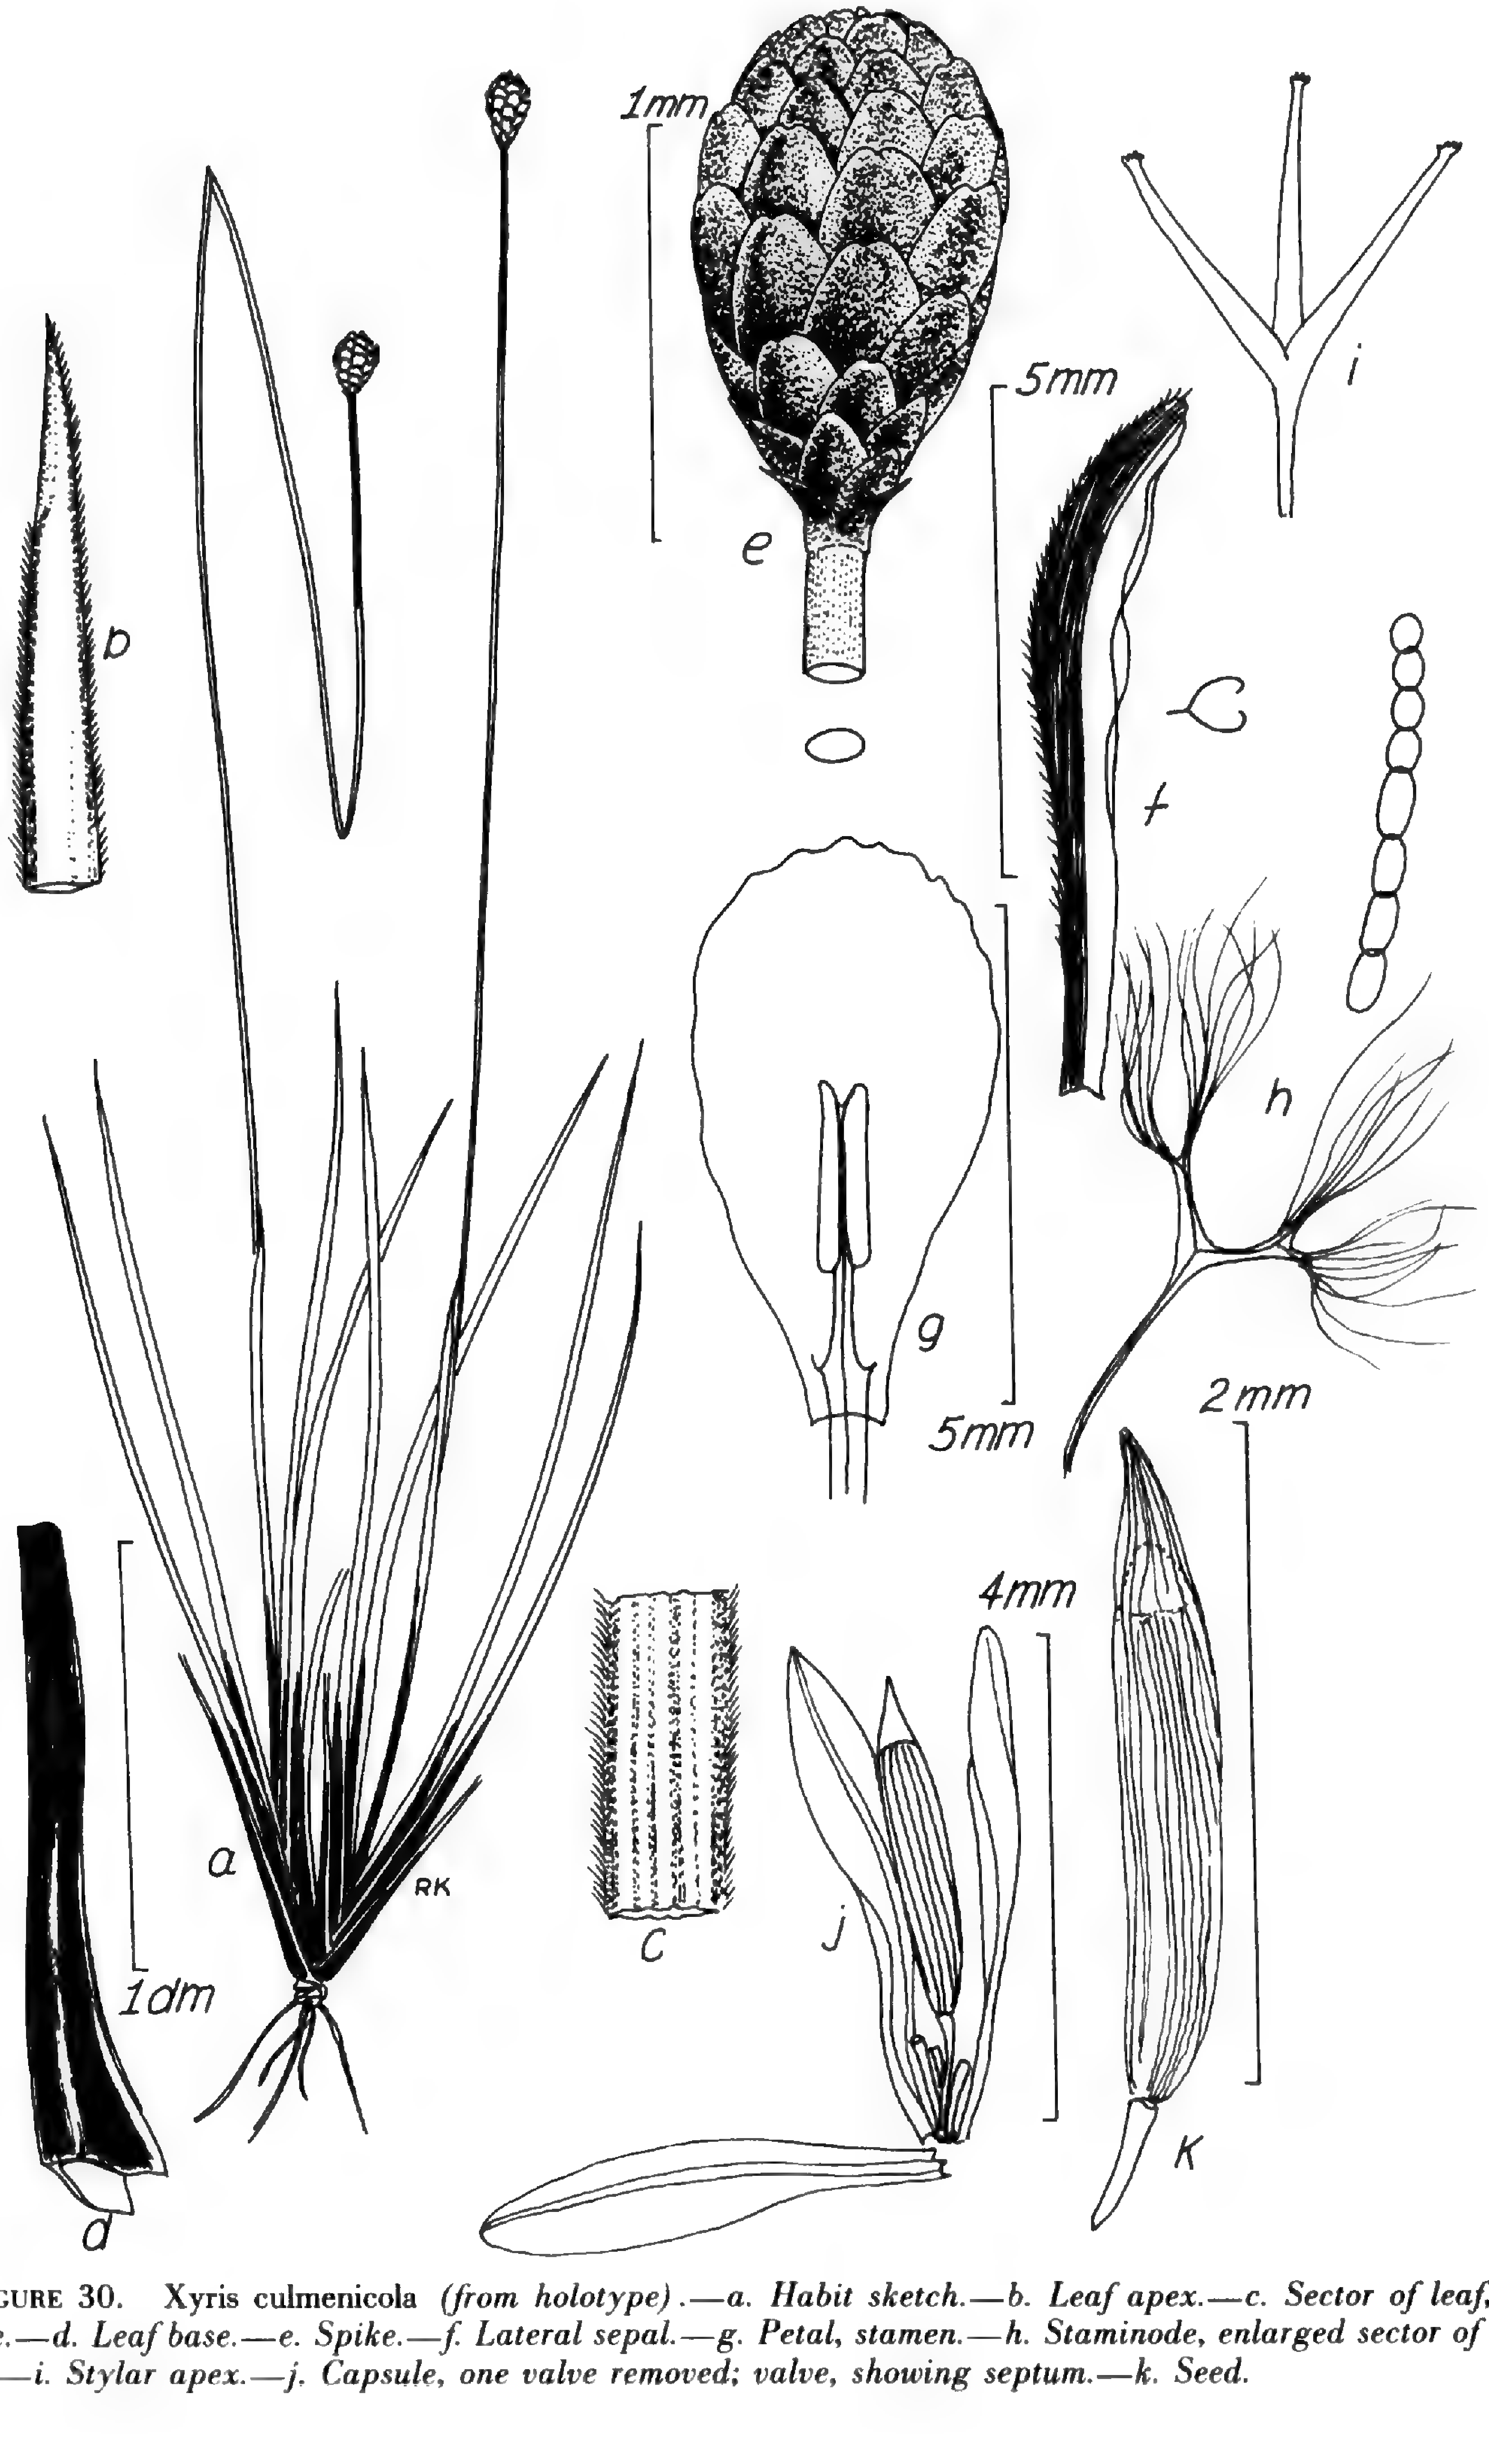

FIGURE 30. Xyris culmenicola *(from holotype)*.—*a. Habit sketch.—b. Leaf apex.—c. Sector of leaf, mid-blade.—d. Leaf base.—e. Spike.—f. Lateral sepal.—g. Petal, stamen.—h. Staminode, enlarged sector of beard hair.—i. Stylar apex.—j. Capsule, one valve removed; valve, showing septum.—k. Seed.*

below to a narrowly acute, erect or curvate apex, the tip slightly callused, the margins pilosulous-ciliate, the surface prominently multinerved, smooth, often with alternating broad, red-brown bands, 2 of these making submarginal borders. Scape sheaths much shorter than leaves, loosely tubular and castaneous below, open above, green, carinate and ciliate-keeled, with a short, erect, ciliate, blade. Scapes straight, slightly twisted, distally slightly compressed but in cross section oval or oblong, smooth, low-ribbed. Spikes dark brown, ovoid to broadly ellipsoid or broadly obovoid, 1.5–2 cm long, blunt, attenuate-based, of many firm, spirally imbricate, entire bracts without dorsal areas. Sterile bracts many, the lowest by far the smallest, keeled, ovate-triangular, grading gradually to fertile bracts, the fertile bracts obovate to oblong, 7–8 mm long, entire (becoming somewhat lacerate), often emarginate, the apex broadly to narrowly rounded, the backs ecarinate, slightly convex, not folded. Lateral sepals free, subequilateral, linear-oblanceolate, ca. 7–7.5 mm long, broadly acute, pale brown, curvate, the strong, dark keel rusty-ciliate from middle to apex. Petal blades broadly obovate, ca. 6 mm long, yellow, the broadly rounded apex erose. Staminodia quadribrachiate, the branches long-penicillate. Anthers oblong, ca. 1.5 mm long, short-bifid, auriculate, on filaments ca. 1 mm long. Capsule cylindric, ca. 4 mm long, the placentation apparently basal but with 3 strong septa intruding except at ovary apex. Seeds few on long funiculi, narrowly cylindric-fusiform, ca. 2 mm long, pale brown, translucent, including a translucent, pale, conic appendage ca. 0.5 mm long (outer integument), the body longitudinally multiribbed with a few coarser ribs produced by the outer integument.

Distribution. Grassy, rocky, wet savanna, summit elevations along Cerro Duida and Cerro Marahuaca, T. F. Amazonas, Venezuela.

Additional specimens examined. VENEZUELA. T. F. AMAZONAS: gallery forest and open area on Plateau of Huachamacari, 1 Mar. 1985, *Liesner 18121A* (MO, VDB, VEN); Cerro Huachamacari, Río Cunucunuma, near E escarpment at 1,900 m, *Maguire et al. 30123* (NY, US); summit of Cerro Duida, Brocchinia Hills, above Vegas Falls, 1 Sep. 1944, *Steyermark 58141* (F, K, NY, VEN, US); summit of Cerro Duida, Savanna Hills, 1,025–1,200 m, 2 Sep. 1944, *Steyermark 58233* (F, NY, US—a cotype); Cerro Marahuaca, cumbre, sección noroccidental, 2,500 m, 16 Feb. 1981, *Steyermark et al. 124426* (MO, VEN); Cerro Marahuaca, cumbre altiplanicie no arbolada, 2,580 m, 31 Jan. 1982, *Steyermark et al. 125892* (VEN, VDB); Cerro Marahuaca, parte aislada al Sur-Oeste del Cerro, 2,480 m, 9–10 Feb. 1982, *Steyermark et al. 126290* (VDB, VEN); Cerro Huachamacari, cumbre, 1,800 m, 10 Feb. 1982, *Steyermark et al. 126451*; Cerro Marahuaca, cumbre, parte central de la Meseta Sur-Este, 2,560 m, 10–12 Oct. 1983, *Steyermark 129444* (VDB, VEN); Cerro Duida, 29 Jan.–11 Feb., 1975, *S. S. Tillett et al. 751-74* (topotype, MYF, NY, VEN).

This falls in treatments next to *X. lugubris*, *X. tatei*, and *X. albescens* but is distinct in its longer spike, duller bracts, and more uniformly tapered, distinctively pigmented leaf blades, these sharper at apex.

31. Xyris lugubris Malme, Bull. Torrey Bot. Club 58: 324, pl. 24, fig. 1A. 1931. TYPE: Venezuela. T. F. Amazonas: summit of Mount Duida, 7,100 ft., Peak No. 7, *G. H. H. Tate 639* (Tyler–Duida Expedition Aug. 1928–Apr. 1929) (holotype, NY; phototype, NY). Figure 31.

Cespitose, hard-based perennial 3–10 dm high, the stems mostly contracted. Leaves erect or ascending, 2–5.5 dm long, the sheaths entire, less than ½ as long as blades, deep lustrous red-brown, smooth or papillate, keeled, gradually narrowed to blade, there eligulate or with an erect, narrowly triangular ligule to 4 mm long, the blades flattened, ensiform, 3–5 mm wide, gradually narrowed above middle to a narrowly acute, straight or incurved, thickened tip, the margins blunt or sharp-edged, smooth to papillose or tuberculate-scabrid, the surfaces dull green or green with long bands of brown or red-brown, multiribbed, smooth or papillate. Scape sheaths shorter than leaves, strongly costate, sharply keeled, with short, cusplike blades. Scapes straight or flexuous, distally subterete or slightly compressed, elliptic or oval in cross section, ca. 2 mm wide, smooth or sometimes striate, often punctate. Spikes broadly ob-

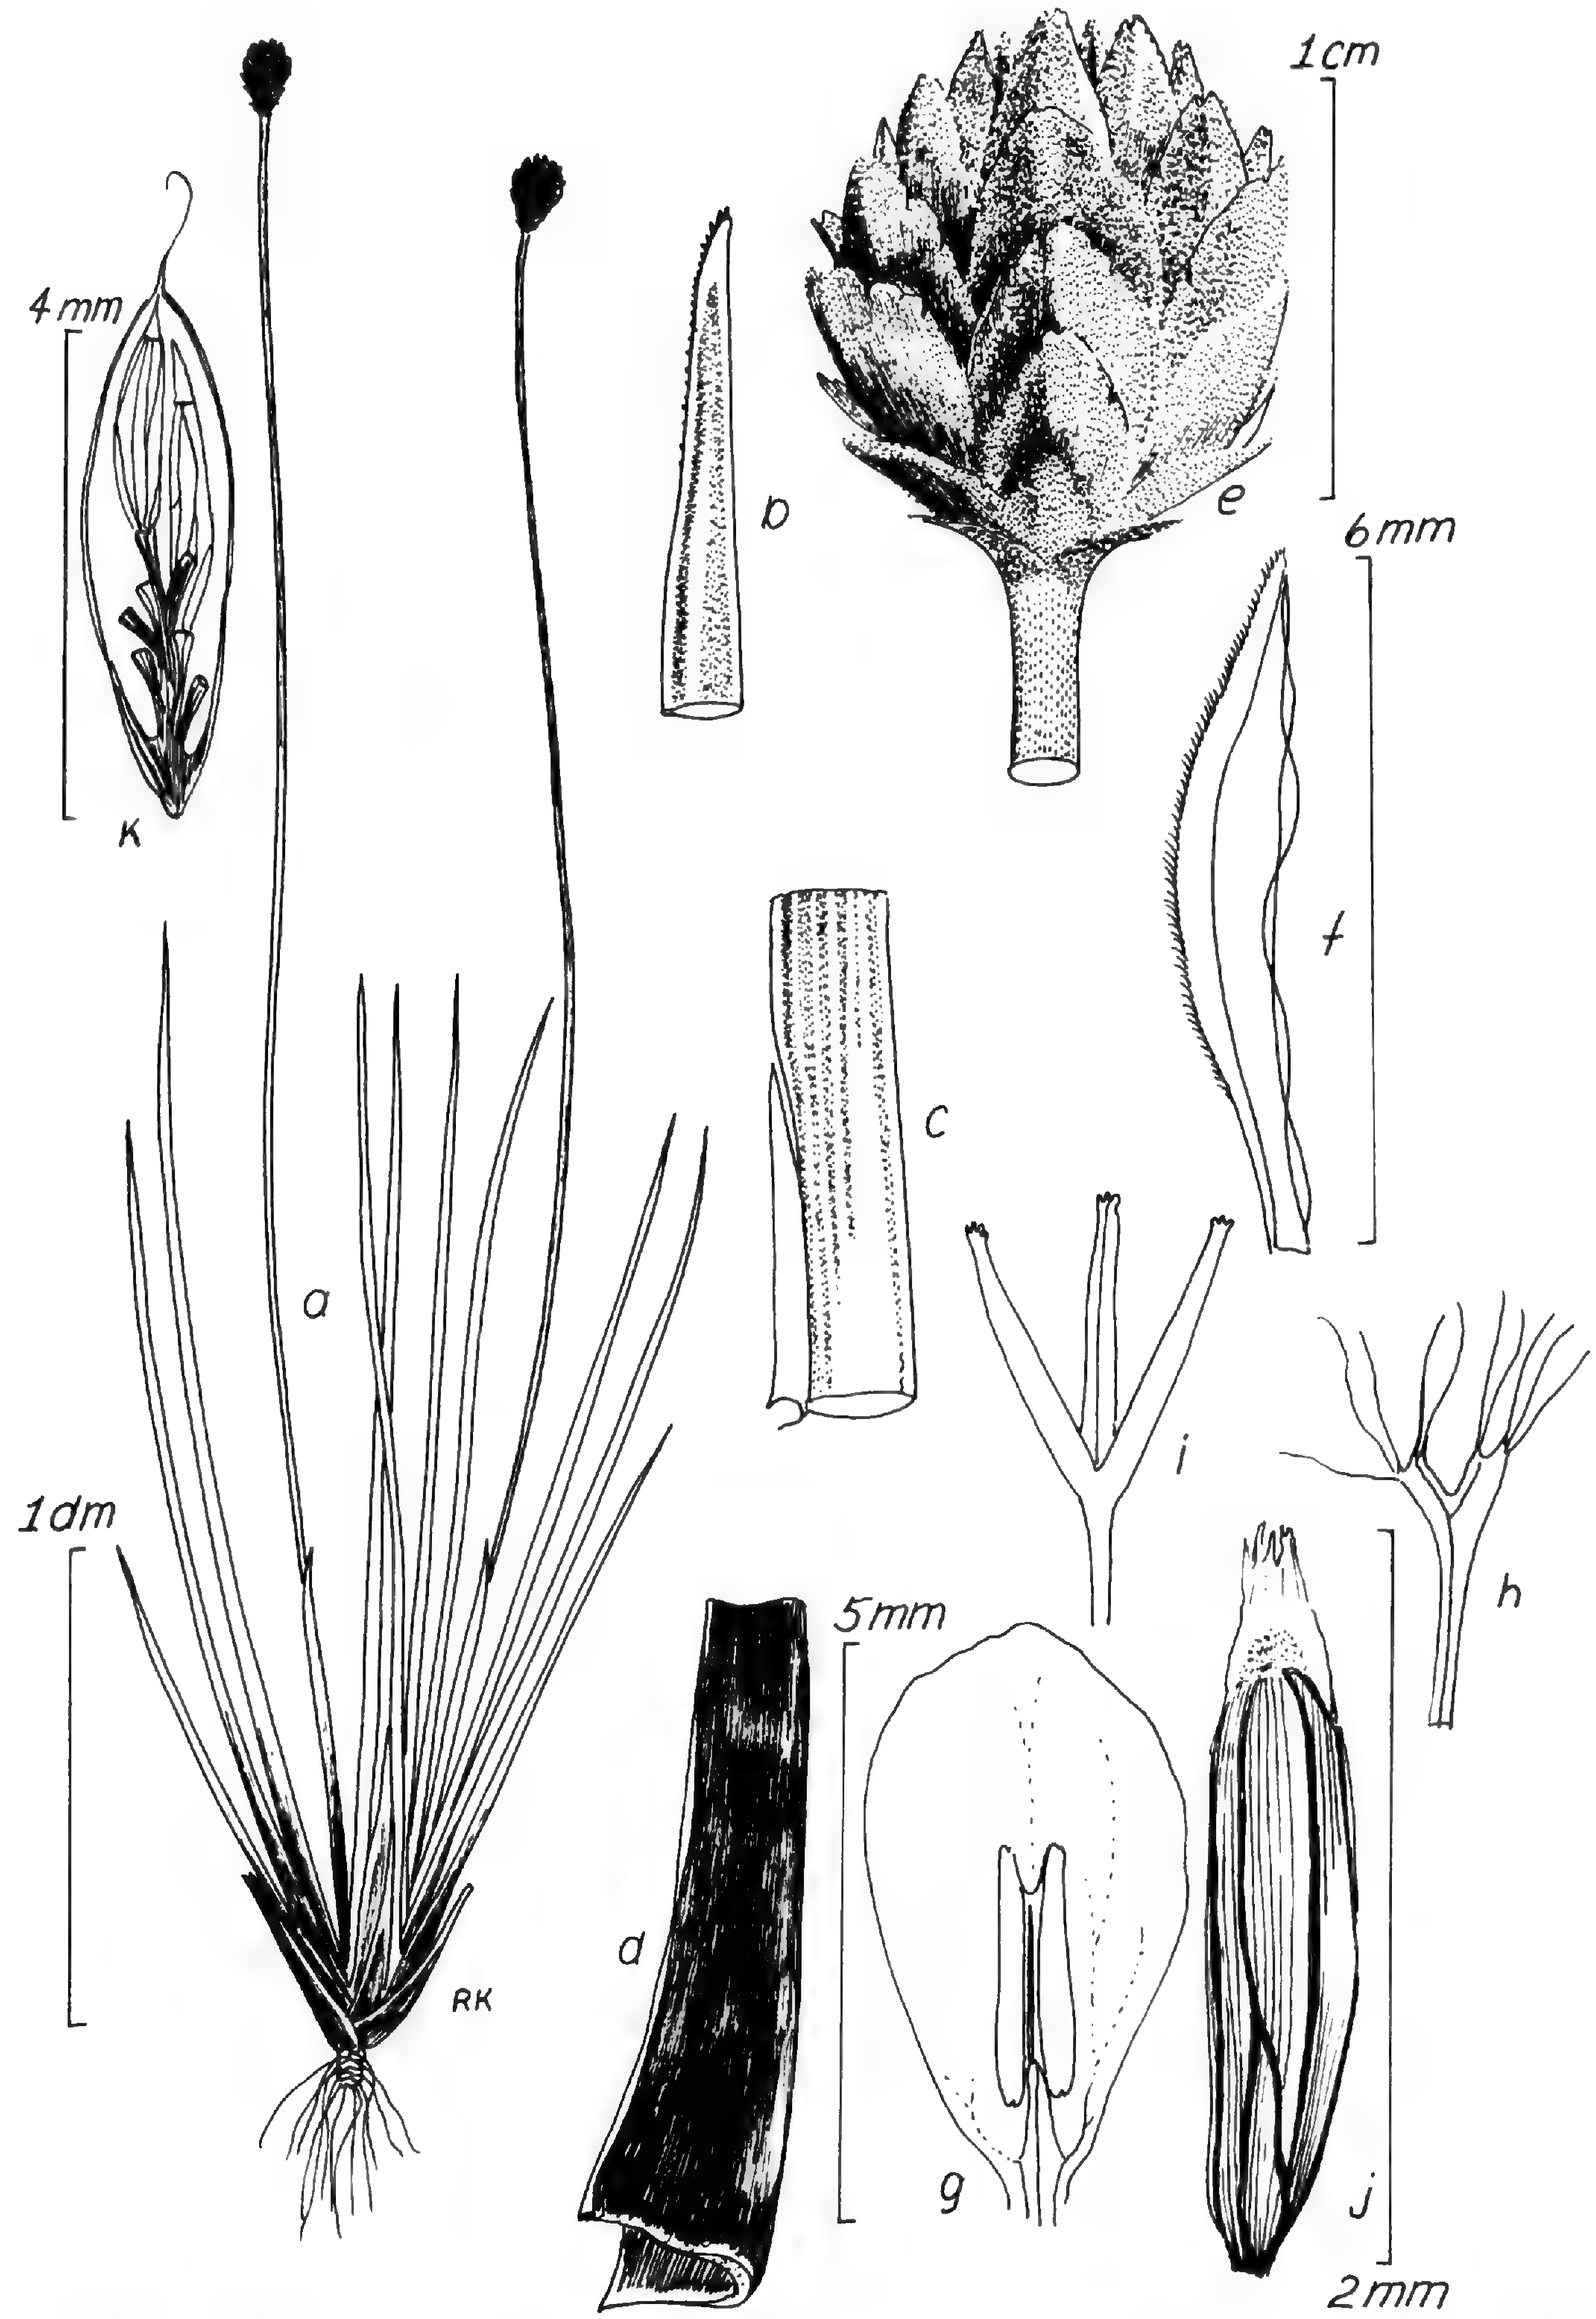

FIGURE 31. Xyris lugubris *(from the holotype)*.—*a. Habit sketch.*—*b. Leaf tip.*—*c. Leaf sheath-blade junction.*—*d. Leaf base.*—*e. Spike.*—*f. Lateral sepal.*—*g. Petal blade, stamen.*—*h. Staminode.*—*i. Stylar apex.*—*j. Seed.*—*k. Fruit, two valves removed to show central-basal placentation.*

ovoid to subglobose or hemispherical, ca. 1 cm long, blunt, of many dull, dark brown bracts in nearly vertical ranks of 5 or more; sterile bracts several, the lowest much smaller than fertile bracts, grading into them, the fertile bracts broadly oblong, 6–8 mm long, rounded and slightly folded, the apex narrowly rounded, the margins entire or lacerate, the backs folded-convex, often low-carinate toward apex. Lateral sepals equaling bracts, 6.5–8 mm long, linear-elliptic, dark red-brown, apically acute or narrow but blunt, the keel ciliolate from near base to apex. Petal blades obovate, 5–7 mm long, yellow, the apex narrowly rounded, the margins subentire. Staminodia bibrachiate, the broad, flattened branches sparsely penicillate. Anthers lance-oblong, ca. 2 mm long, deeply bifid and sagittate, on filaments ca. 0.5 mm long. Capsule ellipsoid, 4–6 mm long, the placentation central, the valves septate only near base. Seeds rather few, cylindrical, ca. 2 mm long, including a pale, squamiform apex ca. 0.5 mm long, coarsely longitudinally few-ribbed and finely lined.

Distribution. Wet, rocky savanna at or near summits, cerros Sipapo, Duida, and Neblina, T. F. Amazonas, Venezuela, infrequent.

Additional specimens examined. VENEZUELA, T. F. AMAZONAS: Camp Savanna, Campo Grande, 1,500 m, Cerro Sipapo, 10 Dec. 1948, *Maguire & Politi 27582* (GH, NY, US, VEN); Duida near summit of Culebra Peak, 1,800 m, 22 Apr. 1949, *Maguire 29155* (GH); Neblina, Río Yatua, west headland, open cumbre savanna 5 km W of Cumbre Camp, 2,000 m, 6 Jan. 1954, *Maguire et al. 37121* (F, K, NY, US, VEN); Neblina, W escarpment savanna 4–8 km S of Cumbre Camp, 1,850–1,900 m, 15 Jan. 1954, *Maguire et al. 37299* (NY); Neblina, en la cumbre del brazo nor-occidental, al norte del campamento base a lo largo del Río Mawarinuma, afluente del Río Baria, 1,880 m, 7–8 Feb. 1984, *Luteyn & Steyermark 9453* (NY, VDB, VEN); *Steyermark & Luteyn 129818* (MO, NY, VDB, VEN).

32. Xyris thysanolepis Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 17, fig. 3A–F. 1963. TYPE: Venezuela. Bolívar: rare around moist depressions and swales bordering river, scrub forest near Summit Camp, 1,925 m, central section Chimantá Massif, 2 Feb. 1955, *J. A. Steyermark & J. J. Wurdack 356* (holotype, NY; isotypes, MO, NY, US, VEN). Figure 32A–C.

A study of Venezuelan *Xyris* done in a way to reveal complexes has brought *Xyris thysanolepis*, *X. jauana*, and *X. sipapoa* into close alignment. In preparing descriptions and illustrations from type material of the three, and in studying materials collected later by myself and other collectors, I was forced to reassess taxonomic rank. *Xyris thysanolepis* and *X. sipapoa* were published in the same work and at that time were considered spatially isolated. *Xyris jauana* was considered well marked primarily on account of its connate lateral sepals, otherwise overlapping morphologically with *X. thysanolepis*. Ordinarily sepal connation, particularly high connation, is a very good character within complexes, but in this complex the character breaks down. A check of the structure shows that while lateral sepals of *X. thysanolepis* may be connate, those of *X. jauana* may be free. A check of type material of *X. sipapoa* shows that sepals range even in a single spike from connate to free. If this usually significant character difference is removed, a complex of three former species becomes a single species of two varieties, as below:

KEY TO THE VARIETIES OF *XYRIS THYSANOLEPIS*

1a. Leaf sheath bases bright to dull brown, eciliate to sparsely ciliate; apices of fertile bracts broadly rounded, the lacerate-scarious borders distinctly red; edges of leaf blades entire or inconspicuously ciliolate .... *X. thysanolepis* var. *thysanolepis* (including *X. jauana*)

1b. Leaf sheath bases lustrous deep brown or pale brown, mostly evidently ciliolate; apices of fertile bracts narrowed, somewhat keeled, the scarious borders pale or pale red-brown; edges of leaf blades densely ciliolate with fine, white hairs .... *X. thysanolepis* var. *sipapoa*

What then seems to emerge is a complex of medium- to high-elevation bog plants with scabrid, mostly unicostate scapes and lacerate-bordered, scarious-edged bracts, habitally similar, and showing a morphological affinity to *X. confusa* Smith & Downs of the Andes, possibly also to the Andean *X. andina* Malme.

Variety *thysanolepis* includes what was treated as *X. jauana*, which varies in regard to sepal connation and which (contrary to the type description) bears no evident dorsal area, only a low, short, apical carina. Variety *thysanolepis* is mostly in high areas of the Gran Sabana, Estado Bolívar, with one known outlier in Territorio Federal Amazonas (Cerro Yavi). The more slender var. *sipapoa* is apparently not rare on Cerro Sipapo, and plants answering to the type description have also been collected in Estado Bolívar (bog by rd. to Salto Aponguayo in rocky, sandy seeps, ca. 11 km SE of jct. with rd. to Kavanayen, 27 July 1983, *Kral & Gonzales 70524*, VDB, VEN).

32A. Xyris thysanolepis var. thysanolepis. Figure 32A, B.

X. jauana Lyman B. Smith & Steyerm., Bol. Soc. Venez. Ci. Nat. 132–133: 277, fig. 2a–g. 1976. TYPE: Venezuela. Bolívar: Meseta del Jaua, Cerro Jaua, selva de galeria al borde del tributario del Río Marajano, cumbre, 4°48′50″N, 64°34′10″W, 1,750–1,800 m, 22–28 Feb. 1974, *J. A. Steyermark, V. C. Espinosa & C. Brewer-Carias 109390* (holotype, VEN; isotypes, NY, US). Figure 32B.

Slender, solitary to cespitose, soft to firm-based perennial 2–10 dm high, the stem short or elongated to 6 cm, thick, the roots slender-fibrous. Leaves erect to spreading flabellately, 1–3 dm long; sheaths mostly ½ or more as long as blades, the slightly to very (orbicular) dilated base ciliate or not, tan to castaneous, shading above to pink, pale brown or stramineous, narrowing gradually into blade, keeled, the keel ciliolate or entire, the apex eligulate; blades linear, 2–5 mm wide, strongly flattened, the apex narrowly incurved-acute or acuminate, the margins usually thin, entire or ciliolate; surfaces pale green or yellow-green flecked with red, finely nerved, otherwise smooth. Scape sheaths shorter than to nearly as long as leaves, below terete and multicostate, above open, producing a short, erect, incurved-tipped, flat blade. Scapes straight or slightly flexuous, slightly twisted, subterete or oval in cross section toward apex, 1–2 mm wide, with 1, 2, (or more) costae, with 1 costa strong often making 1 edge, ciliate to densely ciliolate-scabridulous, the surfaces otherwise smooth, pale green, striate. Spikes pale red-brown, broadly ellipsoid, drying broadly obovoid, turbinate or globose, 0.7–1.3 cm long, of several spirally imbricate, firm, papillate or rarely smooth bracts with broad, scarious-lacerate, reddish or pale reddish brown borders or at least scarious-tipped; sterile bracts few, the lowest pair much smaller and narrower than the fertile bracts, keeled; fertile bracts broadly oblong to obovate, 6–8 mm long, the backs rounded or somewhat folded (inner ones increasingly folded-carinate), the apices narrowly or broadly rounded, the thin, colored borders variously lacerate and erect to squarrose. Lateral sepals free or up to ⅓ connate, subequilateral, thin, pale, lustrous reddish brown, 6–7 mm long, the apex acute, the narrow, curvate keel rusty-ciliolate to low-serrulate-lacerate from at least middle to apex. Petal blades elliptic to obovate, 4–5 mm long, yellow, the broadly to narrowly rounded apex erose. Staminodia bibrachiate, the narrow branches densely penicillate-ciliate. Anthers narrowly lance-oblong to linear-oblong, 1.5–2 mm long, deeply bifid and sagittate, on filaments ca. 1 mm long. Capsule planoconvex, broadly ellipsoid to narrowly obovoid, 3.5–4 mm long, the placentation basal, the valves without septa. Seeds numerous on elongate funicles, cylindric-fusiform, ca. 1 mm long, deep to pale amber, coarsely longitudinally anastomosing-ribbed.

Distribution. Locally abundant along streams through wet, rocky, medium- to high-elevation savanna, in Territorio Federal Amazonas and (more often) Estado Bolívar, Venezuela.

Additional specimens examined. VENEZUELA. T. F. AMAZONAS: depression on summit, Cerro Yavi, 2,200 m, 1–3 Mar. 1947, *Phelps & Hitchcock 38* (NY, VEN). 32B. Xyris thysanolepis var. **sipapoa** (Maguire & Lyman B. Smith) Kral & Lyman B. Smith, stat. nov. *X. sipapoa* Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 18, fig. 4A–F. 1963. TYPE: Venezuela. T. F. Amazonas: frequent, banks of lower Caño Negro along open savannas, alt. 1,400 m, Cerro Sipapo, 25 Dec. 1948, *B. Maguire & L. Politi 27911* (holotype, NY; isotypes, GH, NY, US).

As in the rest of the species but usually somewhat lower in stature, the leaves strongly spreading flabellately, the bases abruptly orbicular-dilated and lustrous, mostly ciliolate, the blades with a fine marginal dusting of white hairs. Spikes mostly ovoid or ellipsoid, drying obovoid, the bracts carinate toward apex, the apex narrowed and folded, the margins pale-lacerate-scarious. Lateral sepals, sometimes in same spike, free to ⅓ connate.

Distribution. Wet to rather dry, medium- to high-elevation rocky savanna, Cerro Sipapo and environs, Territorio Federal Amazonas, Venezuela, and Gran Sabana, Estado Bolívar, Venezuela.

Additional specimens examined. VENEZUELA. T. F. AMAZONAS: Cerro Sipapo: frequent in bog-savanna, terraces S of Caño Negro at 1,600 m, 6 Jan. 1949, *Maguire & Politi 28194* (NY, US); frequent in savanna vic. Campo Grande, 1,500 m, 15 Dec. 1948, *Maguire & Politi 27684* (F, GH, NY, US); bog by rd. to Salto Aponguayo in rocky, sandy seeps, ca. 11 km SE of jct. with rd. to Kavanayen, 27 July 1983, *Kral 70524* (VDB, VEN, and to be distributed); savanna, ca. 1,200 m, Torom-meru, NW of Parupa, 14 Dec. 1984, *Kral 72063* (MYF, VDB, VEN, and to be distributed).

33. Xyris concinna N. E. Br., Trans. Linn. Soc. London, Bot. II(6): 68. 1901. TYPE: Venezuela. Bolívar: summit, Mt. Roraima, 8,600 ft., *McConnell & Quelch 496* (lectotype, K). Figure 33.

Hard-based, densely cespitose perennial 0.8–2 dm high, the stem contracted, to 1.5 cm long. Leaves spreading flabellately, 5–10 cm long; sheaths about as long as blades, entire (rarely with a few brown cilia at base), cochleariform toward base, thence contracted abruptly, ciliate-keeled, gradually narrowing to blade, eligulate; blades flat, narrowly linear, 1.5–2.5 mm wide, gradually tapering distally to an attenuate, terete, or narrowly acute, flattened apex, the tip with a tuft or short fringe of stiff, pale hairs, the margins minutely scabrociliate or papillose, the surface finely nerved, green or maroon, smooth. Scape sheath slightly shorter than leaves, loose, scabrid-keeled, short-bladed. Scapes slenderly linear, stiff, ca. 1 mm thick, oval or terete in cross section, unicostate, also finely fluted, the costa smooth, papillose or scabrociliolate. Spikes ovoid, 5–7 mm long, obovoid in fruit, reddish brown, of several spirally imbricate bracts without dorsal area and with broad, pale laceroscarious borders; sterile bracts 2–4, ovate, keeled, grading larger into fertile bracts, these few, lance-ovate or oblong, acute to acuminate, slightly to very keeled, 6–7 mm long, the backs papillose. Lateral sepals free, narrowly oblanceolate, equilateral, ca. 6 mm long, narrowly acute, the sides dull, pale brown, the keel narrow, firm, dark brown, entire or (usually) ciliate from middle to apex. Petal blades ca. 5 mm long, yellow, elliptic, subacute, wavy-margined. Staminodia bibrachiate, the branches flattened, the hairs penicillate but often multiseriate in narrow sheets. Anthers oblong, ca. 2 mm long, apically short-bifid, basally auriculate, on filaments ca. 1 mm long. Capsule oblong-ellipsoid, ca. 3 mm long, the valves eseptate, the placentation basal, funicles long. Seeds fusiform, ca. 1 mm long, red-brown, translucent, finely longitudinally ribbed.

Distribution. Infrequent in wet, high, sandstone savanna, the higher tepuis of the Gran Sabana, Estado Bolívar, Venezuela.

Additional specimens examined. VENEZUELA. BOLÍVAR: Matahui-tepui, 2,700–3,000 m, 22 Aug. 1982, *A. Castillo 2282* (UCV, VDB); Kukenán-tepui, sector mas septentrional, algo separado del macizo principal,

Venezuela inmediata al sur del hito que marca los limites con Guyana, Brasil y Venezuela, 2,750–2,800 m, 26 Aug.–2 Sep. 1976, *Steyermark et al. 112566* (MO, NY, US, VEN), *112648* (K, MO, NY, US, VEN).

The affinities of this low plant of high-altitude tepuis are definitely with *X. hymenachne* C. Martius, which is frequent in the surrounding lower-elevation savannas of the Gran Sabana. However, the leaves are harder, their bases more orbicularly dilated; the spike bracts are more folded and more acuminate; and the seeds are somewhat longer.

34. Xyris hymenachne C. Martius, Flora 24(2): 55. 1841. TYPE: Brazil: "Prov. Minarum, Mart. Hb. 872" (lectotype, BR; isolectotypes, L, M; phototypes, F, NY). Figure 34.

X. arescens Kunth, Enum. Pl. 4: 3. 1843.
X. submontana Gleason, Bull. Torrey Bot. Club 56: 393. 1929. TYPE: Brazil. Río Branco: Mt. Roraima, Philipp Swamp, 5,100–5,200 ft., 11 Nov. 1927, *G. H. H. Tate 334* (K).

Solitary or cespitose, often bulbous-based, slender perennial mostly 2–6 dm high, the stems contracted. Principal leaves ascending or spreading flabellately, 0.5–2 dm long; sheaths entire or sparsely brown ciliate at dilated base, dull brown or stramineous, at very base sometimes castaneous and abruptly orbicular-dilated, ½ or more as long as blades, tapering above gradually to blade, usually eligulate, the blades flat, straight or twisted, strongly compressed, 1.5–4 mm wide, acute to long-acuminate, the margins with edges thin or slightly thickened, smooth, papillate or ciliolate, the surface smooth to papillose-rugulose, finely nerved, dull green. Scape sheaths slightly to much shorter than leaves, tubular and sharply costate below, above open, strongly keeled, short-bladed. Scapes narrowly lineal, twisted, sometimes flexuous, distally subterete, 0.6–0.7 mm thick, mostly unicostate (sometimes multicostate), the costae low but distinct, smooth to papillate or ciliolate. Spikes obovoid to subglobose, 5–8 mm long, attenuate, dull pale red-brown, of several loosely spirally imbricate bracts, these rounded-convex, often medially low-ribbed, without distinct dorsal area, with erect, broad, pale, scarious-lacerate borders; sterile bracts slightly smaller than fertile bracts but lowest over ½ as long as spike, ecarinate, the inner sterile and lower fertile bracts obovate or broadly oblong, 7–8 mm long, the backs often papillate. Lateral sepals free, very inequilateral, oblong-curvate, 4–6 mm long, obtuse, the darker keel fimbriociliate or ciliate at least from middle to apex. Petal blades obovate, ca. 5 mm long, the apex narrowly rounded, the margins wavy. Staminodia bibrachiate, the broad, thin branches each tipped by a few penicillate hairs. Anthers lanceolaate, ca. 1.5 mm long, deeply bifid and sagittate, on filaments ca. 0.5 mm long. Capsule ellipsoid to broadly obovoid, ca. 4 mm long, the valves without septa, the placentation basal. Seeds cylindric-fusiform or narrowly ellipsoid, on long funicles, 0.6–0.7 mm long, apiculate, amber, longitudinally conspicuously multiribbed.

Distribution. Moist to wet, medium- to high-elevation savanna, South America east of the Andes, in northern South America, Colombia east into Guyana.

Selected Venezuelan specimens. T. F. AMAZONAS: Dto. 1,800 m, 7 May 1964, *Steyermark 93465* (K, NY, VDB, US).

This species, while very highly variable in stature and leaf, is distinguished primarily by the very broad, pale, scarious bract borders and the absence of a dorsal area. The leaf bases range from strongly dilated to indistinctly so, and the numbers of flowers and bracts in a spike vary widely. A perfect range of intermediates connects this to *X. submontana* Gleason, a not uncommon morphology in the Gran Sabana of Estado Bolívar, Venezuela. This last was supposed to be distinguishable on a basis of its comparative smoothness, the depressed-globose spikes, and the granular-papillose spike bracts. The species unfolds its blooms in morning. It is one of the weedier species, often coming in abundantly on moist to wet, nearly totally mineral substrates.

35. Xyris decussata Gleason, Bull. Torrey Bot. Club 56: 392. 1929. TYPE: Venezuela. Bolívar: Mt. Roraima, summit, 26 Nov. 1927, *G. H. H. Tate 427* (lectotype, NY). Figure 35.

Robust but low, cespitose, thick-based perennial 1.5–4.3 dm high, the stems stout and contracted or to 5(–15) cm long, ascending. Leaves rigid, spreading flabellately, 1–2 dm long; sheaths firm, entire, about as long as blades, castaneous, tapering gradually from broad base, apically with a short, often salient, small, narrowly triangular ligule; blades broadly linear, flat, 3–5 mm wide, abruptly broadly rounded at apex, the margin completely and densely rusty ciliate with hairs arising from a dark brown, incrassate border, the surfaces green, finely nerved, smooth. Scape sheaths shorter than leaves, tubular-carinate, the keel ciliate, alate, terminating in a very short, blunt, ciliate blade. Scapes straight, slightly twisted, distally flattened, 2–3 mm wide, bicostate, the costae densely rusty ciliate. Spikes subglobose or depressed-globose to obovoid, ca. 1 cm long, dark brown, of many, firm but loosely appressed bracts without distinct dorsal areas, usually in nearly vertical ranks; sterile bracts several, the lower ones triangular, much shorter than the fertile bracts and grading gradually into them, the fertile bracts ovate or broadly oblong, ca. 6 mm long, apically broadly to narrowly rounded and subentire, the backs ecarinate, slightly convex-rounded. Lateral sepals free, subequilateral, ca. 6 mm long, linear-oblanceolate, obtuse or broadly acute, dark brown, the firm dark keel entire or ciliate or ciliato-lacerate toward apex. Petal blades elliptic, ca. 5 mm long, yellow, the apex broadly and bluntly acute or narrowly rounded, the margin wavy. Staminodia 4-brachiate, the branches long-penicillate. Anthers oblong, 1.5–1.7 mm long, cleft to below the middle, sagittate, on filaments nearly 2 mm long. Capsules ellipsoid, 4–5 mm long, placentation basal-central, the valves with low septa. Seeds numerous, narrowly cylindric-oblanciform, ca. 1.5–1.7 mm long, including a pale, narrowly conic apiculus ca. 0.3 mm long (loose outer integument), the body pale reddish brown, translucent, finely but distinctly longitudinally ribbed.

Distribution. High-elevation tepuis, in boggy savanna, over 2,000 meters, southeastern and southern Estado Bolívar, Venezuela.

Additional specimens examined. VENEZUELA. glance reveals the distinctive dense fringe of rust-colored hairs marginally on the leaf blade. Taller material with more lustrous bracts and longer leaves but having such ciliation has been obtained from Chimantá, Ptari-tepui, and Ilu-tepui. This material appears to be from populations "influenced" by other species such as *X. albescens* Steyerm., or is identified as *X. melanovaginata* Kral & Smith.

36. Xyris albescens Steyerm., Fieldiana Bot. 28(1): 105, fig. 16a, b. 1951. TYPE: Venezuela. Bolívar: Ptari-tepui, *Bonnetia roraimae* forest on southwest-facing shoulder, 2,000–2,200 m, 2 Nov. 1944, *J. A. Steyermark 59734* (holotype, F; isotypes, GH, NY, US). Figure 36.

Robust, cespitose perennial (3.5–)4–10 cm high, the stems short, stout, ascending. Leaves elongate-linear, 2–6 dm long, mostly spreading or ascending; sheaths at least ½ as long as blades, keeled, firm, lustrous, deep red-brown or castaneous, the margins entire, tapering evenly from base to a small, indistinct ligule; blades evenly linear, flat and strongly flattened, pale green, (3–)5–6 mm wide, with apices asymmetrically narrowly acute or (in type) incurved and narrowly rounded, the edges densely white- (rarely pale red-brown-) ciliate, sometimes with a submarginal brown or red border. Scape sheaths much shorter than leaves, short- to elongate-bladed, the blades as in leaves. Scape pale green, distally broad and flattened (2–)2.5–3 mm wide, the edges densely pale ciliate as in leaf blades. Spike broadly ovoid, globose or hemispheric, (1–)1.5 cm long, blunt, rich, lustrous brown or castaneous, multiflowered; sterile bracts very many, triangular-ovate, the lowermost small, often squarrose, grading larger into the fertile bracts, these narrowly ovate to oblong, firm, 6–9 mm long, apically rounded, entire, sometimes somewhat cucullate, the dorsal area absent or inconspicuous, the backs rounded-convex, ecarinate. Lateral sepals equilateral, oblong-linear to linear-oblanceolate, mostly acute, 6–7 mm long, pale except for dark, scabro-ciliate to villosulous keel. Petal blades narrowly obovate, ca. 6–7 mm long, yellow, apically broadly rounded, erose. Staminodia bibrachiate, the slender branches long-penicillate from base to tip. Anthers lanceolate, ca. 2.5 mm long, apically deeply retuse, basally sagittate, on filaments ca. 1 mm long. Capsule narrowly ellipsoid, ca. 5 mm long, the valves deeply septate at base, placentation appearing central but axile at base. Seeds narrowly fusiform-cylindric, 2–3 mm long, pale brown, including a white, triangular-linear scale 0.5–0.7 mm long, the fruit body spirally coarsely parallel-ribbed.

Distribution. Moist to rather dry rocky savanna, high elevations of tepuis, southern Estado Bolívar, Venezuela.

Additional specimens examined. VENEZUELA. BOLÍVAR: Cima del Roraima, Jan. 1977, *Delascio & Brewer-Carias 4802* (VEN); en el paso entre Ptari-tepui y Sororopan-tepui, al N de Kavanayen, 1,370 m, 28 June 1983, *Huber & Alarcon 7725* (NY); Cumbre del Yuruani-tepui, ca. 12 km al NNE del Kukenan-tepui, 29 Feb. 1984, *Huber 9088* (MYF, VDB); Cumbre del Yuruani-tepui, al NNW del Cerro Kukenan, 27 Apr. 1984, *Huber 9414* (MYF, VDB); Kukenan-tepui, cumbre del sector mas septentrional, algo separado del macizo principal, 2,500 m, 28 Apr. 1984, *Huber 9446* (MYF, VDB); Ptari-tepui, vic. "Cave Rock" Camp below southern face of mountain, 1,600–2,000 m, 14–19 Aug. 1970, *Moore et al. 9817* (NY, US); Mt. Roraima, escarpment, 7,600 ft., 1 Nov. 1973, *R. Persaud 149* (K); vic. rd. campamento 150 at km 150 in valley of savanna of Río Urarama below Urarama-tepui, NE of Luepa, 1,220 m, 24–25 Apr. 1960, *Steyermark & Nilsson 641* (NY, VEN); Ptari-tepui, dry sandy and rocky sandstone exposures on plateau portion of southeast-facing slopes, 1,600 m, 1 Nov. 1944, *Steyermark 59683* (F, NY); Chimantá Massif, elfin forest on plateau of southeast-facing upper shoulder of Apacará-tepui, 2,000 m, 19 June 1953, *Steyermark 75757* (F, NY, VEN); Meseta del Jaua, el Este del trib. del Río Marajano, 1,800 m, 26 Feb. 1974, *Steyermark et al. 109558* (F, K, US, VEN)—this differs from all other specimens in its longer spikes to ca. 2 cm; Macizo del Chimantá, altiplanicie en la base meridional de los farallones superiores del Apacará-tepui, sector norte del Macizo, 2,200 m, *Steyermark et al. 128393* (VEN, VDB).

Material of this from Guyana, Upper Mazaruni District, north slope of Mt. Roraima, alt. 2,000–2,300 m, 16 Feb. 1985, *J. Renz 14266*, was lent by U. Other material with affinities, lent by NY, from T. F. Amazonas of Venezuela is Cerro Marahuaca, 2,500 m, 16 Feb. 1981, *Steyermark 124439*.

37. Xyris fuliginea Kral & Lyman B. Smith, sp. nov. TYPE: Venezuela. T. F. Amazonas: Dept. Atabapo, Cerro Marahuaca—FHUIF Cumbre, zona boscosa en la falda este del riachuelo, 2,480–2,500 m, 3°35′N, 65°20′W, 1–2 Feb. 1982, *J. Steyermark, M. Guariglia, N. Holmgren, J. Luteyn & S. Mori 125978* (holotype, VEN; isotype, VDB). Figure 37.

Planta perennis caespitosa, rigida, 3–5.6 dm alta. Radices graciles. Caules breves aut usque ad 5 cm longi. Folia principalia vulgo flabellate expansa, 1.5–3 dm longa, vaginis scaporum parum longiora; laminae vaginas aequantes vel eis leviter aut 1–2-plo breviores, linearotriangulatae, planae, compressae, 3–5 mm latae, olivaceae, glabrae; apices gradatim contracti, acuti, leviter incrassati; margines tenues, subtiliter dense albociliati vel albociliolati; vaginae carinatae, atrocastaneae, nitidae, integrae, ad basin dilatae, in laminas gradatim decrescentes, eligulatae. Vaginae scaporum prope basem castaneae, teretes, tortae, multicostatae, apicem versus apertae, carinatae, laminis brevibus. Scapi apicem versus ancipiti, ca. 2–2.5 mm lati, albociliati, olivacei. Spicae multiflorae, obovoideae, 1–1.5 cm longae, obtusae. Bracteae erectae, subdecussatae vel laxe spiraliter imbricatae, firmae, ecarinatae, fuligineae, sine area dorsali, integrae tum laceratae; bracteae steriles plures, triangulato-ovatae, pari infimo valde carinato, carinis ciliatis, anguste acuto, ca. 3-plo spica brevius, paribus intimis fertilibus breviores, in fertiles gradatim transientes; bracteae fertiles latae oblongae vel oblongo-lanceolatae, 7–9 mm longae, late acutae vel anguste rotundatae. Sepala lateralia libera, subaequilatera, ca. 7–8 mm longa, atroferruginea, leviter curvata, late acuta; ala carinali lata, a medio ad apicem rufociliata. Laminae petalorum late obovatae, 5.5–6 mm longae, luteolae, apice late rotundatae, erosae. Staminodia bibrachiata, brachiis longipenicillatis. Antherae lanceolatae, ca. 2 mm longae, profunde emarginatae et sagittatae; filiis latis, ca. 1 mm longis. Capsula ellipsoidea, 5 mm longa, placentae centralis sed valvis capsulae ad basim profunde septatis, sic placentio subaxilis. Semina numerosa, anguste ellipsoidea vel anguste claviformes, ca. 1.5 mm longa, longitudine prominente spiraliter multicostata, conicam pallidam squamellam ca. 0.5 mm longam includens.

Stiff tufted perennial 3–5.5 dm high. Roots slender, fibrous. Stems short or up to 5 cm long. Principal foliage leaves commonly spreading flabellately, 1.5–3 dm long, slightly longer than the scape sheaths; blades equal to sheaths or to ½–⅔ as long, linear-triangular, level, flattened, 3–5 mm wide, olivaceous, smooth; apices gradually narrowed, acute, slightly thickened at tips; margins thin, finely densely white ciliolate or white ciliate; sheaths carinate, deep-castaneous, shining, entire, dilated at base, narrowing gradually into blades, eligulate. Sheaths of scapes castaneous toward base, terete, twisted, multicostate, opening toward apex, carinate, with short blades. Scape ancipital toward apex, ca. 2–2.5 mm wide, white-ciliate, olivaceous. Spikes multiflorous, obovoid, 1–1.5 cm long, obtuse. Bracts erect, subdecussate to loosely spirally imbricate, firm, ecarinate, fuligineous (charcoal brown), without dorsal area, entire, lacerate; sterile bracts several, triangular-ovate, the lowest pair strongly carinate, carinae ciliate, narrowly acute, ca. 3 times shorter than the spike, the inner pairs shorter than the fertile pairs, grading into them; fertile bracts broadly oblong to oblong-lanceolate, 7–9 mm long, broadly acute to narrowly rounded. Lateral sepals free, subequilateral, ca. 7–8 mm long, deep red-brown, slightly curvate, broadly acute; keel broad, red ciliate from middle to apex. Petal blades broadly obovate, 5.5–6 mm long, yellow, broadly rounded apically, erose. Staminodia bibrachiate, the branches long-penicillate. Anthers lanceolate, ca. 2 mm long, deeply emarginate and sagittate on broad filaments ca. 1 mm long. Capsule ellipsoid, 5 mm long, the placentae central but the capsule valves deeply septate toward base, thus the placentation subaxile. Seeds numerous, narrowly ellipsoid to narrowly claviform, ca. 1.5 mm long, longitudinally spirally prominently ribbed, and including a pale, conical scale ca. 0.5 mm long.

Distribution. Confined to the Cerro Marahuaca, wet high altitude, rocky savanna, elevation over 2,000 m, T. F. Amazonas, Venezuela.

Paratypes. Summit, northeast, headwaters of small stream, 2,500 m, 16 Feb. 1981, *Steyermark et al. 124439* (MO, NY, VDB, VEN); same locality, date, and collectors as type, *Steyermark et al. 125991, 125993* (VEN), *126018* (VDB, VEN); extremo noreste, 3°50′N, 65°28′W, 2,580–2,600 m, 30 Mar.–1 Apr. 1983, *Steyermark & Delascio 129224* (VDB, VEN); cumbre parte central de la Meseta Sur-Este, a lo largo de la Quebrada Yekuana, afluente del Río Negro, 2,560 m, 10–12 Oct. 1983, *Steyermark 129470* (VDB, VEN).

This species has been more of a problem than most in that it appears to be a meld of

three other high-country species: *X. albescens* (ancipital scape, white-ciliate leaf and scape edges), *X. culmenicola* (obovoid, sooty brown spikes, ciliate, linear-triangular leaf blades), and *X. lugubris* (similar bract, spike and leaf characters). Yet the uniformity of the now rather large set of samples from Cerro Marahuaca collected by Steyermark and oth-

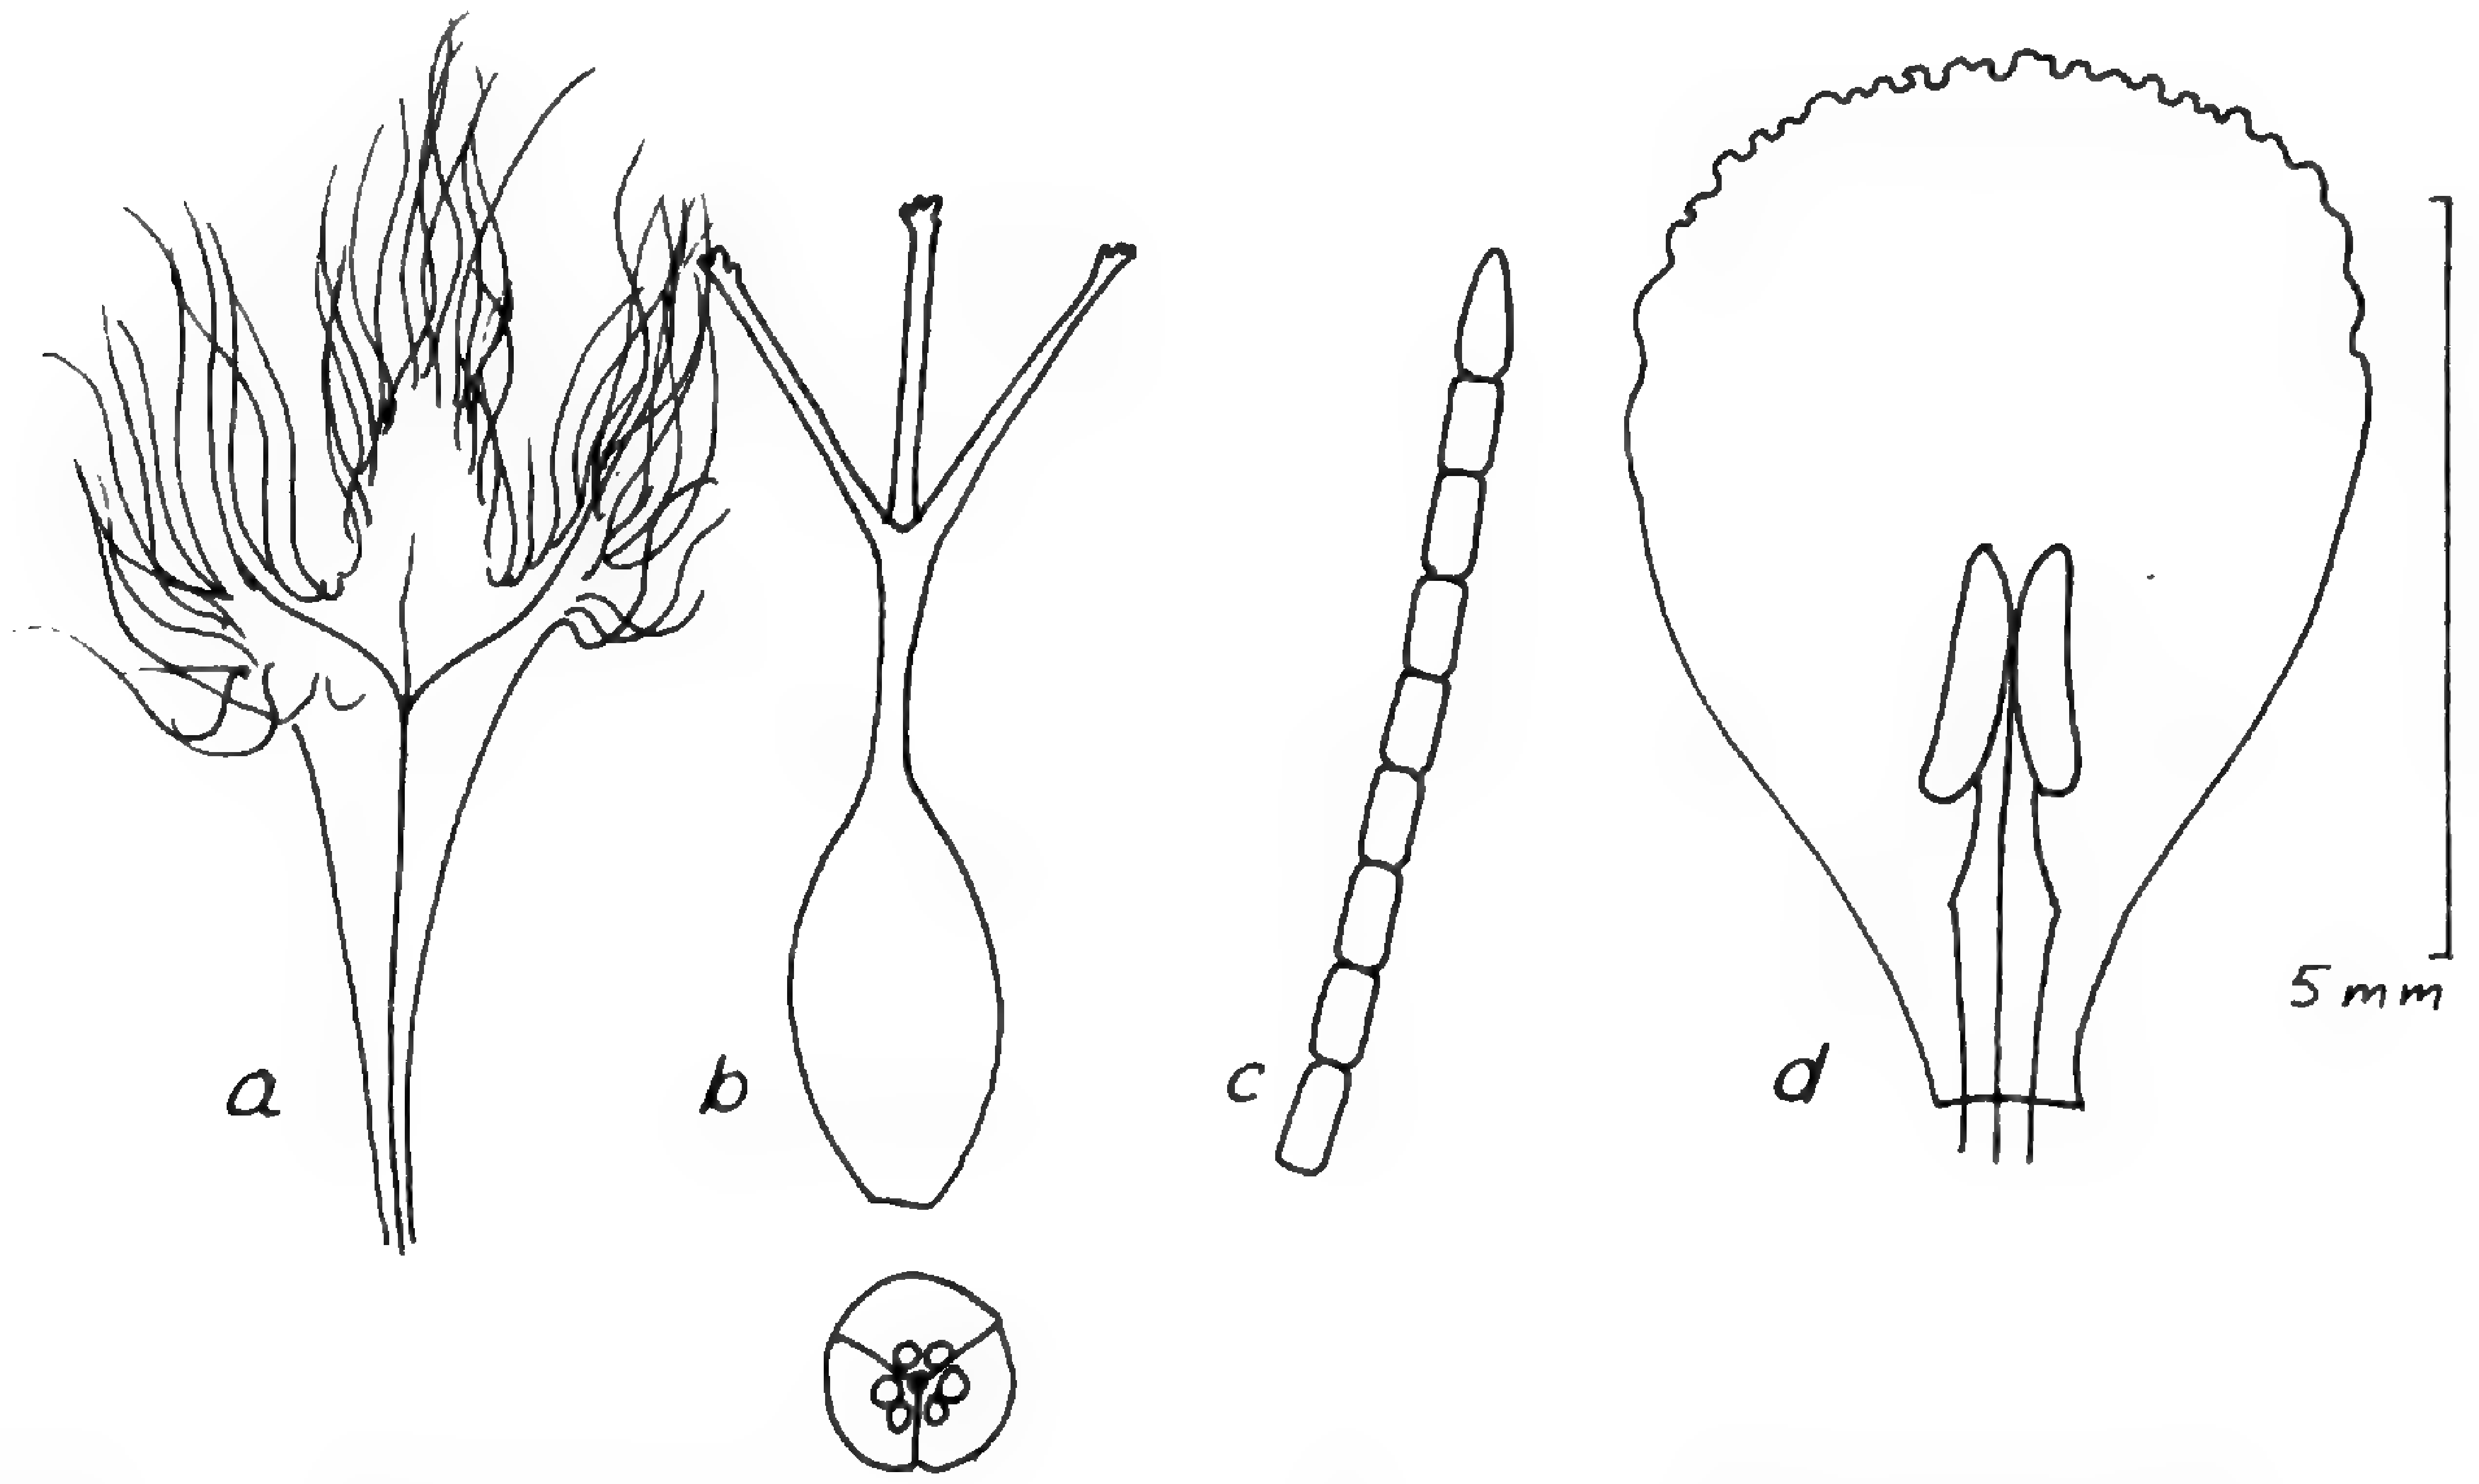

FIGURE 38B. Xyris ptariana *(from the type).—a. Staminode.—b. Ovary and style branches; cross section below.—c. Enlarged staminodial beard hair tip.—d. Petal blade, stamen.*

ers makes description of this cryptic morphology necessary.

38. Xyris ptariana Steyerm., Fieldiana, Bot. 28(1): 110, fig. 16I, J. 1951. TYPE: Venezuela. Bolívar: forming dense tufts, wet bluffs, 2,000 m, Ptari-tepui, Gran Sabana, *Steyermark 59919* (holotype, F; isotypes, F, NY, US, VEN). Figure 38A, B.

Robust, densely cespitose, usually smooth, perennial to 1 m high, the stems elongate, branching from the base and rebranching, the ultimate branches forming frondlike plates of leaves. Leaves spreading-ascending, 1.5–3.5 dm long; sheaths mostly deep red-brown, sometimes pale brown, nearly as long as blades or longer, entire-edged, strongly keeled, narrowing evenly from the dilated base to the blades, there producing a triangular, scarious, spreading or recurved-tipped ligule to 3 mm long; blades flat, straight, linear-ensiform, (3–)3.5–12 mm wide, the apex incurved-acute, flat, the margins usually entire (on Abacapa-tepui densely red ciliate) or papillose-tuberculate, the base narrowed ca. 2–3 cm from ligule on ventral side, the surfaces deep green, strongly multinerved. Scape sheaths shorter than leaves, proximally tubular and multicostate, lustrous brown, distally opening, strongly keeled, with a short blade. Scapes slender but stiff, straight or slightly flexuous and slightly twisted, distally flattened or in cross section narrowly ovate or elliptic, sometimes ancipital, 1.5–3 mm wide, the costa(e) 1–2, usually making up edges, smooth to tuberculate-scabrid or (on Abaca-tepui) red ciliate. Spikes ellipsoid to broadly obovoid, 1–1.5(–2) cm long, blunt, pale brown or olivaceous brown to reddish brown, of many spirally imbricate, thinnish bracts without dorsal areas, the lowest sterile bracts much smaller than the fertile bracts, ovate, obtuse-angled to acute, slightly keeled, grading into the larger, flatter fertile bracts, these obovate-oblong, 0.8–1 cm long, the apex broadly rounded, entire to erose, the backs but slightly convex, toward apex often with a low, lustrous costa. Lateral sepals free, subinequilateral, oblanceolate or spathulate, 6–8 mm long, blunt, thin, with a broad, darker, entire to ciliolate keel. Petal blades broadly obovate to suborbicular, 6–7 mm long, yellow, the broadly rounded apex erose. Staminodia clavate-trilobate when present (in the type), distally densely long-penicillate. Anthers lance-oblong, 1–2 mm long, deeply bifid and sagittate, on filaments 1–1.5 mm long. Capsule ellipsoid, ca. 6–7 mm long, the placentation appearing free-central but the 3 valves with strong, deep septa reaching the capsule axis, thus placentation actually axile. Seeds very numerous, asymmetrically ellipsoid, 1–1.5 mm long, pale amber with a pale, narrowly conic apical scale, longitudinally finely but distinctly ribbed.

Distribution. Boggy, seepy, rocky areas of savanna, at elevations of 1,300 meters or more, Territorio Federal Amazonas and Estado Bolívar, Venezuela.

Additional specimens examined. VENEZUELA. T. F. AMAZONAS: Cerro Sipapo (Paraque) common in bogs about pool, Caño Negro savannas at 1,400 m, 15 Dec. 1948, *Maguire & Politi 27703* (GH, K, US, VEN)—very large material as to plant height, leaf width, spike, etc.; summit, Cerro Marahuaca, 2,685 m, 15 Jan. 1981, *Maguire 65634* (NY); Cerro Sipapo, wet cliffs below escarpment, 1,300 m, frequent, Dec. 1948, *Maguire & Politi 27498* (F, NY, US); Cerro Paraque, 1,800 m, Feb. 1946, *Phelps 47* (US); summit of Cerro Duida, on high moist ridgetop, 1,820–2,075 m, 4 Sep. 1944, *Steyermark 58350* (F); Cumbre del Cerro Autana: sabana y afloramientos expuestos, 1,230–1,240 m, 20–22 Sep. 1971, *Steyermark 105124* (F, MO, US); summit of Mount Duida, 5,500–6,000 ft., 26 Nov.–16 Dec. 1927 *G. H. H. Tate 417* (NY)—this with scape broader than norm. BOLÍVAR: Cerro Apacara, 2,300 m, Río Caroni, 11 Nov. 1946, *F. Cardona 1942* (US); Cumbre del Aprada-tepui, sector sur, ubicado ca. 30 km al E de Uriman, 2,500 m, 30 June 1984, *Huber 9565* (MYF, VDB); Chimantá Massif, NW part of summit of Abacapa-tepui, above first line of sandstone bluffs, 2,125–2,300 m, 14 Apr. 1953, *Steyermark 74998*—this material with red-bordered scapes and leaf blades (F, NY, VEN).

This species may be a complex of varieties held together by a combination of elongate and elongate-branched axes producing frondlike plates of leaves, by the curious ligule, and by the distinctive, indented ventral margin of leaf blade just above the sheath. At one end of the variation is the type, narrowest example of *X. ptariana* in leaf and scape, and which differs the least from *X. witsenioides* F. Oliver. At the other extreme, to the far west in Territorio Federal Amazonas, is *X. xiphophylla* Maguire & Lyman B. Smith. Several summit elevations in Estado Bolívar and some in Amazonas are now known to have this taxon, and populations on each are distinguishable, yet not sufficiently to allow a specific treatment.

39. Xyris witsenioides F. Oliver, Thurn, Timehri 5: 207. 1886; Trans. Linn. Soc. II. 2: 285, pl. 50, figs. 9–15. TYPE: "British Guiana, Roraima, ledge 7,300 ft.," *Everard F. im Thurn*, 14 Dec. 1884 (lectotype, K). Figure 39A, B.

Densely cespitose, multibranched perennial (1.2–)2–6 dm tall, the primary branches elongate, ascending, rebranching to form frondlike plates of leaves, the whole producing large dome-shaped masses with bases buried in substrate. Leaves ascending, rarely spreading, 5–20 cm long; sheaths eciliate, the bases tightly imbricate, distichous on the elongate stems, castaneous or light brown, often persistent long after blades, fully as long as blades, strongly keeled, narrowing gradually to scarious, triangular, erect ligules 1–2 mm long; blades gladiate-linear, flattened, straight or falciform, 1–3(–4) mm wide, gradually narrowing from just below middle to apex, there incurved-acute or erect-acute, slightly thickened; margins thin, smooth or scaberulous-papillate, rarely ciliolate; surfaces yellow-green, smooth, finely but evidently multinerved. Scape sheaths shorter than leaves, closed at base, ciliate-keeled, multicostate, above with short, erect, ciliate blades. Scapes straight or flexuous, distally subterete to slightly compressed and oval or narrowly oblong-elliptic in cross section, 0.7–1 mm wide, ecostate or 1(–2 or more) costate, the costae smooth, scaberulous or rarely ciliolate, the surfaces otherwise smooth. Spikes ellipsoid to obovoid, drying broader, 0.7–1.4 cm long, olive-brown or red-brown, of loosely spirally imbricate thin bracts without evident dorsal areas; sterile bracts several, the lowest much smaller and narrower than the fertile bracts, these oblong to obovate, shallowly convex, low-carinate toward apex, 5–7 mm long, rounded, entire, aging lacerate. Lateral sepals free, subequilateral, ca. 5–7 mm long, oblong-curvate, obtuse, the broad thin keel subentire to ciliate, aging lacerate. Petal blades broadly obovate to suborbicular, yellow, 5–6 mm long, the broad, shallowly rounded apex erose-denticulate to nearly entire. Staminodia distally above a short geniculation producing a single,

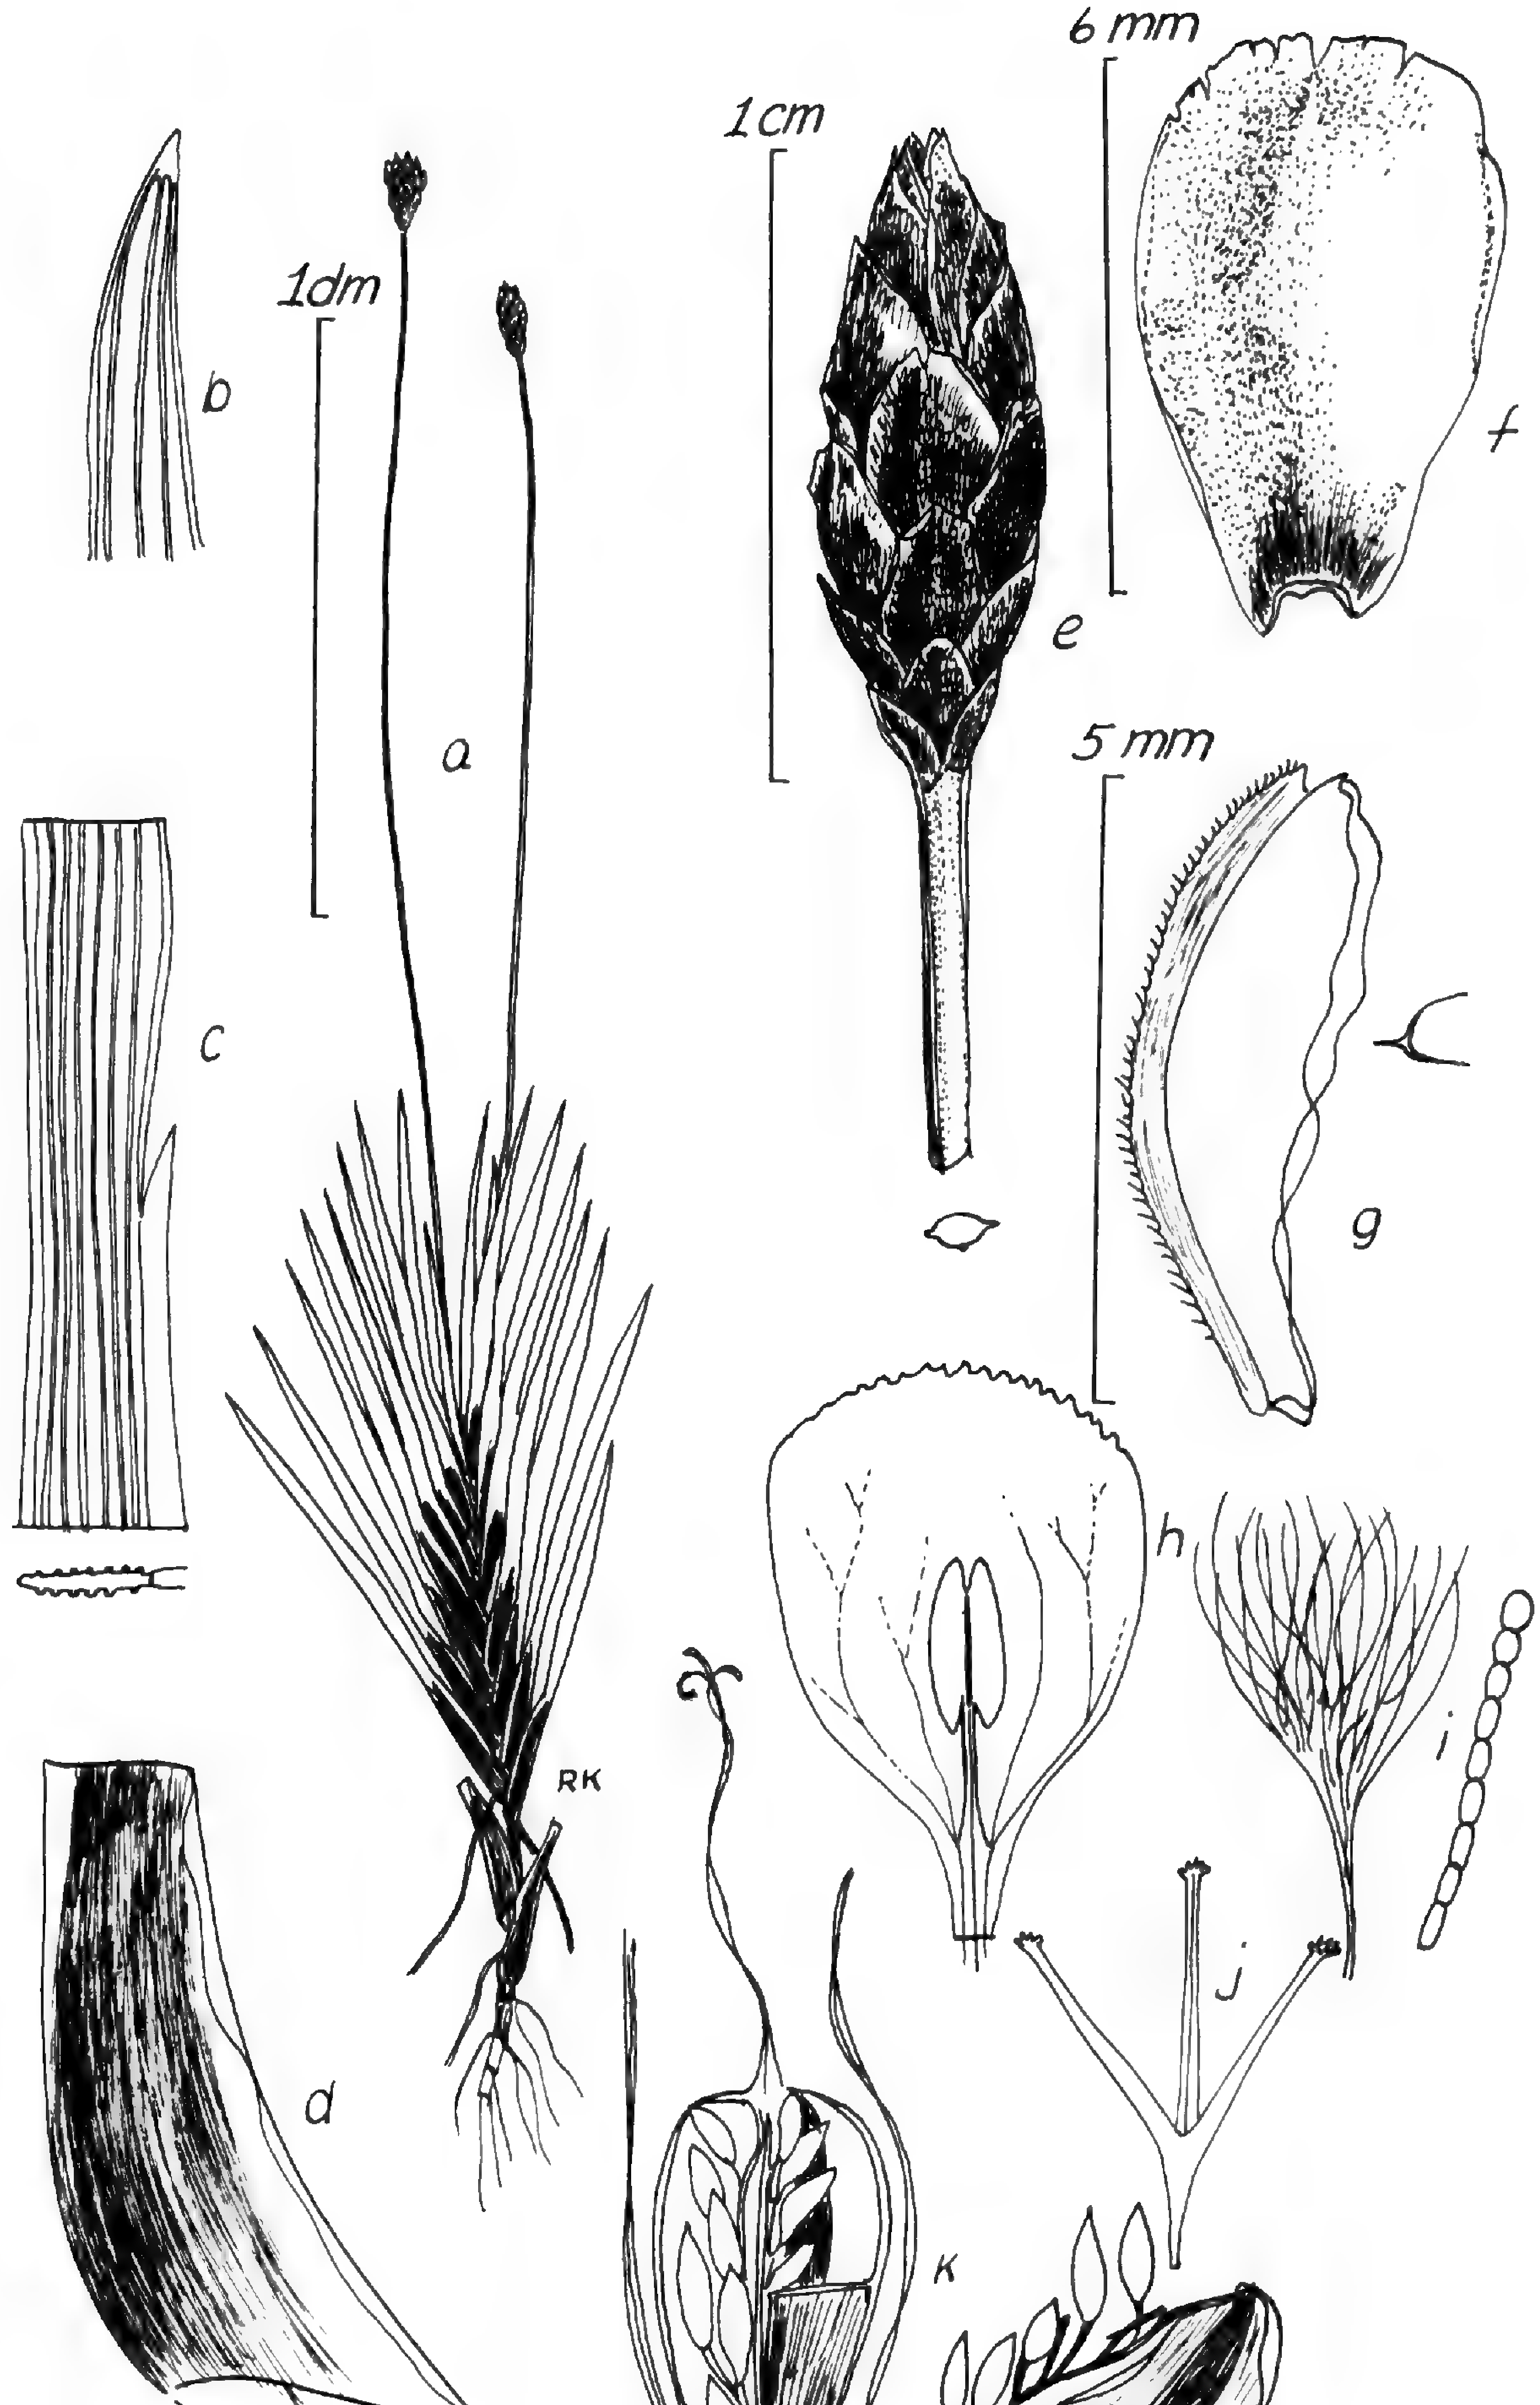

FIGURE 39A. Xyris witsenioides (Kral 70395).—*a. Habit sketch.—b. Leaf apex.—c. Leaf blade-sheath junction.—d. Leaf base.—e. Spike, upper part of scape, cross section of scape.—f. Fertile bract.—g. Seed.*

densely penicillate pubescent blade. Anthers oblong, 1.5–1.7 mm long, deeply bifid and sagittate, on filaments ca. 1 mm long. Capsules narrowly obovoid, 3.5–4 mm long, the valves with complete septa, at fruiting maturity with placentae separating from each other except at base and apex and from the septa. Seeds fusiform, ca. 1–1.3 mm long, deep to pale amber, finely longitudinally ribbed, the fine ribs overlain by a coarser, broader, subanastomosing ribbing.

Distribution. Steep bluffs and rocky wet savanna, summits of tepuis, southern Territorio Federal Amazonas and Estado Bolívar in Venezuela, east to the boundary of Venezuela with Brazil and Guyana at the type locality: Roraima.

Additional specimens examined. BRAZIL: Roraima, Dec. 1909, *E. Ule 8547* (L). GUYANA: Mt. The above citations, while far from complete, help illustrate the considerable variation in habit, leaf, and spike characters displayed sometimes even on the same tepui. This is perhaps one of the most distinctive morphologies in the genus, individual plants forming enormous dome-shaped clumps of foliage from which the slender scapes stand out like long pins from a pincushion. Out of so many collections, some represented by many duplicates, few capsules with full seed can be found, thus this species appears to be one of the poorest seed setters in *Xyris*. The question then arises as to why it is so widespread and seemingly successful.

40. Xyris xiphophylla Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 20–21, fig. 6A–E. 1963. TYPE: Venezuela. T. F. Amazonas: abundant in wet escarpment savanna, 4–8 km south of Cumbre Camp, 1,850–1,900 m, Cerro de La Neblina, Río Yatua, 15 Jan. 1954, *B. Maguire, J. J. Wurdack & G. S. Bunting 37312* (holotype, NY; isotypes, US, VEN). Figure 40.

Robust, densely cespitose, smooth perennial 5–8 dm high, the stems short and stout or up to 5 or 6 cm long; sheaths eciliate, as long as blades or longer, with broad, dark reddish brown or castaneous bases, gradually narrowing to blades and with a triangular erect or divaricate ligule to ca. 2–3 mm long; blades straight, strongly flattened, narrowly lance-linear, 5–10 mm wide, broadening just above ligule, then narrowing evenly to an acute, erect or slightly falcate apex, the tip slightly thickened; margins smooth, edges thin, producing a narrow, subcartilaginous border; surfaces deep green, smooth, with numerous low, wide nerves. Scape sheaths shorter than most leaves, deep brown, multicostate, carinate at base, opening and producing a short blade above. Scapes somewhat flattened distally (narrowly elliptic or ovate in cross section), sometimes slightly ancipital, 2–3 mm wide, the edges blunt, the surfaces smooth, sometimes striate. Spikes narrowly cylindric-obovoid, to ca. 2 cm long, the base acute to attenuate, the apex blunt, the inflorescence of many, loosely imbricate but firm, dark brown or pale brown, dull bracts in nearly vertical rows and without dorsal areas, the sterile bracts much smaller, narrower than the fertile bracts and grading into them, the fertile bracts oblong, 10–15 mm long, apically narrowly rounded, with a short, subapical, glossy carina or apiculus, the margins entire, aging lacerate. Lateral sepals free, subequilateral, lineal, 10–12 mm long, acute, the narrow, dark keel entire or papillate toward apex. Petal blades broadly obovate, 6–7 mm long, yellow, the shallowly rounded apex crenulate. Staminodia not evident. Anthers narrowly oblong, 2–2.5 mm long, deeply bifid and sagittate, on short filaments to ca. 0.5 mm long. Capsule cylindric, 6–8 mm long, strongly septate from tip to base, the placentation axile, the placental axis extending ¾ up the fruit. Seeds lance-ovoid, 1.5–2 mm long, pale to deep amber, finely longitudinally anastomosing-ribbed.

Distribution. Wet, rocky savanna, summit elevations, Cerro de La Neblina, Territorio Federal Amazonas, Venezuela, locally abundant.

Additional specimens examined. VENEZUELA. T. F. AMAZONAS: low bush slopes near Cumbre Camp, 1,800 m, 4 Jan. 1954, *Maguire et al. 37051* (paratype, NY, US); planicie de Zuloaga, Río Titirico, 2,300 m, 10–15 Oct. 1970, *Steyermark 103825* (K, NY, US, VEN). More recent collections, not yet fully distributed, are: Valle de Titirico N of Pico Phelps, ca. 2,300 m, 1 Dec. 1984, *Kral 71914*; Camp 2, 2.8 km NE of Pico Phelps, 2,100 m, open bog, 15 Apr. 1984, *Stein & Gentry 1578* (MO, VDB, etc.); al norte del campamento base a lo largo del Río Mawarinuma, afluente del Río Baria, 1,880 m, 7–8 Feb. 1984, *Steyermark & Luteyn 129819* (MO, NY, VDB).

This species is another with the tendency to form frondlike plates of leaves and is superficially closest to forms of *X. ptariana* Steyerm. In the savanna of the Valle de Titirico it is the dominant xyrid, its pale yellow flowers unfolding in morning.

41. Xyris spruceana Malme, Bih. Svensk. Vet. Akad. Handl. 26(3)[19]: 12, pl. 1, f. 2. 1901. TYPE: Venezuela: ad fluv. Guainía v. Río Negro supra ostium fluvensis Casiquiari, in 1854, *R. Spruce 2993* (isolectotypes, GH, NY). Figure 41.

X. applanata Idrobo & Lyman B. Smith, Caldasia 6(29): 239–240, fig. 27a–h. 1954. TYPE: Colombia. Vaupés: Río Kananari, Cerro Isibukuri, piedra de arenisca, 250 m, 28 Oct. 1951, *R. E. Schultes & I. Cabrera 14466* (holotype, COL; isotypes, F, GH, MG, US, VDB).

Low, cespitose annual 0.8–2.5 dm tall, the stems contracted. Leaves ascending or spreading flabellately, mostly 5–15 cm long; sheaths from ½ as long to longer than blades, eciliate, sharply keeled, brown at very base, above stramineous, pink or pale purple, shading to pale green, progressively narrowing into blade, there either eligulate or with a narrowly triangular ligule less than 1 mm long; blades ensiform-linear, flat, 1.5–3 mm wide, narrowing gradually to an acute apex above middle, the margins slightly incrassate, papillose

to scabridulous or minutely ciliate, the surfaces green, often bordered by a pale brown band and a strong submarginal nerve, smooth, multinerved. Scape sheaths carinate at base, strongly bladed, similar to foliage leaves. Scapes appearing strongly flattened, distally 2–3 mm wide, scape body slightly flattened, usually with 1–2 ribs/side, the lateral costae alate, broader than scape body, ciliolate or papillate or entire. Heads turbinate to hemispheric, 0.7–1 cm high, with several spirally and loosely imbricate bracts, involucrate, with at least some sterile bracts leaflike with foliaceous, spreading or ascending, green-keeled blades, the blades elongate, sharply and ciliately keeled, spreading or overtopping, longer than the spike to slightly shorter, and with bases broadly margined, scarious, reddish, fimbrio-ciliate; fertile bracts ovate or lance-ovate, 5.5–6.5 mm long, strongly carinate, the large green, venose dorsal area excurrent to form an acuminate-subulate apex, or merely acute. Lateral sepals free, inequilateral, thin, broadly lanceolate, ca. 4 mm long, acute, the darker firmer keel ciliolate or villose with rusty hairs. Petal blades elliptic, 3.5–4 mm long, yellow, subacute, the margin undulate. Staminodia bibrachiate, the oblong, flat branches long-penicillate-ciliate. Anthers oblong, ca. 1 mm long, deeply bifid and sagittate, on filaments ca. 1 mm long. Capsule obovoid, 2–3 mm long, placentation basal, the valves without septa. Seeds numerous, ovoid to ellipsoid, ca. 0.5 mm long, apiculate, lustrous but opaque, with ca. 14 strong, dark brown, longitudinal ribs.

Distribution. Locally common in wet, sandy, savanna–forest transition or in white-sand savanna, along the Rio Negro and tributaries from Amazonian Brazil (Amazonas) northward into southern Colombia and southern Territorio Federal Amazonas, Venezuela.

Additional specimens examined (only Colombian and Venezuelan records are cited here). COLOMBIA. X. vaupesiana Idrobo & Lyman B. Smith, Caldasia 6(29): 237–238, fig. 26a–f. 1954.

This complex of little plants varies so much as to leaf and scape, trichomal features, relative length of spike and sterile bracts, and degree of sepal connation, that it is understandable that several variants have been described as species. Certainly two varieties appear, as follows:

KEY TO VARIETIES OF *XYRIS ULEANA*

1a. Scapes distally ancipital, the costae produced as 2 flat wings comprising the edges; leaf blades over 1 mm wide .... 42a. *X. uleana* var. *uleana*
1b. Scapes at most low-costate, terete, rarely with 1–few low costae; leaves 1 mm wide or less .... 42b. *X. uleana* var. *angustifolia*

42A. Xyris uleana Malme var. **uleana.** Figure 42.

Cespitose, soft-based annual 0.6–1.5(–2.2) dm high, the stems contracted. Leaves erect to spreading flabellately, 3–10 cm long; sheaths eciliate, keeled, ½ as long as blades or more, brownish or tan, narrowing gradually to blades and usually eligulate; blades linear, strongly flattened, 1–3.5 mm wide, tapering to incurved-acute tips; margins thin or comprising a yellowish-incrassate nerve, smooth or papillate toward leaf apex; surfaces green or tinged with pink or maroon, finely nerved or with some strong, yellowish nerves, glabrous. Scape sheaths mostly shorter than leaves, keeled and multicostate proximally, distally with strong blades similar to leaves. Scapes straight, slightly twisted, appearing strongly flattened, 1–3 mm wide, with scape body actually often round and with 2 lateral costae, alate, in combined width broader than scape body, the wings smooth or scaberulous-ciliate, sometimes scape faces with 1 or 2 more low costae. Spikes broadly to narrowly ovoid, 3–5(–10) mm long, acute, of several tightly imbricate bracts, these with large dorsal areas, otherwise thin, scarious, papillose, pilose-ciliate, the lowest pair sterile, often with backs alate-keeled, with excurrent-bladed dorsal areas, often longer than the other bracts, sometimes exceeding spike and with tips incurved-cucullate or erect; fertile bracts 2–3.5 mm long, broadly obovate or suborbicular, cucullate, broadly rounded at apex, ecarinate, papillate, the margins usually pilose-ciliate. Lateral sepals free or connate at base, strongly inequilateral, 2.5–3 mm long, blunt, the broad, curvate keel ciliolate and/or papillate. Petal blades very broadly obovate, ca. 2 mm long, yellow, the wide, shallowly rounded apex coarsely few-toothed. Staminodia bibrachiate, the narrow, flat branches long-penicillate-ciliate. Anthers lance-oblong, ca. 0.5 mm long, deeply bifid and auriculate, on flat filaments ca. 0.5 mm long. Capsule broadly obovoid, ca. 1.5 mm long, the placentation basal. Seeds narrowly ovoid or ellipsoid, 0.5–0.7 mm long, pale amber, longitudinally with many wavy, narrow, sharp lines, sometimes also with a few, irregular, stronger, dark red ribs.

Distribution. Sandy wet savanna at low to high elevations, northern South America west of the Andes, the Amazon system and tributaries, southern Colombia east to the Guianas, also including the upper Orinoco and tributaries; northern Brazil from Mato Grosso and Amazonas east into Pará. Only some of the collections from Colombia, Venezuela, and the Guianas are cited below.

Additional specimens examined. COLOMBIA. VAUPÉS: Río Atabapo, 1 km W Cacagual, *Maguire et al. 36293* (NY, VEN); Río Kubiyú, Cerro Kanenda, ca. 800–900 ft., 10 Nov. 1952, *Schultes & Cabrera 15398* (id. as *X. applanata* Idr. & Sm.—COL, F, GH, MG, US, VDB), *18337* (GH), *18398* (COL, GH, VDB); Río Kuduyari, Yapoboda, ca. 900–1,000 ft., 18 Nov. 1952, *Schultes et al. 18531* (F, GH). Agostini 266* (VEN); top of Salto Aicha near E base of Uaipan-tepui, 1,100 m, 27–28 Nov. 1982, *Davidse & Huber 22857* (MO, VDB); Vallé Encantado, lado derecho del Salto Angel, Auyantepuy, *Foldats 7178* (id. as *X. duidensis*—VEN); Serania Guayay sector nor-oriental, 20–28 Oct. 1985, *Huber 10967* (MYF, VDB); S foot of peaks of Uaipan-tepui, 1,200 m, 6 Mar. 1967, *Koyama & Agostini 7513* (NY, US, VEN); along Río Karuai, NW of Kavanayen, 1,220 m, 30 Nov. 1944, *Steyermark 60823* (F, US, VEN); Sierra Ichun, Salto Maria Espuma del Río Ichun, 28 Dec. 1961, *Steyermark 90340* (F, NY, US, VEN); Sierra Pakaraima, 4–5 May 1973, *Steyermark 107266* (F, MO, U, VEN, US); cumbre de Cerro Guaiquinima, Salto del Río Szczerbanari, 750 m, 20–25 Jan. 1977, *Steyermark et al. 113150* (MO, NY, US, VEN); Cerro Marutani, 1,200 m, 11 Jan. 1981, *Steyermark 123881* (NY, VDN). Two *Kral* numbers from the Gran Sabana collected with *A. Gonzalez* in 1983 and with distributions to F, MO, NY, US, VDB are *Kral 70389* and *70610*; two more from the Gran Sabana in Dec. 1984 and awaiting full distribution are *72157* and *72192*.

This variety is one of the weediest of the annual *Xyris* species, coming in solidly in disturbed sandy moist savanna and sandy washes in the Guayana Highland. It can, in dense populations, range from dwarf plants a few centimeters tall to quite tall. Generally, well-spaced individuals on moist, peaty sites range between one and two decimeters in height. The pale yellow flowers open in the morning.

42B. Xyris uleana var. **angustifolia** Lanj., Kew Bull. 1939: 562. 1939. TYPE: Guyana: Kaieteur Savanna, in damp sand, ca. 1,200 ft., petals deep orange-yellow, 7 Sep. 1937, *N. Y. Sandwith 1421* (holotype, K; isotypes, NY, U).

X. connectens Malme, Ark. Bot. 19(13): 2. 1925. TYPE: Brazil. Pará: cerca Belem, *Ducke* (type at BM).

The plants usually more slender and lower than in the type variety, the leaf blades narrower, mostly 0.5–1 mm wide, the edges smooth or papillate, the lower bracts typically shorter than the larger fertile ones, all bracts with papillate-tuberculate dorsal areas as in the type variety but bracts themselves with acute tips and entire to lacerate, eciliate margins. Lateral sepals mostly free.

Distribution. Low- to medium-elevation savanna, from Territorio Federal Amazonas in Venezuela west through southern Estado Bolívar to Guyana, infrequent. Also in Amazonas and Pará, Brazil.

Additional specimens examined. VENEZUELA. T. F. AMAZONAS: Rincones de Chacorro, 30 km N of Puerto Ayacucho, savanna, 80 m, 5 Nov. 1980, *Maas & Huber 5127* (US). BOLÍVAR: seeps among sandstone boulders by Ven. 10, ca. 800 m, N of Río Yuruani Ferry at Puente Kumerepa, 12 Dec. 1985, *Kral 72193* (MYF, VDB, VEN, and to be distributed). GUYANA: Pakaraima Mt., Mt. Aymatoi, 1,150 m, 15 Oct. 1981, *Maas et al. 5687* (U); Kaietuk Savanna, 1,100 ft., Aug. 20, 1933, *Tutin 497* (K).

This low variety of *X. uleana* is often in mixed populations with the type variety but is less frequent and could be mistaken for smaller, shorter-spiked *X. paraensis* var. *paraensis*. However, the dorsal areas of the latter are not strongly papillose-tuberculate. The terete scapes have sharp but low costae, very unlike the usually winged costae of the type variety.

43. Xyris calderonii Kral, Lyman B. Smith & Wanderley, sp. nov. TYPE: Brazil. Amazonas: Transamazon Highway, 9 km W of Rio dos Pombos, ca. 1.5 km E of Igarapé dos Pombos, and ca. 64 km E of the Aripuanã. Common in white sand campina, flowers yellow, 18 June 1979, *Cleofé E. Calderón, O. P. Monteiro & J. Guedes 2549* (holotype, INPA; isotypes, US, VDB). Figure 43.

Planta humilis, annua, praeter inflorescentiam glabra. Radices filiformes. Folia linearia, solum basalia, 3–7 cm longa, flabellate expansa, vulgo vaginis scaporum longiora. Laminae vaginis 2–4-plo longiores, 0.5–1 mm latae, planae, rectae, longitudine paucicostatae, a basi ad apicem compressae, porphyreae vel flavovirentae, apicibus abrupte contractis, incurvato-acutis, marginibus integris, non incrassatis; vaginae carinatae, porphyreae, pluricostatae, praeter costas scariosae, marginibus scariosis stramineis, in laminas gradatim convergentibus aut ad apicem ligulam scariosam curtam latam fascientibus, infime gradatim expansae, acies integrae. Vaginae scaporum laxae, plerumque apertae, rectae, carinatae, laminis aut similis laminis foliorum aut brevibus. Scapi subteretes, filiformes plus minusve spiraliter torti, 5–10 cm alti, 0.4–0.5 mm crassi, distaliter leviter multicostati, costis laevibus. Spicae subglobosae vel late ovoideae, 3–5 mm longae, pluriflorae, obtusae, involucratae. Bracteae steriles 2–4, subdecussatae, villosiciliatae; par infimum foliaceum, rigidum, spica 2–5-plo longiorum, lanceolatum vel oblongum, 2–3 mm longum, carinatum, areis dorsalibus linearibus, viridibus et laminis similis laminis foliorum sed triangulatis; par intimum ovatum, convexum, scariosum, acutum vel acuminatum, profunde villosiciliatum, areis dorsalibus valde papillosis, vulgo sine laminis. Bracteae fertiles late ovatae vel suborbiculatae, 2.5–3 mm longae, valde rotundato-convexae, villosiciliati, areis dorsalibus ovatis, valde granulato-papillosis. Sepala lateralia libera, oblonga vel ovata, 2–2.5 mm longa, valde inaequilatera; ala carinali lata, a basi ad medium integra, a medio distante ciliata, apicem versus lacerata. Laminae petalorum late obovatae, ca. 3 mm longae, luteolae, ad apicem late rotundatae et valde erosae. Staminodia bibrachiata, brachiis parce longipenicillatis. Antherae oblongae, sagittatae, ca. 0.5 mm longae; filamenta ca. 0.8–1 mm longa. Capsula matura late obovata, planoconvexa, ca. 1 mm longa, placenta basalia. Semina late ellipsoidea, ca. 0.3 mm longa, pallide brunneola, plus minusve reticulata.

Low annual, smooth except for the inflorescence. Roots filiform. Leaves linear, strictly basal, 3–7 mm long, spreading flabellately, commonly longer than the scape sheaths. Leaf blades 2–4 times longer than sheaths, 0.5–1 mm wide, flat, straight, longitudinally few-costate, flattened from base to apex, brown to yellow-green, the tips abruptly narrowed, incurved-acute, the margins entire, not thickened; sheaths carinate, brown, many-ribbed, scarious except for the ribs, with the thin edges stramineous, gradually narrowing into the blades or apically producing a short, scarious, broad ligule, gradually dilating toward base, the edges entire. Sheaths of scape lax, mostly open, straight, carinate, with blades similar to those of foliage leaves or shorter. Scapes subterete, filiform, ± spirally twisted, 5–10 cm high, 0.4–0.5 mm thick, distally with many low, smooth costae. Spikes subglobose to broadly ovoid, 3–5 mm long, several-flowered, obtuse, involucrate. Sterile bracts 2–4, subdecussate, villous-ciliate, the lowermost pair foliaceous, rigid, 2–5 times longer than the spike, lanceolate to oblong, 2–3 mm long, carinate, the dorsal areas linear, green, with blades similar to those of foliage leaves but triangulate; inner pair (if present) ovate, convex, scarious, acute, very villous-ciliate, the dorsal areas strongly papillate, without blades. Fertile bracts broadly ovate to suborbicular, 2.5–3 mm long, strongly rounded-convex, villous-ciliate, the dorsal areas ovate, strongly granular-papillose. Lateral sepals free, oblong to ovate, 2–2.5 mm long, very inequilateral, with keel broad, distantly ciliate from base to middle, lacerate toward apex. Petal blades broadly obovate, ca. 3 mm long, yellowish, broadly rounded and strongly erose at apex. Staminodia bibrachiate, the branches sparsely long-penicillate. Anthers oblong, sagittate, ca. 0.5 mm long; filaments ca. 0.8–1 mm long. Mature capsule broadly obovoid, plano-convex, ca. 1 mm long, the placenta basal. Seed broadly ellipsoid, ca. 0.3 mm long, pale brown, ± reticulate.

There is no question that the affinities of this little plant are with *X. uleana* Malme; in the production of narrow leaf blades it is most similar to var. *angustifolia* Lanj., which also sometimes produces long-tipped basal bracts. However, the lateral sepals are smaller with a somewhat different keel configuration, and the dorsal areas are consistently long-excurrent to produce acicular blades several times longer than the subtended spike. The scapes are uniformly terete.

44. Xyris esmeraldae Steyerm., Fieldiana, Bot. 28(1): 109, fig. 16c. 1951. TYPE: Venezuela. T. F. Amazonas: Esmeralda Savanna, 200 m, Cerro Duida, 22 Aug. 1944, *J. Steyermark 57821* (holotype, F; isotype, NY). Figure 44A (44B—see synonym).

Xyris rugulosa Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 29, fig. 13A–E. 1963. TYPE: Venezuela. T. F. Amazonas: Cerro Sipapo (Paraque), frequent along banks of small shaded stream savanna about pool, Caño Negro, 1,300 m, 15 Dec.

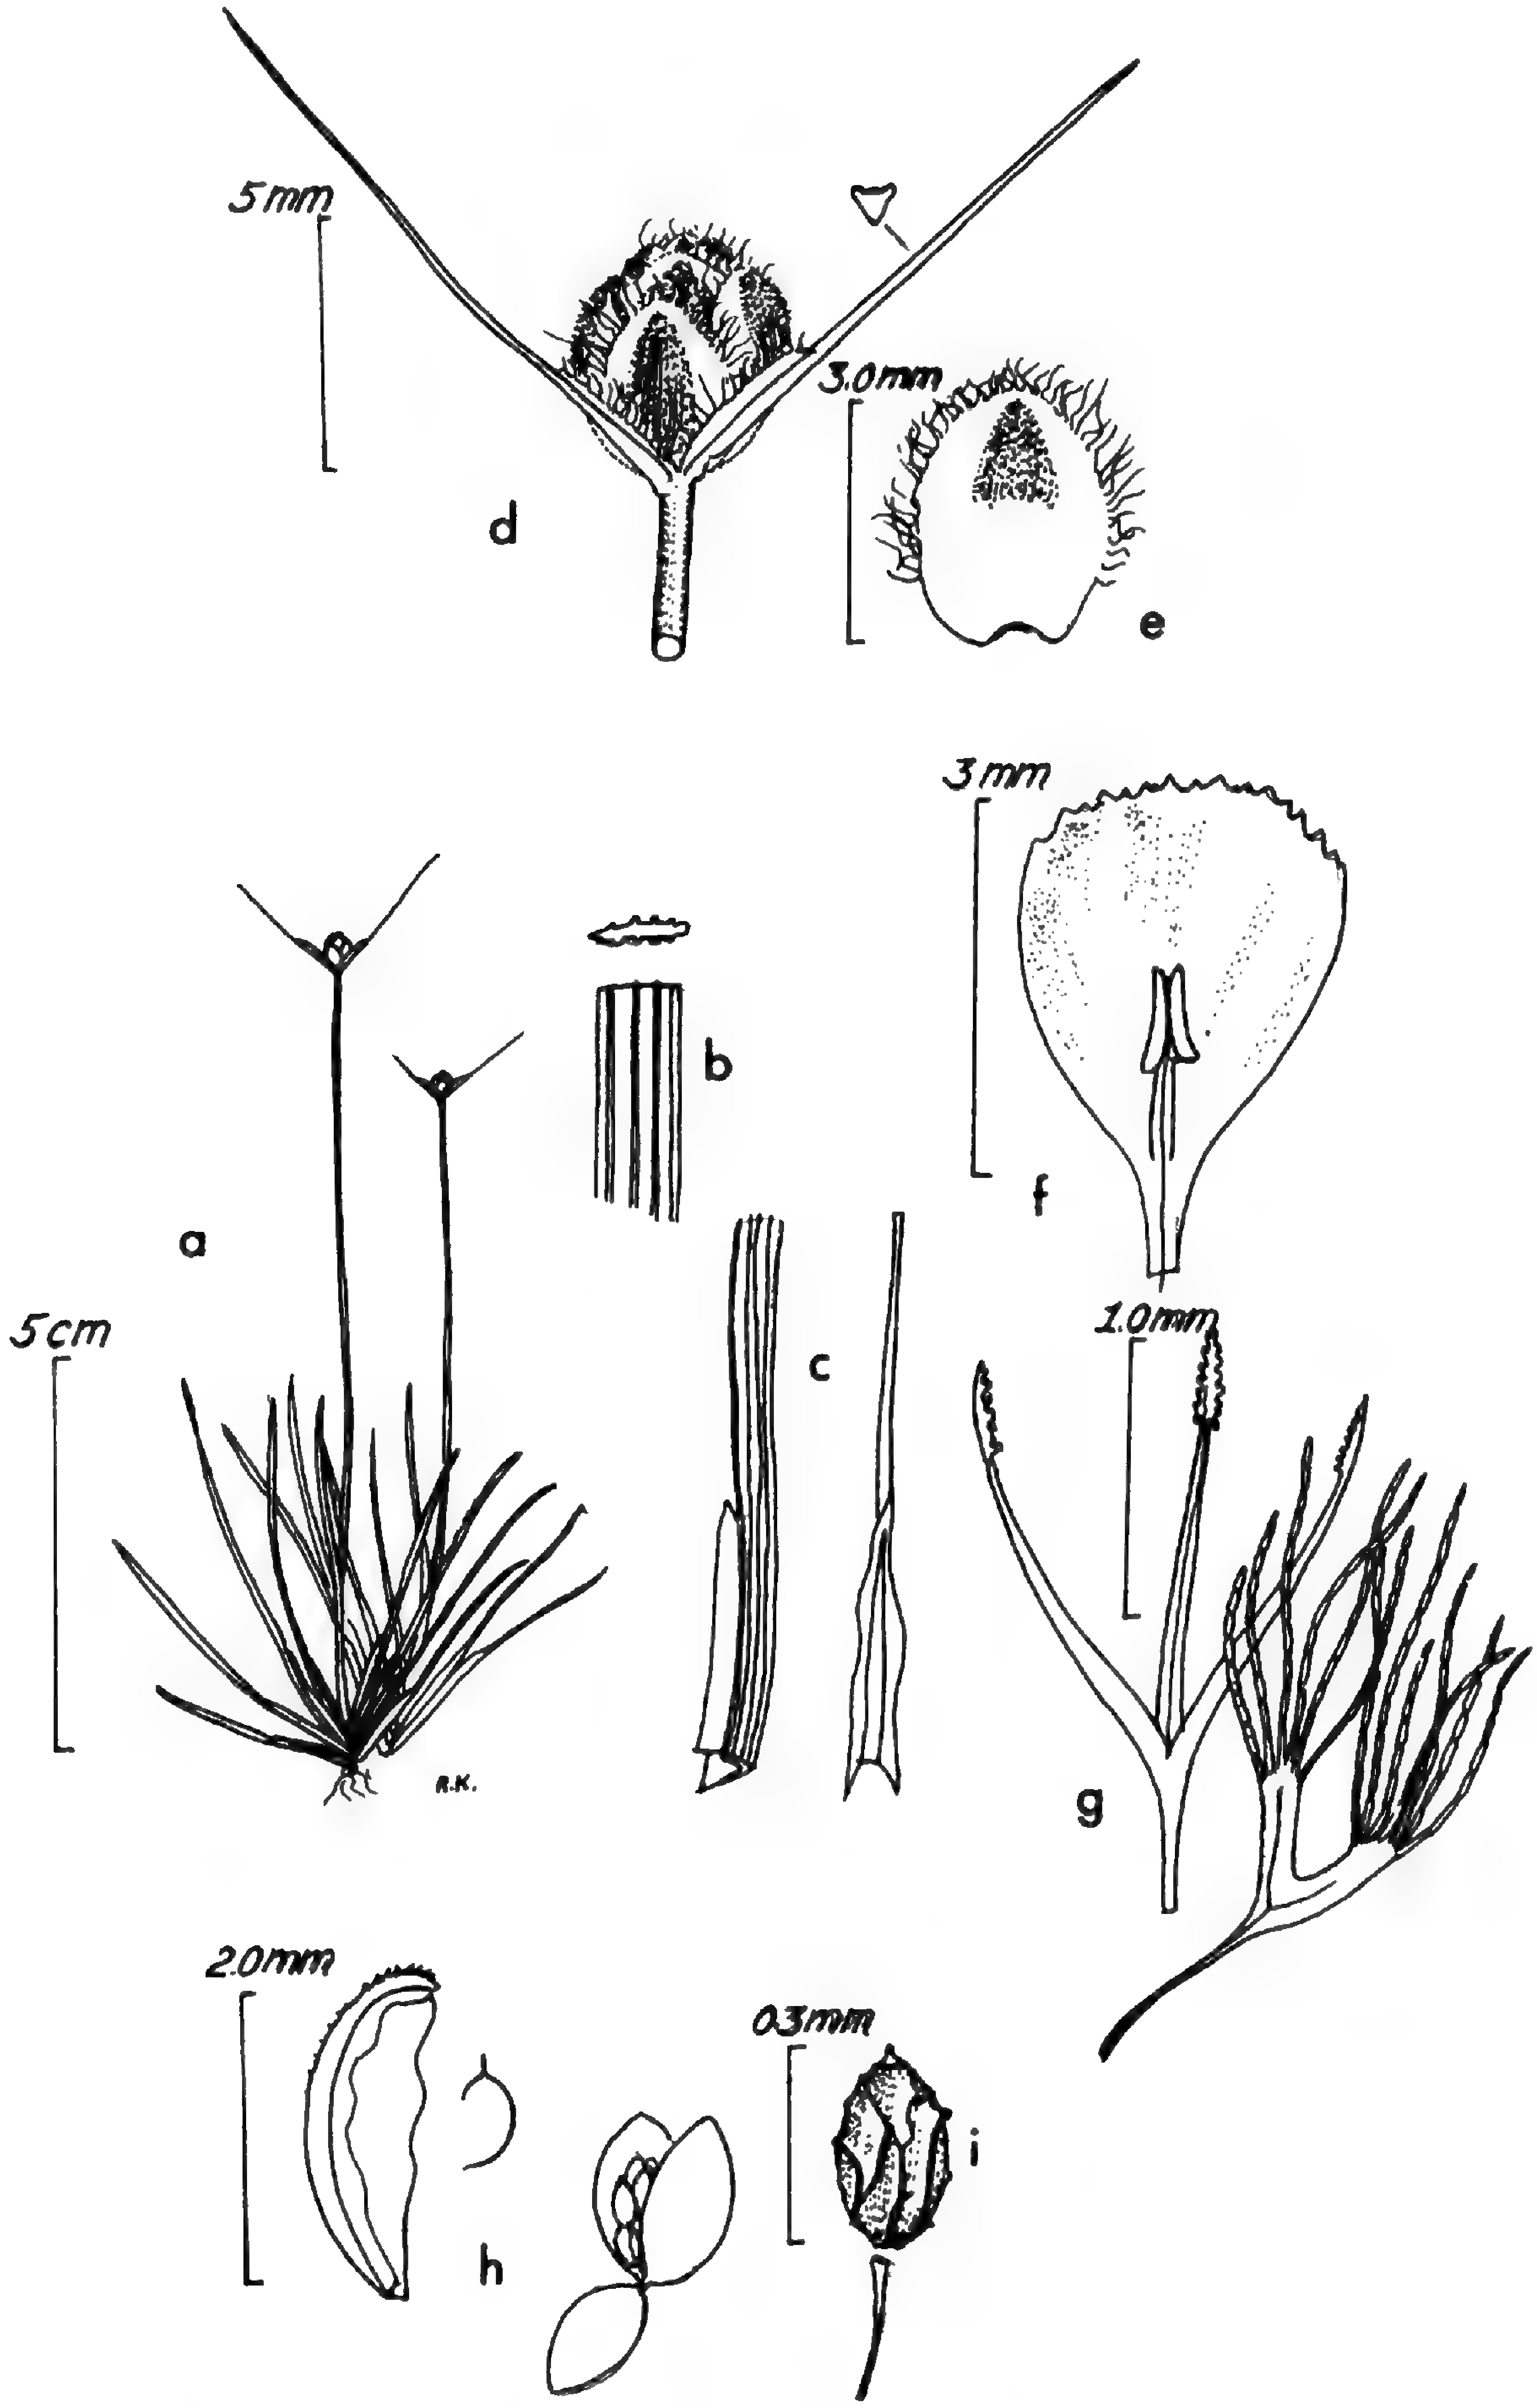

FIGURE 43. Xyris calderonii (Calderon et al. 2549).—*a. Habit sketch.—b. Leaf at midblade.—c. Leaf blade-sheath junction, side (left) and ventral (right) views.—d. Mature spike.—e. Fertile bract.—f. Petal blade and stamen.—g. Stylar apex, staminode.—h. Lateral sepal, capsule.—i. Seed.*

1948, *B. Maguire & L. Politi 27699* (holotype, NY; isotypes, US, VEN). Figure 44B.

Low, slender, cespitose, smooth to papillose-rugulose annual 0.5–3 dm high, the stems contracted, the roots filiform. Leaves ascending or spreading flabellately, 1–5 cm long, often absent by full anthesis or represented only by scalelike sheaths; sheaths of longer foliage leaves less than ½ as long as blades, pale lustrous brown, tapering gradually from base to blade, there with a narrowly triangular, erect ligule to 2 mm long, at this level broader than blade is wide, the blades linear, flat or somewhat twisted, much compressed, ca. 1 mm wide, green or maroon, gradually narrowing toward apex, to a narrowly acute or acuminate tip, this dorsally scabrid, the margins mostly pale-incrassate, scaberulous or smooth, the surfaces strongly few-ribbed, smooth, rugose or rugulose. Scape sheaths shorter than most leaves, the base tubular, ribbed, keeled, the apex short-bladed or with a cusplike blade. Scapes much twisted, straight or flexuous, flattened distally, ca. 0.8–1 mm wide, ancipital with smooth or tuberculate-scabrid costae making edges, the surfaces ribless or with 1–2 ribs per side, smooth or rugulose-scabrid. Spikes elliptic-lanceolate, 3.5–5 mm long, acute, uniflorous, subtended by a narrow castaneous collar, of few, strongly convoluted, erect, reddish brown, decussate bracts with distinct dorsal areas; sterile bracts 2 pair, shorter than the fertile bracts, the lowest pair ovate to lance-triangular, acute, strongly keeled, the inner pair ovate-triangular, slightly keeled, distally with a strong, narrow midnerve, acute or narrowly rounded, entire or lacerate; fertile bract solitary, narrowly to broadly obovate, much inrolled, ca. 4–6 mm long, broadly acute or narrowly rounded, with broad dorsal area and strong midnerve. Lateral sepals ca. ⅓ connate, 4–4.5 mm long, the lobes oblong, subequilateral but excentrically folded, pale red-brown, acute, the narrow firm keel scabrociliate at least from middle to apex. Petal blades obovate or elliptic-oblong, 2–3 mm long, yellow, the rounded apex lacerate-dentate. Staminodes either not evident or with obreniform, beardless blades. Anthers oblong, ca. 1 mm long, deeply bifid and sagittate on filaments ca. 1 mm long. Capsules obovoid, 2–3 mm long, the valves eseptate, the placentation basal. Seeds several on long funiculi, ellipsoid, 0.7–1 mm long, including a short, silvery apiculus (outer integument), the body deep amber, finely longitudinally and spirally anastomosing-ribbed.

Distribution. Low (mostly under 500 m) savanna, southeastern Colombia eastward along the upper Río Orinoco and the Río Negro and tributaries in Venezuela.

Additional specimens examined. COLOMBIA. AMAZONAS: Río Caquetá, Araracuara, sabana de la Angostura, 400 m, 21 Dec. 1951, *H. It becomes necessary to consider this the same as *X. rugulosa* Maguire & Lyman B. Smith, which does not differ in any essential character but only in the tendency in the latter toward narrower bract tips and more leafiness (cf. Fig. 44A, B). The rugulous epidermal feature supposed to be critical for *X. rugulosa* appears also on leaves of *X. esmeraldae.* Some of the trouble in past interpretation must come from the fact that *X. esmeraldae* proper tends to lose most of its larger foliage leaves as the plants approach seeding. However, when one finds these leaves, they are remarkably the same as those of *X. rugulosa.*

45. Xyris subuniflora Malme, Rec. Trav. Bot. Neerl. 9: 129. 1912. TYPE: Dutch Guayana: "In arenosis humidis, Suriname," *Splitgerber 990* (lectotype, L; isolectotype, U). Figure 45.

Xyris capillaris Steyerm., Fieldiana, Bot. 28: 107. 1951. TYPE: Venezuela. T. F. Amazonas: between Esmeralda Savanna and southeastern base of Cerro Duida, 200 m, 22 Aug. 1944, *J. A. Steyermark 57835* (holotype, F; isotypes, GH, NY, VEN).

Densely cespitose, low and delicate, smooth, annual or short-lived perennial 3–10 cm high, the stems contracted. Leaves erect or spreading flabellately, 1–7 cm long; sheaths eciliate, soft, ½ as long as blades or less, the bases tan or pink, keeled, tapering evenly into blades or with a short, erect, triangular ligule less than 1 mm long; blades filiform but flat, 0.3–0.5 mm wide, tapering slightly above middle, then abruptly acute-apiculate or incurved-acute, the margins entire, the surfaces very finely nerved, maroon with olive tints. Scape sheaths ca. as long as leaves, twisted, tubular proximally and multicostate, distally open with a strong flat blade as in leaves. Scapes filiform, straight or flexuous, twisted, ca. 0.3 mm thick, distally terete, ecostate, finely striate, olivaceous to maroon. Spikes narrowly ellipsoid or linear-ellipsoid, drying lance-ovoid, 4–5 mm long, few-bracted, uniflorous; bracts with distinct lanceolate dorsal areas, the sterile bracts 4, 2.5–3 mm long, lanceolate, navicular, acute or narrowed-retuse; fertile bracts oblong to ovate, conduplicately folded around floret, ca. 4 mm long. Lateral sepals ca. ½ connate, ca. 3–3.5 mm long, the narrowly triangular, erect lobes inequilateral, acute with very low smooth keels similar to dorsal areas of bracts but narrower. Petal blades broadly obovate, ca. 3 mm long, yellow, the broadly rounded apex denticulate-lacerate. Staminodia bibrachiate, arising from just below sinus between petal blades, the branches short-penicillate-pubescent. Anthers oblong, ca. 0.8 mm long, deeply bifid and sagittate, on filaments ca. 0.5 mm long. Capsule broadly ellipsoid, brown, ca. 1.5 mm long, the placentation basal. Seeds few, broadly ellipsoid, 0.5–0.6 mm long, apiculate, dark brown and opaque, rather coarsely longitudinally ribbed and cross-ribbed.

Distribution. Low-elevation savanna, locally abundant, southeastern Colombia (Vaupés) eastward into Surinam and in contiguous Pará, Brazil.

Additional specimens examined. COLOMBIA. VAUPÉS: Caño del Caribe and vic., 850–900 ft., 2 Nov. 1952, *Schultes, Baker & Cabrera 18276-A* (US). ing, 2–5 cm long; sheaths reddish brown, ca. ½ as long as blades, tapering evenly from keeled base to blade, or with an erect, narrowly triangular ligule to 0.5 mm long; blade flat, linear, often twisted, 0.8–1.2 mm wide, the apex incurved-acute, slightly thickened, papillose-tipped, the margin a narrow, pale, cartilaginous band, the surface green or maroon, finely nerved. Scape sheaths ca. the same length as leaves, proximally tubular, multicostate, opening toward middle, at apex bearing a blade similar to that of leaves. Scapes filiform, maroon, terete, with 1 low but strong costa. Spikes ellipsoid, in fruit broadly obconic, ca. 0.5 mm long, red-brown, of 2–3 flowers. Sterile bracts ca. 4, decussate, triangular-ovate, keeled, smaller than and grading into the fertile bracts, these 3–4 mm long, ovate, acute, entire, the backs ecarinate, with prominent lanceolate dorsal areas, excurved in fruit. Lateral sepals ca. 4 mm long, connate in basal ⅓, the lobes subequilateral, oblong, acute, pale brown, firm, keel in middle ⅓ papillate-tuberculate. Petal blades broadly obovate, 3 mm long, yellow, the narrowly rounded apex erose. Staminodia bibrachiate, the flattened branches with sparse penicillate hairs distally. Anthers oblong, ca. 1 mm long, deeply bifid apically, auriculate basally, on filaments ca. 0.5 mm long. Capsule ellipsoid, ca. 1.5 mm long, placentation central. Seeds numerous on elongate funicles, ellipsoid, ca. 0.5 mm long, biapiculate, deep brown, many-ribbed longitudinally.

Distribution. Rocky moist savanna, known only from the type locality (additional material, *Kramer & Hekking 2940*, U).

This species is so similar to the widespread *X. guianensis* as to make the observer doubt their distinctness. However, until more collections from the region show intermediacy in sepal connation, it is perhaps best to include it here as distinct.

47. Xyris guianensis Steudel, Syn. Pl. Glum. 2: 285. 1855. TYPE: Guayana: "Guiana anglica. *Schomburghk No. 1038*" (lectotype, K; isolectotypes, K, L). Figure 47.

Xyris filiscapa Malme, Repert. Spec. Nov. Regni Veg. 3: 112. 1906. TYPE: Brazil. Amazonas: "In arenosis humidis, Manaos, Amazonas, Brasil," *Ule 6172* (lectotype, S; isolectotypes, L, NY, US).

Low, densely tufted, smooth annual 0.5–3 dm high, the stems mostly contracted, sometimes 1–2 cm long. Principal leaves spreading flabellately, often maroon or red-brown, 2.5–7 cm long; sheaths entire, glossy red-brown, ½ the blade length or less, keeled, the keel often papillate-ciliolate, incrassate, tapering gradually to blade, there often with a scarious, narrowly triangular, erect, ligule to 2 mm long or eligulate, the blades flattened, linear, often twisted, 0.5–1 mm wide, the apex narrowly acute to acuminate, the tip sometimes with a tuft of scabrosity, the margins narrow, incrassate, a pale or dark, smooth band, the surfaces finely multinerved and smooth, often with strong maroon tints. Scape sheaths longer than to slightly shorter than leaves, below terete and deep glossy red-brown, distally opening and keeled, producing a blade similar to leaf. Scapes filiform, twisted, sometimes flexuous, ca. 0.5 mm thick, distally terete or slightly compressed, ecostate to low-bicostate, the costae smooth. Spikes ellipsoid, drying obovate or turbinate, 4–7 mm long, pale red-brown with 2–3 (rarely a few more) florets; bracts few, decussate, with strong, green or maroon, lance-ovate dorsal areas bisected by a strong midnerve; sterile bracts mostly 4, the lower pair triangular, keeled, slightly shorter and narrower than the inner pair, the fertile pairs again slightly longer or equal to inner sterile pair, oblong, ca. 4.5–5 mm long, less keeled, more often convex-rounded or rounded-navicular, apically narrowly to broadly rounded, entire, scarious-bordered, the narrow tips often villosulous-ciliate. Lateral sepals pale red-brown, thin, subequilateral, oblanceolate, 4–5 mm long, acute, the narrow, firm keel papillate or ciliolate above middle, or the keel smooth.

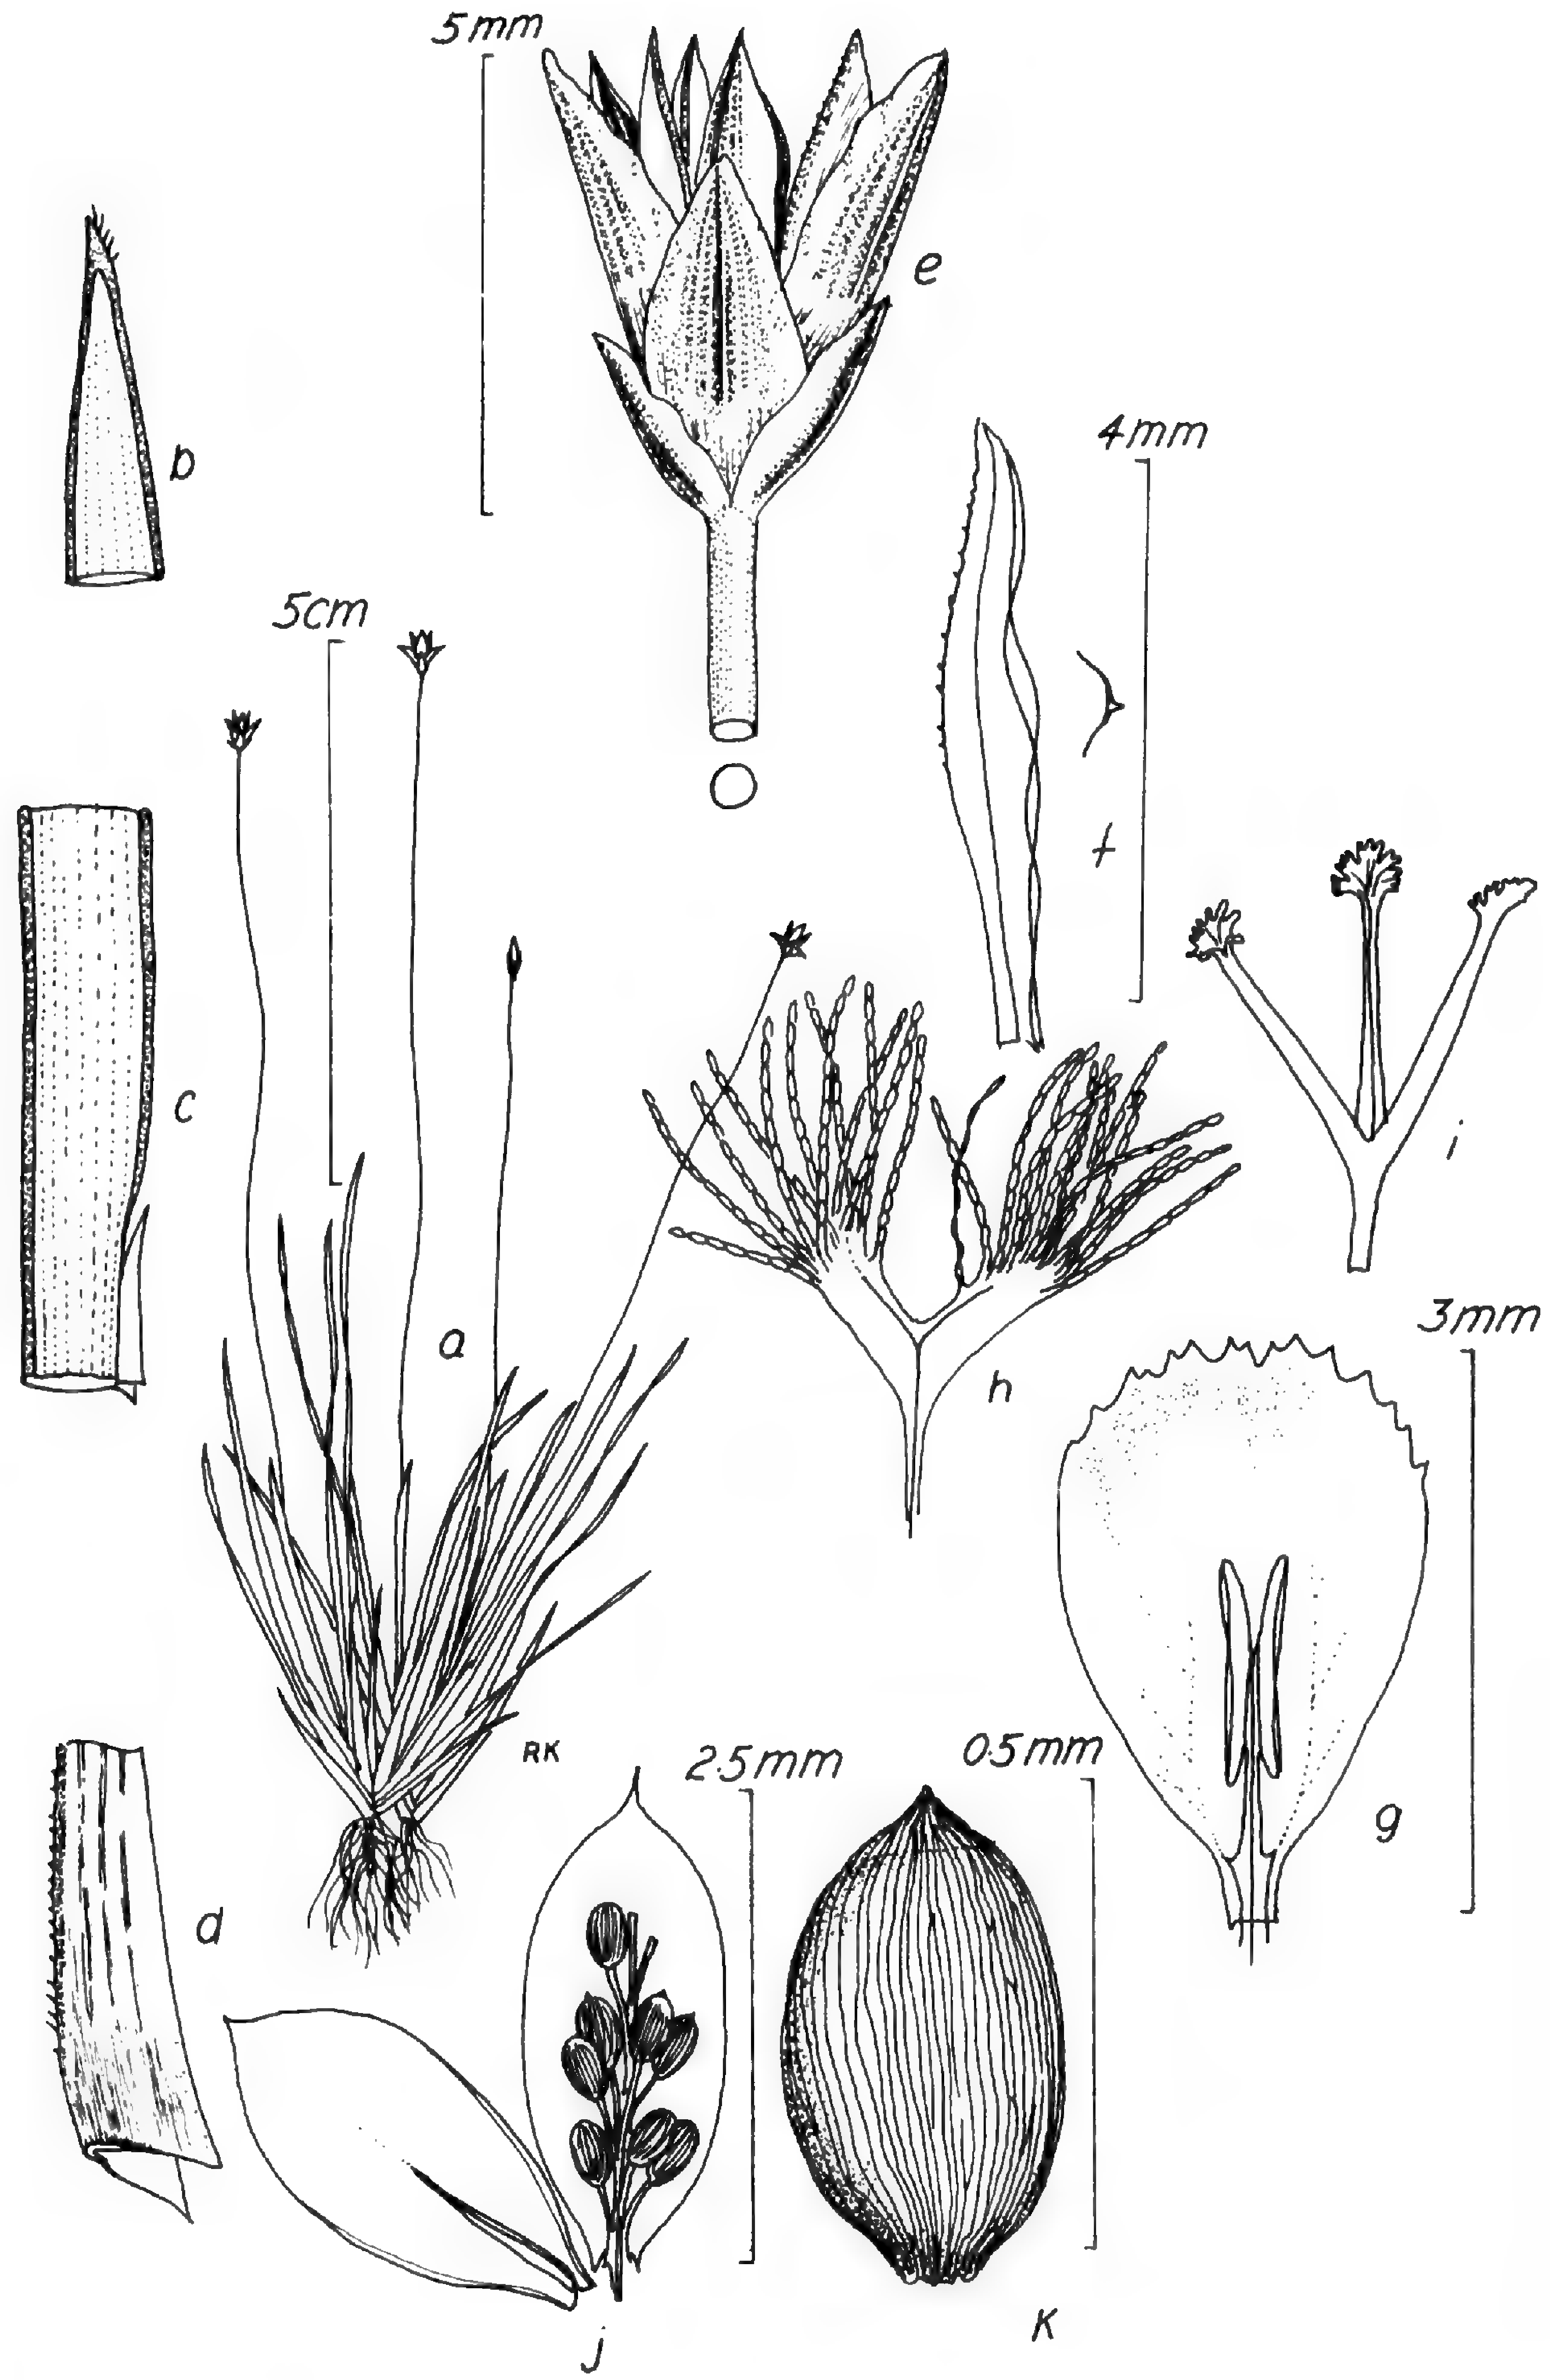

FIGURE 47. Xyris guianensis (Steyermark 75771).—*a. Habit sketch.—b. Leaf apex.—c. Leaf blade–sheath junction.—d. Leaf base.—e. Spike.—f. Lateral sepal.—g. Petal, stamen.—h. Staminode.—i. Stylar apex.—j. Capsule spread to show two of the three valves and placentation.—k. Seed.*

Petal blades broadly obovate, ca. 3 mm long, yellow, the broadly rounded apex lacerate-dentate. Staminodia bibrachiate, the broad, thin branches penicillate-ciliate. Anthers oblong, ca. 1 mm long, deeply bifid and sagittate, on filaments ca. 0.5 mm long. Capsule ellipsoid, ca. 2.5 mm long, the placentation basal-central, the valves with narrow septa below the middle. Seeds numerous, ovoid to ellipsoid, ca. 0.5 mm long, apiculate, dark amber, lustrous, finely ribbed longitudinally.

Distribution. Locally abundant in low- to medium-altitude savanna, southeastern Colombia eastward into Surinam and in adjacent Brazil south into Goiás.

Selected specimens examined. COLOMBIA. AMAZONAS–VAUPÉS: Río Apaporis, Raudal de Jirijirimo, ca. 900 ft., 12 Aug. 1951, *Schultes & Cabrera 13506* (GH). Examination of the type of *X. filiscapa* Malme reveals that this differs in no significant way; that is, a broad range of specimens of *X. guianensis* shows sepal keels varying from entire to ciliolate and leaf blade margins ranging from strongly to weakly incrassate bordered. Elements of the former described as having ciliate sheaths are either ciliate-keeled *X. guianensis* or ciliate-leaf-sheathed *X. tenella* Kunth (*X. steyermarkii* Maguire & Lyman B. Smith). Therefore Colombian material identified as *X. filiscapa* turns out to be *X. guianensis.*

48. Xyris spathacea Lanj., Pulle, Rec. Trav. Bot. Neerl. 34: 484, fig. 4. 1937. TYPE: Surinam: "Sanderij I, Sept. 1914, Leg. *Essed*" (holotype, L; isotype, U). Figure 48A, B.

Xyris exserta Idrobo & Lyman B. Smith, Caldasia 6: 229, f. 21. 1954. TYPE: Colombia. Vaupés: sands in rapids, Río Guaimia, Caño del Caribe near San José, 850–900 ft., 2 Nov. 1953, *R. E. Schultes, R. E. D. Baker & Is. Cabrera 18276* (holotype, COL; isotypes, GH, US).

Xyris yapobodensis Idrobo & Lyman B. Smith, Caldasia 6: 231–232, fig. 22. 1954. TYPE: Colombia. Vaupés: "elevated sandstone savanna known in Kubeo as 'Yapoboda,' Alto Cuduyari, ca. 400 m. alt." 10 Dec. 1943, *P. H. Allen 3287* (holotype, MO).

Mostly low, slender, soft-based, solitary or cespitose, sometimes short-rhizomed ephemerals (5–)10–30 cm high. Leaves erect or spreading, dimorphic, those of dry stages or of innovations 0.5–5 cm long, with sheaths over ½ as long to longer than blades, the broad, scarious margins abruptly converging distally to the short, terete, 0.2–2.5 mm thick, conic-tipped, stiff, often maroon blades, also often producing apically a scarious, triangular or oblong ligule 2 mm long; "wet" or submersed-stage leaves lax, flaccid, filiform, mostly 1–2 dm long, the thin sheaths much less than ½ as long as blades, pale brown or stramineous, sparsely costate, tapering gradually from base to blade, there with a scarious, narrowly triangular ligule to 3 mm long, the blades terete or at intervals somewhat flattened, ca. 0.3 mm thick. Scape sheaths loosely tubular, much raised above the "dry"-season foliage, shorter than the lax "wet"-phase leaves, twisted and fluted, multicostate, distally open, carinate, producing a short, cusplike blade. Scapes soft, filiform, straight or slightly flexuous, slightly twisted, terete, striate, 0.3–1 mm thick, ecostate. Spikes elliptic to obovoid, 3–5 mm long, sometimes proliferous, acute, 2–4-flowered, of a few spirally arranged, scarious-bordered, loosely imbricate bracts with distinct, elliptic-ovate, brown to green, papillose dorsal areas over ½ as long as the bract body; sterile bracts 3–4, narrowly ovate, slightly shorter than the fertile bracts and grading into them, the two lowest keeled, navicular, subacute; fertile bracts broadly elliptic to obovate, ca. 3 mm long, subacute, the margins sometimes white-villosulous-ciliate at apex, the backs rounded-convex, ecarinate, the dorsal areas bisected by a narrow but distinct midnerve. Lateral sepals free, subequilateral or somewhat inequilateral, lanceolate to linear-oblanceolate, ca. 3–3.5 mm long, acute, the broad, low keel sparsely papillose or short-ciliate from middle to apex. Petal blades obovate, 3–3.5 mm long, yellow, the broadly rounded apex lacerate-dentate. Staminodia bibrachiate, the broad, flat branches copiously penicillate apically. Anthers oblong, ca. 1 mm long, bifid to below middle, sagittate, on filaments ca. 0.6–0.7 mm long. Capsule short-cylindric to narrowly obovate, ca. 2.5 mm long, the placentation basal, the valves without septa. Seeds numerous on long funicles, ellipsoid, 0.4–0.5 mm long, pale brown, translucent, with an irregular, coarse, partly anastomosing reticulum of a few strong, deep brown ribs.

Distribution. Locally abundant in low, riverine and intermittently inundated savannas, southeastern Colombia, southern Venezuela, eastward to Surinam and contiguous Amazonian Brazil (Amazonas, Mato Grosso, Pará).

Additional specimens examined. BRAZIL. AMAZONAS: basin of Rio Negro, Rio Uneiuxi, 5 km above mouth, 8 Nov. 1971, *Prance et al. 16183*, with nom. nud. "*X. prolifera* K. & S." (NY, US, VDB). FIGURE 48A. Xyris spathacea *(from the type).—a. Habit sketch.—b. Leaf apex.—c. Leaf blade–sheath junction.—d. Leaf.—e. Leaf base.—f. Spike.—g. Lateral sepal.—h. Petal blade, stamen.—i. Staminode.—j. Stylar apex.—k. Capsule, median.—l. Seed.*

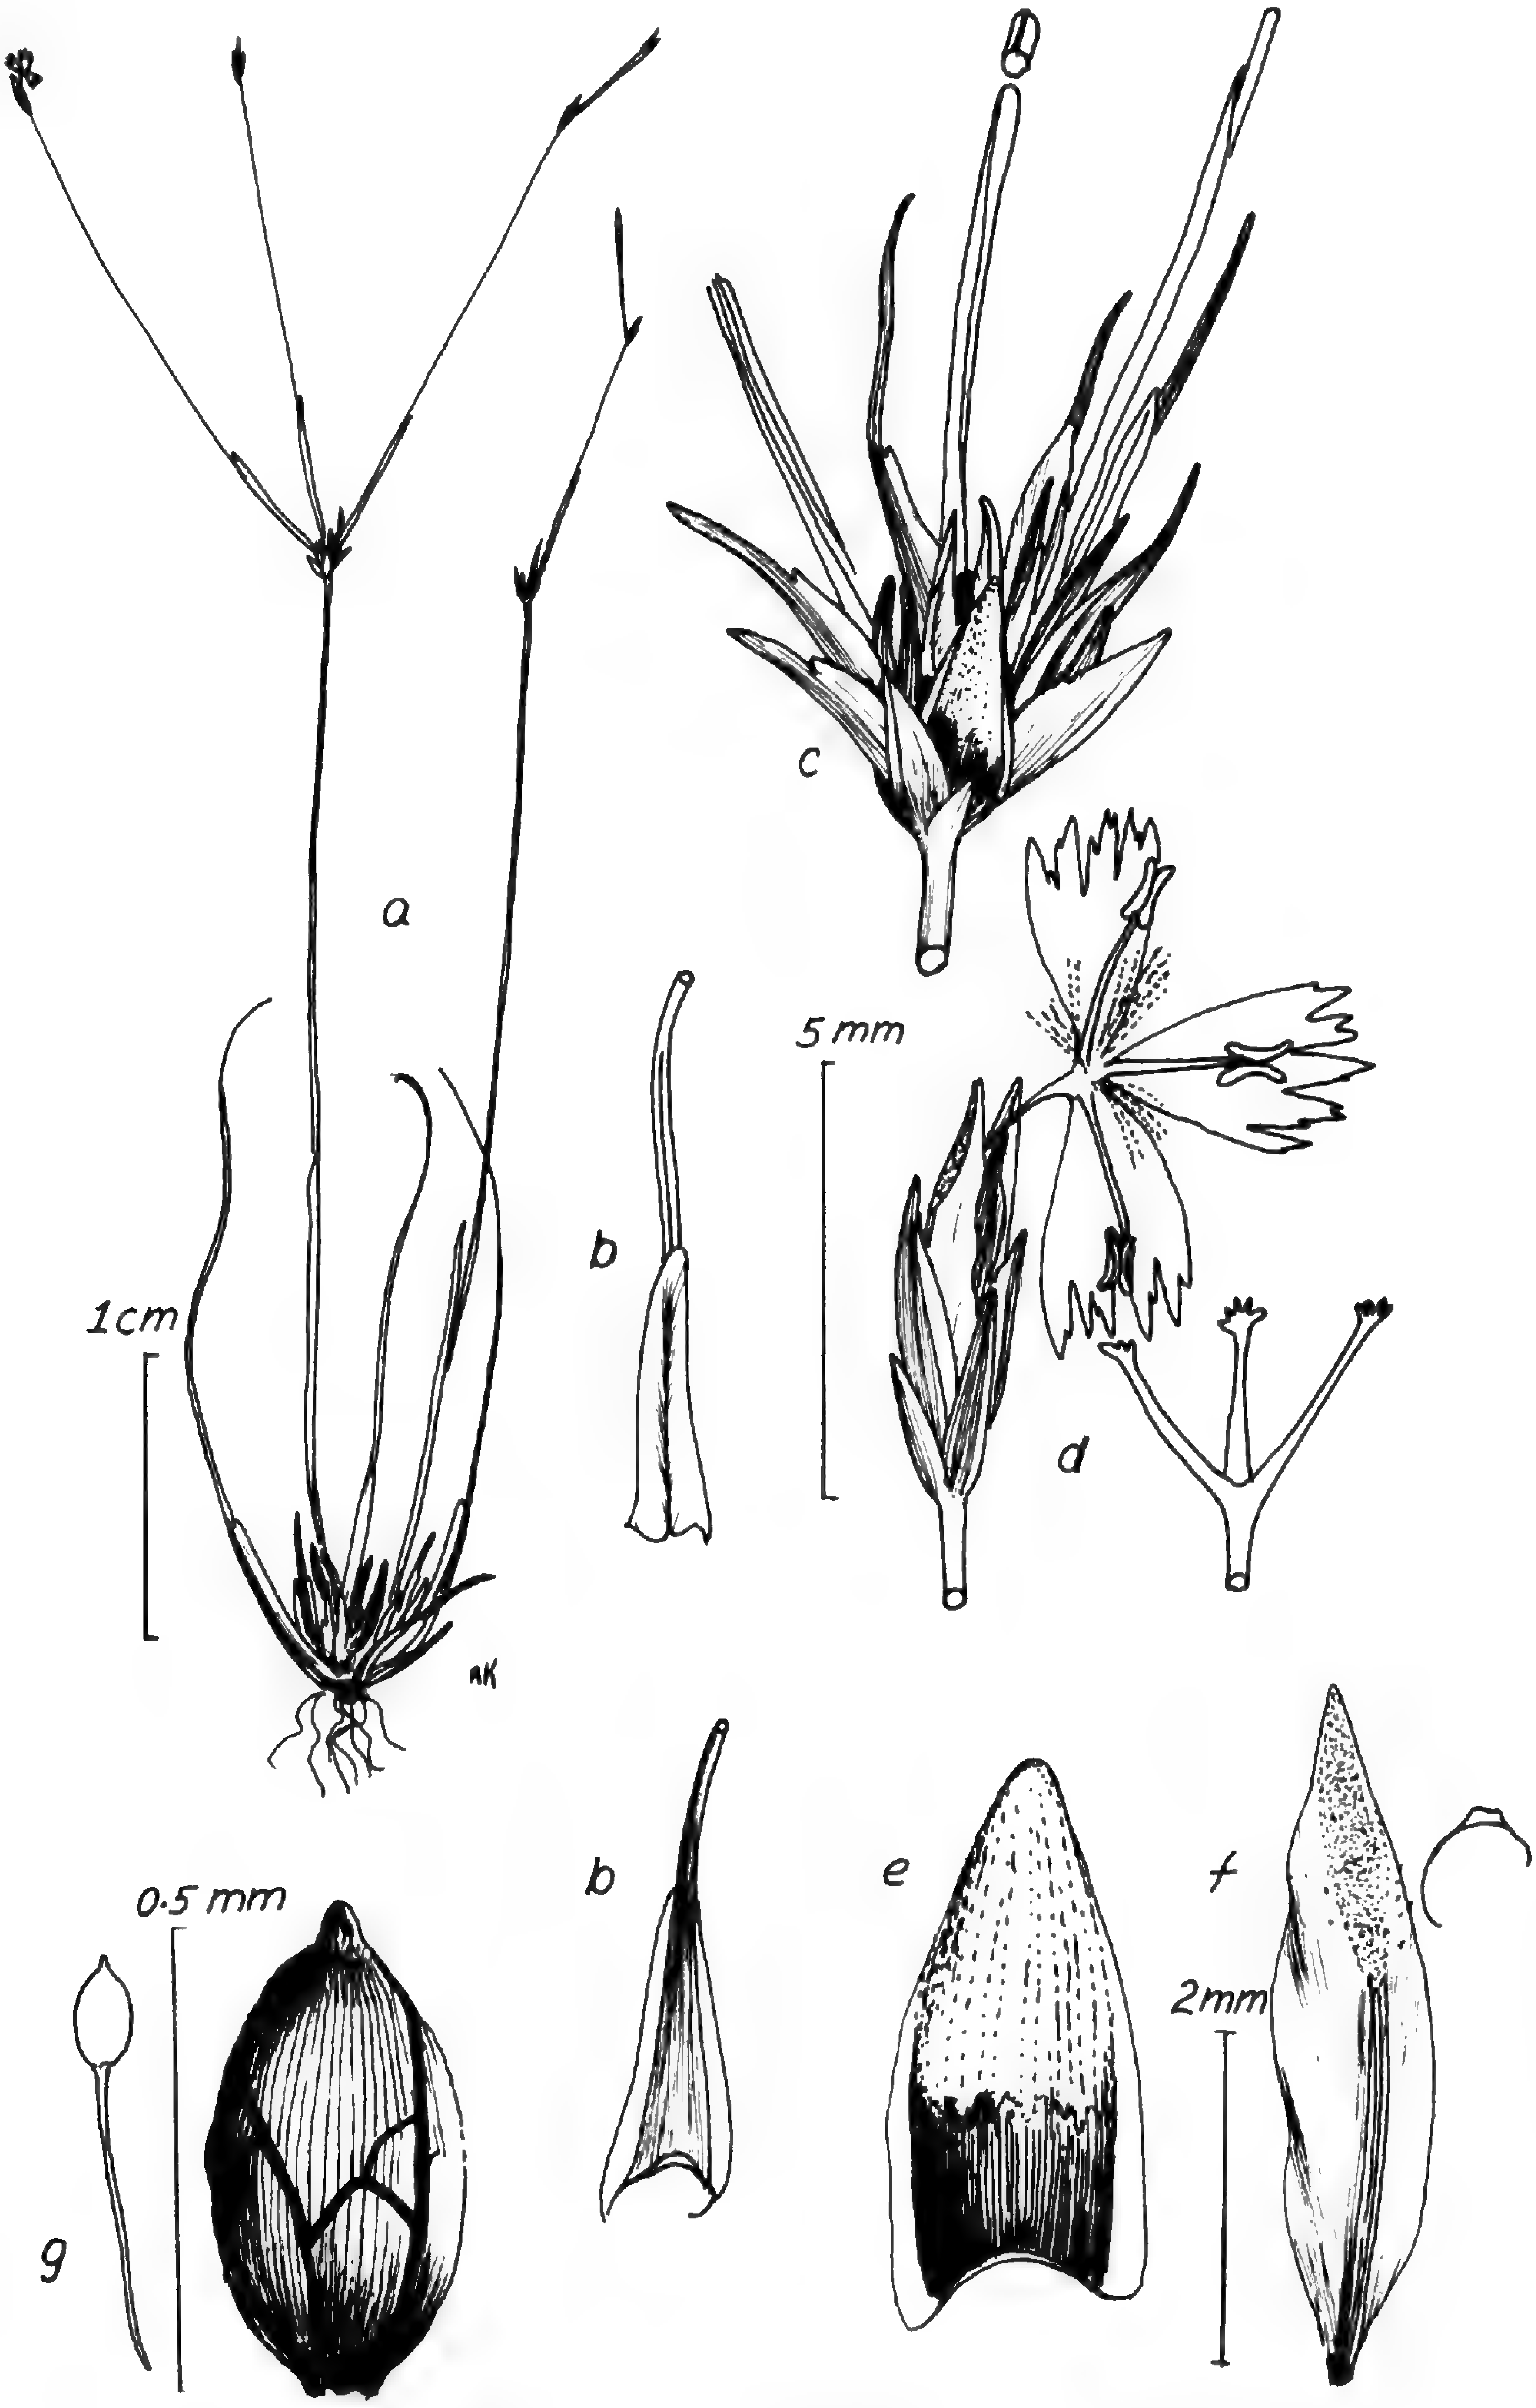

FIGURE 48B. Xyris spathacea (Huber 3185).—*a. Habit sketch.—b. Leaf sheath–blade junction.—c. Spike, showing exserted sepals, proliferous habit.—d. Spike, flower, stylar apex.—e. Fertile bract.—f. Lateral sepal.—g. Seed.*

This species has a low stature and very short leaf blades when developing on drying sites left by retreating waters. On the other hand, such plants produce much longer, laxer leaves when water rises to submerse them or their bases. I find no way to distinguish material of *X. spathacea* (Fig. 48A) from what is being called *X. exserta* (Fig. 48B) from the upper Amazon Basin of western Brazil and from the low savanna of Venezuela and Colombia. The only difference that is of any real interest is the tendency toward proliferative spikes in the latter, doubtlessly this trait induced environmentally. Some such Venezuelan and Brazilian extremes produce strong branches (scapes) that radiate umbel-like from the primary spike and terminate in floriferous spikes (*Huber 3185, Prance et al. 16183*). The type of *X. exserta* differs not at all from longer-leaved *X. spathacea* from Surinam.

49. Xyris cyperoides Gleason, Bull. Torrey Bot. Club 56: 17. 1929. TYPE: Guyana: Kaieteur Savanna, Potaro River, Sep.-Oct. 1881, *G. S. Jenman 1056* (holotype, K). Figure 49.

Xyris epicarae Kral & Smith, Phytologia 53: 436-437, fig. 6. 1983. TYPE: southeast escarpment of Cerro Pitón, 400 m, Cordillera Epicara, Río Chicanan, 5 Sep. 1962, *B. Maguire et al. 53651* (holotype, VEN; isotypes, NY, US, VDB).

Densely cespitose, the firm, pale reddish brown bases covered by persistent old leaf bases, the stems short to somewhat elongated, erect or ascending; roots slender. Principal leaves subdistichous, erect, twisted, flexuous, 0.8-1.8 dm long, longer than the scape sheaths (and often the scapes themselves); blades 5-6 times longer than sheaths, filiform, angulate to terete or somewhat compressed, 0.2-0.4 mm wide, longitudinally strongly nerved, shining, smooth with nerves reddish brown, wider than the greenish intervals; tips gradually narrowed, fimbriolate with clavate trichomes at apex; margins entire or minutely scabrid toward base; sheaths ecarinate, entire, strongly multicostate, smooth, gradually dilating to base, producing an acute, scarious ligule to 1.5 mm long at apex. Scape sheaths similar to leaves but shorter. Scapes filiform, 1.5-2 dm long, 0.3-0.4 mm wide, slightly twisted and flexuous, terete, finely 1-several-costate, olivaceous, smooth. Spikes 2-flowered, ellipsoid or in mature state obconic, ca. 4 mm long; bracts loosely imbricate, decussate, triangular-ovate, mostly 6, smooth, pale lustrous reddish brown, sparsely ciliate toward apex, marginally scarious; sterile bracts 4, unicostate, the lowest pair lanceolate, ca. 2.5 mm long, cymbiform, the inner pair triangular-ovate, ca. 3 mm long, ecarinate; fertile bracts ovate, ca. 3 mm long, strongly convex or navicular, at length excurvate; dorsal area olive, then ferrugineous, conspicuous, large, nearly as long as bract. Lateral sepals oblong, ca. 3.5 mm long, slightly curvate, subequilateral, obtuse and slightly emarginate to acute; keel narrow, entire. Petal blades obtriangular, ca. 3 mm long, yellow, subtruncate at apex, erose. Staminodia bibrachiate, the branches sparsely penicillate apically. Anthers oblong, 1.2 mm long, deeply bifid and sagittate, on filaments ca. 1 mm long. Capsule ellipsoid, ca. 2 mm long, the valves without septa, the placentation central. Seeds numerous, broadly ellipsoid, ca. 0.5 mm long, amber, finely longitudinally multiribbed.

Distribution. Sandy, medium- to high-elevation savanna, apparently rare, from southern Estado Bolívar, Venezuela southward into contiguous Amazonas, Brazil and eastward to Surinam.

Additional specimens examined. BRAZIL. AMAZONAS: Manaus-Caracarai Highway, forest at km 130, *Steward et al. P20348* (specimen bearing nomen nudum *X. sulcata* (US). GUYANA: Kaieteur Plateau, along Mure-mure Creek to ca. 3 mi. above mouth, ca. 1,400 ft., 15-16 Mar. 1962, *Cowan & Soderstrom 2179* (US). SURINAM: Kappel savanna, Tafelberg, 300 m, Natte struik-savanne in het Z. deel, 23 Feb. 1961, *Kramer & Hekking 3308* (U). VENEZUELA. BOLÍVAR: Cerro Pitón, 400 m, cordillera Epicara, Río Chicanan, 3 Sep. 1962, *Maguire & Steyermark 53563* (NY, VDB); same locality, 9-11 Sep. 1962, *Maguire et al. 53713* (NY, VDB); Cerro Guaiquinima, Salto del Río Szczerbanari, 1-2 km río arriba del Salto Szczerbanari, 750 m, 20-25 Jan. 1977, *Steyermark et al. 113116-A* (US, VDB, VEN); cumbre de Auyan-tepui, sector oriental, al norte de la Misión de

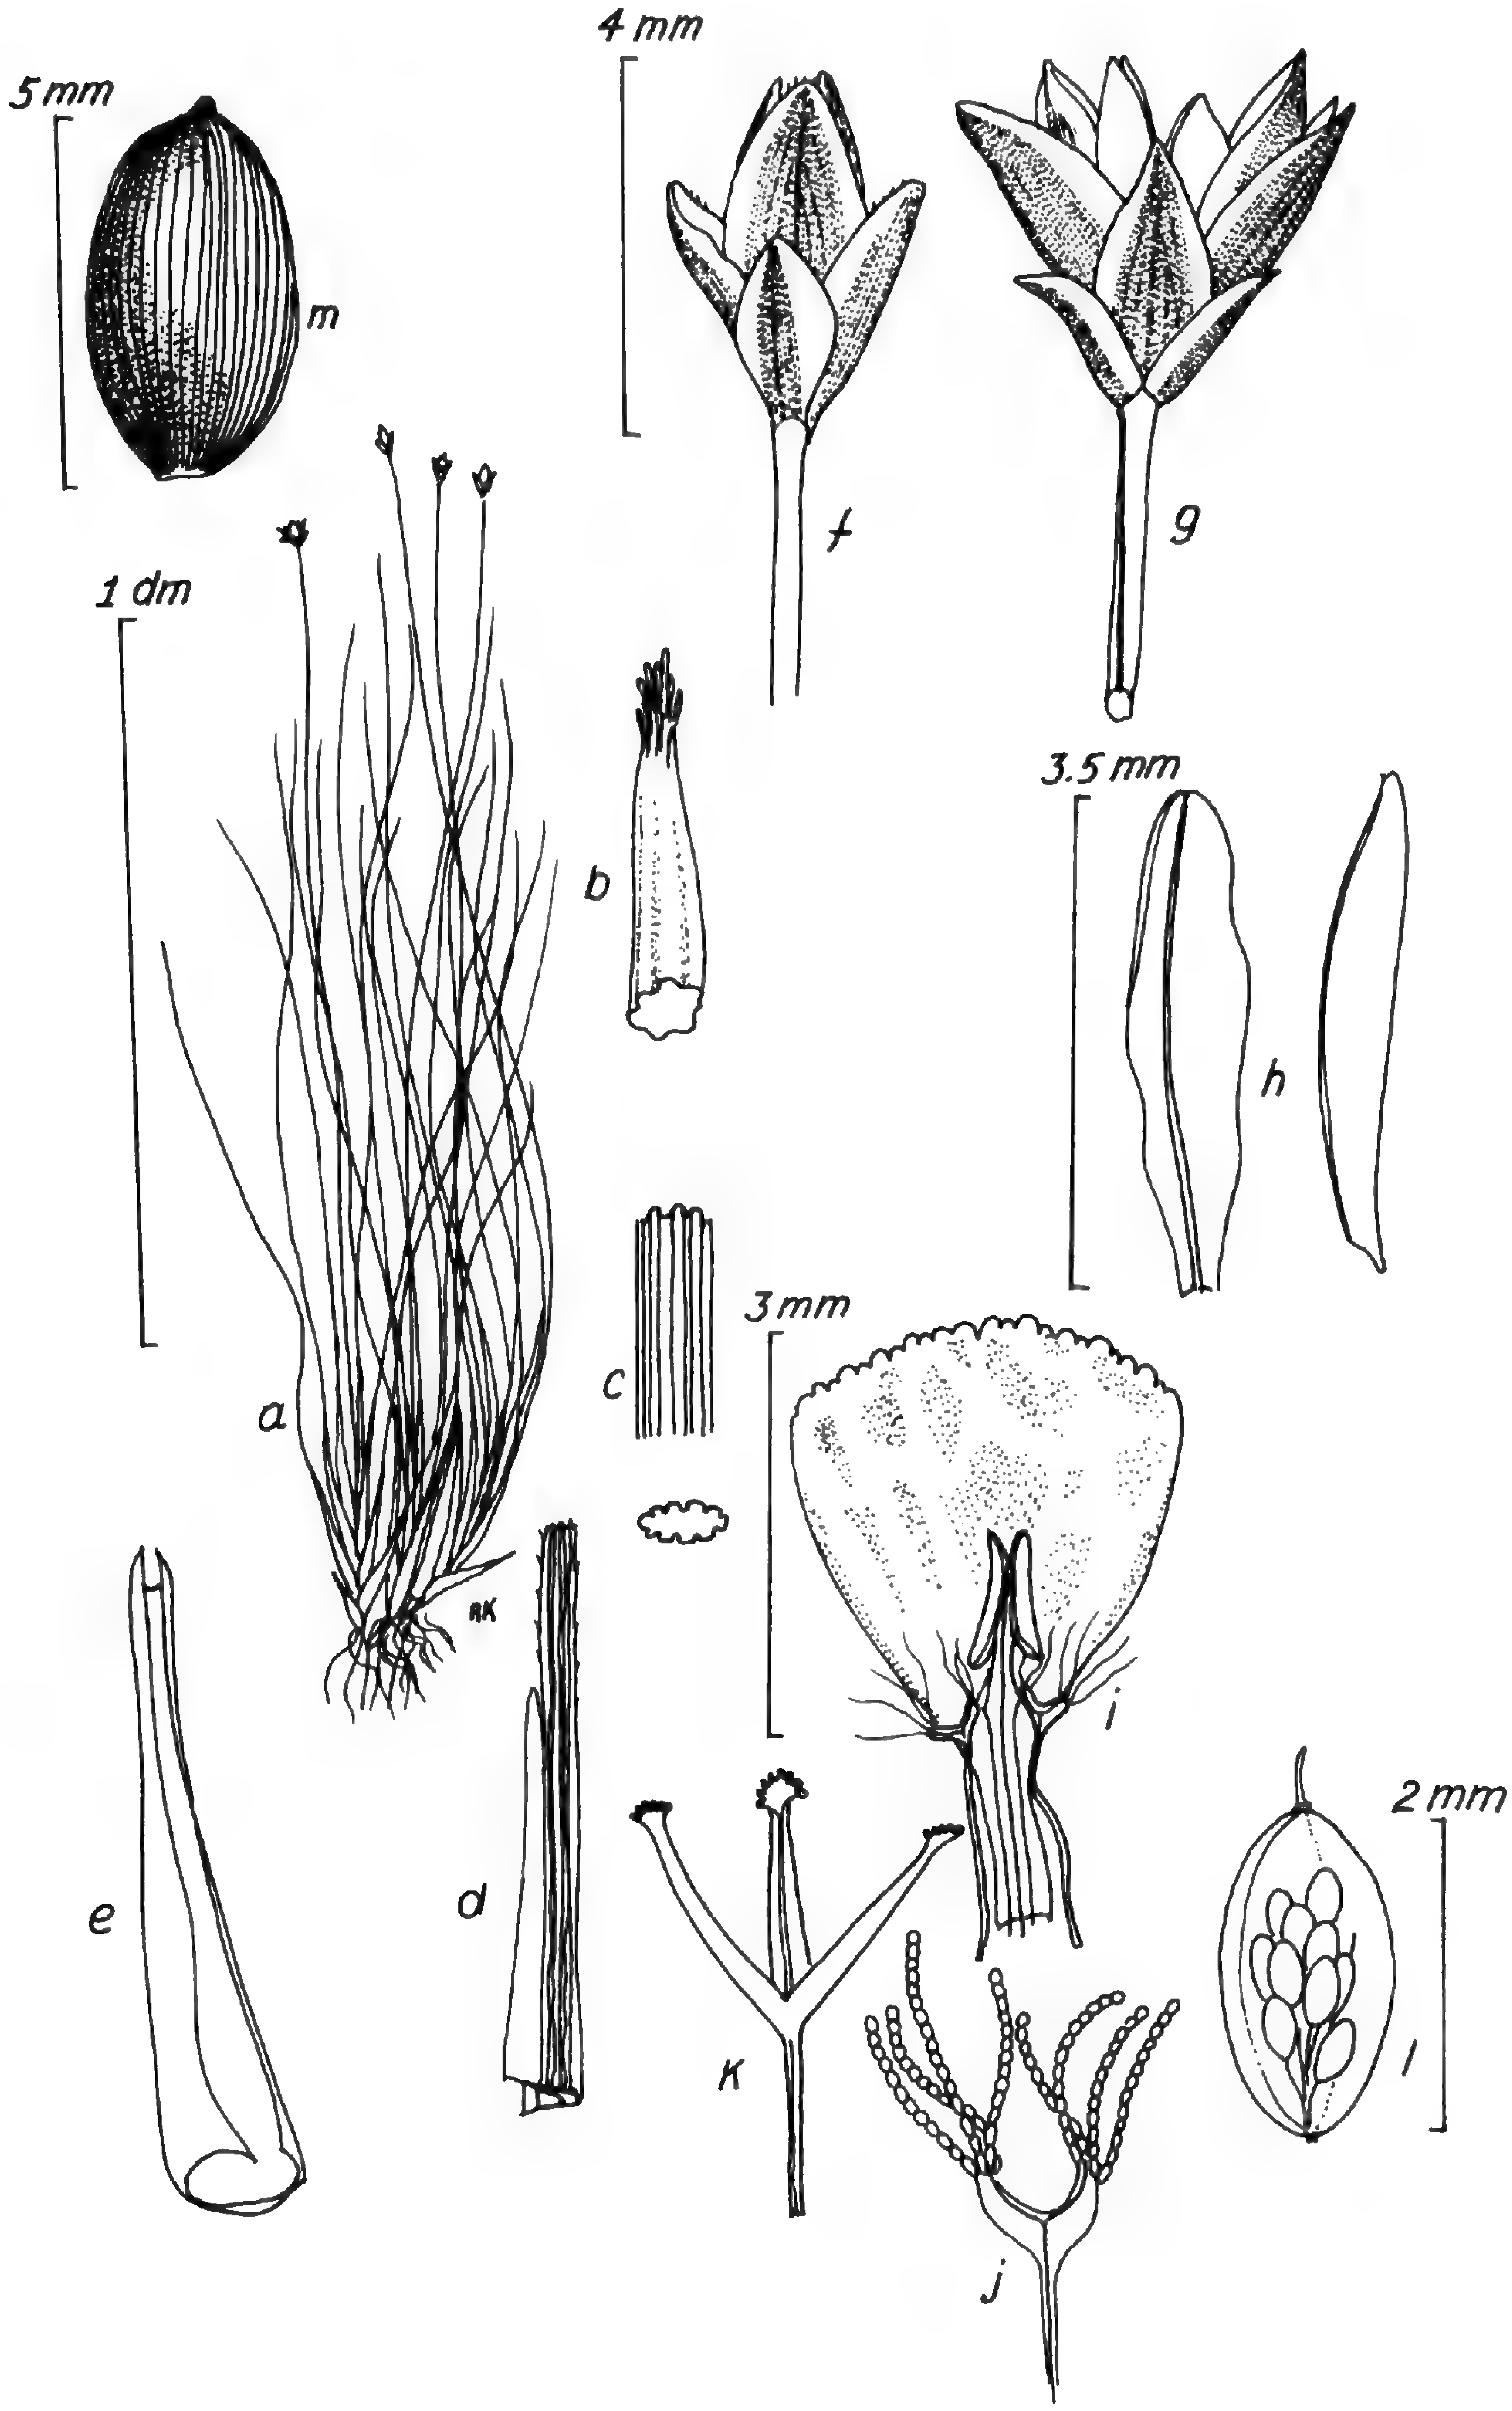

FIGURE 49. Xyris cyperoides *(from holotype of* X. epicarae*).—a. Habit sketch.—b. Leaf apex.—c. Leaf at midblade.—d. Leaf at blade-sheath junction.—e. Leaf base.—f. Spike at anthesis.—g. Spike past anthesis.—h. Lateral sepal.—i. Petal and stamen.—j. Staminode.—k. Stylar apex.—l. Capsule, one valve removed.—m. Seed.*

Camarata, 2,140 m, 28 Feb. 1978, *Steyermark et al. 116133* (MO, VDB, VEN).

In the spike this resembles *X. guianensis* Steud., but it is definitely longer-leaved in relation to scape, and the lateral sepal keels are entire.

50. Xyris toronoana Kral, sp. nov. TYPE: Venezuela. Bolívar: Distr. Piar, Macizo del Chimantá, sector centro-meridional. Amplio valle ubicado entre el borde nororiental del Torono-tepui y la sección central del Chimantá-tepui, drenando hacia el Sur, ca. 6°16′N, 62°09′W, ± 2,100 m, 11–15 Feb. 1985, *O. Huber, Teuvo Ahti & J. J. Pipoly 10,223* (holotype, VEN; isotypes, K, MYF, NY, US, VDB). Figure 50.

Herba humilis, perennis, glabris, caespitosa, rhizomate crassa, brevi, subverticali. Radices fibrosa. Folia linearis, (2–)4–7 cm longa, erecta vel leviter expansa, vaginis scaporum parum longiora. Laminae foliorum principalium compressae, planae vel leviter tortae, 0.9–1.2 mm latae, vaginis ca. 2-plo longiores, longitudine paucinervosae, atrovinosae; apices gradatim contracti, incurvato-acuti, leviter incrassati, ad marginem incrassati, papillosi; margines leviter incrassati, minute ciliati vel scabriduli; vaginae carinatae, integrae, eligulatae, stramineae, infime abrupte dilatatae, marginibus in laminas gradatim contractis. Vaginae scaporum multicostatae, laxae, tortae, laminis brevibus. Scapi recti vel aliquantum flexuosi, torti, 1.2–1.5 dm alti, olivacei, distaliter leviter compressi, ca. 1 mm lati, acute bicostati, costis scabridis. Spicae anguste obovoideae vel ellipsoideae, 5–7 mm longae, ferrugineae, pauciflorae, bracteis laxe imbricatis, distaliter minute papillosis, matricibus tenuibus, ad marginem valde laceratis, ferrugineis vel roseolis. Bracteae steriles 2–4, subdecussatae, ca. 5 mm longae, paro infimo anguste ovato, ca. 5 mm longo, valde carinato, areis dorsalibus anguste linearibus, paro intimo ovato, solum ad apicem carinato, areis dorsalibus brevilinearibus. Bracteae fertiles oblongae, ca. 4, 6–7 mm longae, naviculares, distaliter carinatae, areis dorsalibus linearibus, ca. 3 mm longis. Sepala lateralia libera, inaequilatera, anguste lanceolata, 5.5–6.5 mm longa, acuta, leviter curvata; ala carinali integra. Laminae petalorum angustae obovatae, ca. 5 mm longae, luteolae, anguste rotundatae. Staminodia bibrachiata, brachiis longipenicillatis. Anthera oblongae, sagittatae, 1.5 mm longae; filamenta ca. 0.7–1 mm longa. Capsula anguste ellipsoidea, 3 mm longa; placenta basalis. Semina numerosa, anguste ovoidea, acuminata, 0.6–0.7 mm longa, translucida, ferruginea, longitudine subtiliter multicostata.

Low, densely cespitose, smooth herb, the rhizome thick, short, subvertical; roots fibrous. Leaves linear, (2–)4–7 mm long, erect to slightly spreading, a little longer than the scape sheaths. Principal leaf blades flattened, sometimes slightly twisted, 0.9–1.2 mm wide, about twice as long as the sheaths, few-nerved, dark red-brown; tips gradually narrowed, incurved-acute, slightly thickened, the margins thickened, papillose; blade margins slightly thickened, minutely ciliate to scabridulous; sheaths carinate, entire, eligulate, stramineous, abruptly dilated below, the margins gradually narrowed into the blades. Scape sheaths multicostate, loose, twisted, short-bladed. Scapes straight or somewhat flexuous, twisted, 1.2–1.5 dm high, olivaceous, slightly compressed distally, ca. 1 mm wide, acutely bicostate, the costae scabrid. Spikes narrowly obovoid to ellipsoid, 5–7 mm long, ferrugineous, few-flowered, the bracts loosely imbricate, minutely papillose distally, the matrix thin, strongly lacerate at margin, ferrugineous or roseolate. Sterile bracts 2–4, subdecussate, ca. 5 mm long, the lower pair narrowly ovate, ca. 5 mm long, strongly carinate, with narrowly linear dorsal areas, the upper pair ovate, carinate only at apex, the dorsal areas short-linear. Fertile bracts oblong, ca. 4, 6–7 mm long, navicular, distally carinate, the dorsal areas linear, ca. 3 mm long. Lateral sepals free, inequilateral, narrowly lanceolate, 5.5–6.5 mm long, acute, slightly curvate; carinal keel entire. Petal blades narrowly obovate, ca. 5 mm long, yellow, narrowly rounded. Staminodia bibrachiate, the branches long-penicillate. Anthers oblong, sagittate, 1.5 mm long; filaments 0.7–1 mm long. Capsule narrowly ellipsoid, 3 mm long; placenta basal. Seeds numerous, narrowly ovoid, acuminate, 0.6–0.7 mm long, translucent, red-brown, finely ribbed longitudinally.

The low habit and the delicate, lacerate, thin bracts with narrow, dark dorsal areas would appear to put this species into the *X. tenella* complex. However, the sheaths are entire and long-ciliate, and the lateral sepals are entire and more inequilateral. The tufts of erect or ascending, thick rhizomes covered with leaf bases are distinctive. It is known from only the type locality.

51. Xyris aquatica Idrobo & Lyman B. Smith, Caldasia 6: 206, fig. 9. 1954. TYPE: Colombia. Amazonas: on rocks in swift brook, Río Caquetá, vic. La Pedrara, Apr. 1924, *R. E. Schultes 5855* (holotype, COL; isotypes, GH, US). Figure 51.

Slender, lax, glabrous, soft-based, cespitose and profusely slenderly, scaly-rhizomatous perennial, 3–5 dm high but usually bent and trailing in rapid shoalwater. Leaves very soft, variously elongate, to 3 dm long, polystichous, the sheath less than ½ as long as the blade, the margins entire, the base lustrous pale brown or greenish brown, ecarinate, dilated, narrowing gradually upward to a prominent, narrow, scarious ligule to 6 mm long, there abruptly contracted to a terete, filiform, fluted blade up to ca. 0.5 mm thick. Scape sheath inflated-tubular, tan, opening distally to a bifid or acute apex, bladeless. Scapes straight or slightly flexuous, terete, 1–1.5 mm thick, ecostate. Spikes ovoid, narrowly ellipsoid or cylindric, 1–1.5 cm long, blunt, of many spirally imbricate, brown bracts, the sterile bracts several, ovate, slightly smaller than and grading into the fertile bracts, these oblong to obovate, ca. 5 mm long, broadly rounded, entire, backs rounded-folded, ecarinate, with ovate-elliptic, greenish dorsal areas. Lateral sepals free, curvate, subequilateral, linear-oblanceolate, 4–5 mm long, acute, lustrous brown with a narrow, dark, firm keel, this scabrociliate from below middle to apex, or subentire. Petal blades obovate, ca. 5 mm long, the broadly rounded apex erose. Staminodia bibrachiate, the branches lineal, densely penicillate-pubescent from base to tip. Anthers oblong, ca. 1.5 mm long, the upper ⅓ bifid; filaments ca. 2 mm long. Capsule obovoid, ca. 2 mm long or longer; placentation basal-central; valves eseptate. Seeds numerous, ovoid, ca. 0.5 mm long, apiculate, reddish brown, translucent, finely irregularly longitudinally striate or subreticulate by anastomosing ribs.

Distribution. A true aquatic, usually in shallow rapid shoalwaters of streams in the Amazon Basin of northern Brazil, southeastern Colombia, and T. F. Amazonas in Venezuela.

Additional specimens examined. BRAZIL. AMAZONAS: Mun. Humaitá, estrada Humaitá—km 150, a 65 km ao Sul, rio de nome Branco, *L. O. A. One of the few truly aquatic *Xyris*, the whole plant is apparently often totally submersed. Nearest it morphologically are *X. apureana* Kral & Lyman B. Smith and *X. spathacea* Lanjouw, but these usually have smaller spikes, often flatter leaf blades, and larger seeds.

52. Xyris apureana Kral & Lyman B. Smith, Ann. Missouri Bot. Gard. 69: 412–414, fig. 1a–i. 1982. TYPE: Venezuela. Apure: Dist. Pedro Camejo, ca. 2 km S of Caño la Cochina de La Pica along main road south of Paso de San Pablo to the Río Cinaruco, 70 m, 2 Mar. 1979, *G. Davidse & A. C. Gonzalez 15948* (holotype, US; isotypes, MO, VDB, VEN). Figure 52.

Perennial, lax, densely cespitose, smooth herb. Rhizomes slender, short to elongate, ascending (relating to degree of depth in substrate). Roots slender. Leaves linear, 1.5–3 dm long, erect or slightly spreading, subdistichous, longer than the scape sheaths; blades 5–10 times longer than sheaths, 1–2 mm wide, flat, straight, longitudinally few–many-nerved and sulcate, flattened from base to middle, terete or subterete toward apex, the

0.6 mm thick, olive to reddish. Spikes several-flowered, elliptic, 5–6 mm long, acute, the bracts subdecussate, navicular or convex, ecarinate but medially 1-nerved, scarious, ferrugineous, erose; sterile bracts 4, the lowest pair at least ½ as long as the spike, oblong, the inner pair ovate, ca. 3 mm long; fertile bracts ovate, to 4 mm long, with reddish-scarious, entire to somewhat lacerate borders; dorsal area lanceolate, reddish brown or brown, ½ as long as or equal to the bract. Lateral sepals lanceolate, strongly inequilateral, ca. 4 mm long, acute; carinal keel narrow but strong, entire. Petal blades broadly obovate, 2.5–3 mm long, yellow, broadly rounded, strongly erose, cuneate. Staminodia bibrachiate, the branches long-penicillate. Anthers oblong, ca. 1.5 mm long, retuse and sagittate, slightly longer than the slender filaments. Capsule oblong, planoconvex, 2.5 mm long, amber, longitudinally finely multiribbed.

Distribution. Known thus far only from the type locality in Apure, Venezuela.

This subaquatic is superficially nearest *X. aquatica* on the one hand, and *X. spathacea* on the other. From both it differs in its more slender rhizomes, flattened leaves, and longer seeds.

53. Xyris stenostachya Steyerm., Fieldiana, Bot. 28(1): fig. 16K, L. 1951. TYPE: Venezuela. T. F. Amazonas: among rock outcrops, 100 m, Sanariapo, Río Orinoco, *J. Steyermark 58437* (holotype, F; isotypes, NY, US). Figure 53.

Solitary or cespitose, soft-based annual mostly 1–4 dm high, the stems contracted. Leaves spreading flabellately, 0.3–1.5 dm long; sheaths ½ as long as blades or shorter, tan or roseate, papillose or rugulose, narrowing evenly to blades, there producing a short, erect, scarious ligule, or ligule absent; blades linear-ensiform, flat, 1–3 mm wide, tapering above middle, then abruptly incurved-acute, the tip callused, the margins proximally tuberculate-scabrid or papillose, distally mostly smooth, the edges thickened-rounded, the surfaces maroon to yellow-green, papillose-rugose at least proximally and finely nerved. Scape sheaths as long as or shorter than leaves, tubular, twisted, costate, with short, erect blades similar to leaves. Scapes straight or flexuous, twisted, ca. 0.5 mm wide, subterete or angulate distally, striate and/or with 1–few costae and strongly scaberulous-rugose. Spikes lineal or lance-lineal, flattened, 1.5–5 cm long, the numerous distichous bracts navicular with strong dorsal areas medially unicostate and with narrowly rounded backs; sterile bracts ca. 4, the lowermost sometimes with long-excurrent, green dorsal areas, more often smaller than the fertile bracts and grading into them; fertile bracts lance-ovate to broadly oblong, 5–6 mm long, conduplicately rounded-folded around floret, apically broadly rounded, the margins scarious, a broad, pale entire to (in age) lacerate border around the large, lance-elliptic dorsal areas. Lateral sepals free, subequilateral, elliptic-linear or lance-linear, ca. 4 mm long, apically subulate or narrowly acute, tan, the narrow, firm, brown keel ciliolate to entire. Corollas gamopetalous, the limb ca. 5 mm long, the lobes lance-oblong, ca. 4.5 mm long, yellow, the apex acute, the margin remotely lacerate-dentate. Staminodes subsessile in sinuses of corolla, bibrachiate, the fleshy narrow branches with numerous penicillate, clavate hairs. Anthers lance-oblong, 0.5 mm long, on fleshy filaments ca. 1 mm long. Capsules narrowly ellipsoid, ca. 3 mm long; placentation basal. Seeds 3–6, some on funicles longer than themselves, fusiform, 1–1.5 mm long, amber, finely longitudinally striate, often with an irregular retinaculum of wider, reddish brown ridges.

Distribution. Wet sandy savanna, pools and seeps on and around granite outcrops, southeastern Colombia (not on basis of specimens but on basis of similar geology immediately across the Río Orinoco from an abundance of Venezuelan localities) eastward into the Orinoco of Territorio Federal Amazonas and Estado Bolívar, Venezuela.

Selected specimens examined. VENEZUELA. T. F. AMAZONAS: 12.5 km S of Puerto Ayacucho, 50 m, 2 Nov. 1971, *Davidse 2829A* (MO); la margen derecha del Río

This distinctive little annual is most abundant in the shallow pools or seeps in and around granitic lajas within the Venezuelan "piedmont" above the Great Bend of the Orinoco. No other species remotely resembles it. The pale yellow flowers open in the morning.

54. Xyris stenocephala Malme, Bih. Kongl. Svenska Vetensk.-Akad. Handl. 22, Afd. 3(2): 18, tab. 1, fig. 1. 1896; Smith & Downs, Fl. Bras. 9(II): 105–106, tab. 34, figs. 1020–1027. 1968. TYPE: Brazil. Mato Grosso: lugar aberto, pantanoso, cerca de Santa Ana da Chapada, 700–800 m, 28 Nov. 1894, *Malme 1426* (holotype, S; isotype, MO; phototype, F). Figure 54.

Perennial or annual, solitary or cespitose, glabrous plants (1–)2–5 dm high, the stem short. Leaves erect to spreading flabellately, 5–20 cm long; sheaths at least ½ as long as blades, entire, strongly nerved, carinate, pale brown to deep red-brown, sometimes papillose, often with a strong, deep brown, lustrous costa, tapering gradually from a slightly dilated base to the blade, there eligulate or with a short, scarious ligule; blades narrowly linear, flattened, twisted, 1–4 mm wide, strongly nerved, tapering gradually to an incurved-acute, cartilaginous-bordered tip, the margins thickened, lustrous, pale to deep brown, rarely scabrociliate, the sides pale green to reddish green or ferrugineous. Scape sheaths shorter than principal leaves, tubular, ferrugineous, multicostate below, apically with short, flat blades. Scapes flexuous and twisted, distally terete, 1–1.5 mm thick, rarely unicostate with scabrid costa, mostly just striate, olivaceous to green-brown. Spikes mostly ellipsoid, 1–2 cm long, acute, smooth, of several tightly spirally imbricate bracts; sterile bracts usually 4, the lowest pair oblong, carinate, slightly shorter than the fertile bracts, these broadly ovate or obovate to suborbicular, 4.5–5.5 mm long, strongly convex and ecarinate, broadly to narrowly rounded apically, the matrix pale to deep lustrous brown with a pale, thin, entire to erose border, the dorsal areas pale to deep green or brown, ovate, large but subapical, with a strong but fine midrib. Lateral sepals free, strongly inequilateral, strongly curved, acute, ca. 4 mm long, the keel firm and broad, ciliolate from near base to tip; petal blades ca. 4 mm long, obovate, broadly rounded, lacerate, yellow. Staminodia bibrachiate, the branches densely penicillate. Anthers oblong, ca. 1.5 mm long, on filaments 0.5–0.7 mm long. Capsule planoconvex, obovoid, 2–2.5 mm long, the placenta basal. Seeds few, fusiform-curvate, 1.2–1.7 mm long, dark red-brown, translucent, strongly beaked, longitudinally multicostate.

Distribution. Wet, rocky and/or sandy savanna, mostly in northern Brazil, in Amazonas, Pará, Mato Grosso, and with an outlier in São Paulo.

Selected specimens examined. BRAZIL. AMAZONAS. "Estrada do Estanho," road to Igarapé Preto, 60 km SE of Transamazon Hwy., in white-sand savanna, 2 July 1979, *Calderon et al. 2737* (INPA, US, VDB). FIGURE 54. Xyris stenocephala (Silva et al. 82).—*a. Habit sketch.—b. Leaf tip.—c. Leaf blade-sheath junction.—d. Leaf base.—e. Spike.—f. Fertile bract.—g. Lateral sepal.—h. Petal blade, stamen.—i. Stylar apex.—j. Staminode.—k. Outline of capsule, showing placentation.—l. Seed.*

This taxon is most abundant in low-elevation, white-sand savanna, particularly in eastern Mato Grosso (Norte) and southwestern Pará but should be looked for in comparable areas north of the Amazon. It borders on larger forms of *X. paraensis*, particularly var. *longiceps*, but differs markedly in its glassy-bordered leaf blades and markedly larger seeds. Populations appear to be sometimes annual, although they are usually perennial. Perhaps this is a matter of degree of disturbance of habitat, particularly the very seasonal nature of moisture in white-sand savanna. Or it could be that crowding produces a depauperate, annual habit.

55. Xyris cylindrostachya Kral & Wanderley, sp. nov. TYPE: Brazil. Amazonas: Mun. Presidente Figueiredo, "Campina das Pedras," ubicada en el km 115, de la Rodovia BR-174 (Manaus–Caracaraí), en el lado oriental del Igarapé das Lajes, 1°58'S, 60°02'W, ca. 100 m, 29–30 June 1985, *O. Huber & Luíz O. Adao Teixeira 10663* (holotype, INPA; isotypes, NY, VDB). Figure 55.

Herba perennis, glabra, densicaespitosa; radices graciles. Caules breves. Folia principalia anguste linearia, 10–30 cm longa, erecta vel flabellate expansa, vaginis scaporum longiora. Laminae foliorum compressae, leviter tortae, 0.8–1 mm latae, vaginis 2–4-plo longiores, longitudine indistincte nervosae, dilute virides; apices gradatim contracti, subulati, subteretes; margines leviter incrassati, integri, pallide brunneoli vel ad basin fuscobrunneoli, persaepe nitidi; vaginae carinatae, integrae, rufobrunneolae vel ferrugineae, papillosae, multicostatae, infime gradatim dilatatae, tum margines in laminas gradatim contractae, ad apicem anguste acutam ligulam scariosam usque ad 2 mm longam efferentes. Vaginae scaporum tortae, tubulosae, multicostatae, ferrugineae, ad apicem apertae, laminis brevibus. Scapi recti vel flexuosi, torti, 30–60 cm longi, ad apicem teretes, 1–2 mm crassi, persaepe rubelli, subtiliter striolati. Spicae ovoideae vel (vulgo) cylindricae, 1–3 cm longae, 5–7 mm crassae, obtusae, multibracteatae, brunneolae, bracteis arcte spiraliter imbricatis. Bracteae steriles 2–4, oblongae, ca. 3 mm longae, naviculares, carinatae, in fertiles leviter transientes; bracteae fertiles late ovatae vel suborbiculatae, 4–5 mm longae, integrae, ecarinatae, valde convexae, areis dorsalibus late ovatis, fuscoviridibus. Sepala lateralia libera, valde inaequilatera, curvata; ala carinali lata, a basi ad apicem ciliolata. Laminae petalorum obovatae, 4–4.5 mm longae, luteolae, latae rotundatae, laceratae. Staminodia bibrachiata, brachiis dense longipenicillatae. Antherae oblongae, sagittatae, 1.5 mm longae; fila ca. 1 mm longa. Capsula planoconvexa, obovoidea, ca. 2 mm longa; placenta basalis. Semina curvato-ellipsoidea, apiculata, 0.6–0.7 mm longa, pallide rufobrunneola, translucida, longitudine subtiliter multicostata.

Smooth, densely cespitose perennial with slender roots. Stems short. Principal leaves narrowly linear, 10–30 cm long, erect to spreading flabellately, longer than the scape sheaths. Blades of leaves flattened, slightly twisted, 0.8–1 mm wide, 2–4 times as long as the sheaths, indistinctly nerved, pale green; tips gradually narrowed, subulate, subterete; margins slightly thickened, entire, pale brown to red-brown at base, often shining; sheaths carinate, entire, red-brown to ferrugineous, papillose, multicostate, gradually dilating below, then gradually narrowed into the blades, at apex producing a narrow, acute, scarious ligule to 2 mm long. Sheaths of scapes twisted, tubular, multicostate, ferrugineous, open at apex, with short blades. Scapes straight to flexuous, twisted, 30–60 cm long, terete toward apex, 1–2 mm thick, usually reddish, finely striate. Spikes ovoid to (commonly) cylindric, 1–3 cm long, 5–7 mm thick, obtuse, multibracteate, brownish, the bracts tightly spirally imbricate. Sterile bracts 2–4, oblong, ca. 3 mm long, navicular, carinate, but slightly grading into the fertile bracts; fertile bracts broadly ovate to suborbicular, 4–5 mm long, entire, ecarinate, strongly convex, with broadly ovate, red-green dorsal areas. Lateral sepals free, strongly inequilateral, curvate; carinal keel broad, ciliolate from base to apex. Petal blades obovate, 4–4.5 mm long, yellow, broadly rounded, lacerate. Staminodes bibrachiate, the branches densely long-penicillate. Anthers oblong, sagittate, 1.5 mm long; filaments ca. 1 mm long. Capsule planoconvex, obovoid, ca. 2 mm long; placenta basal. Seeds curvate-ellipsoid, apiculate, 0.6–0.7 mm long, pale red-brown, translucent, longitudinally finely multicostate.

Paratypes. BRAZIL. AMAZONAS: Mun. Presidente Figueiredo: "Campina das Pedras," ubicada en el km 115 de la Rodovia BR-174 (Manaus–Caracaraí), en el lado oriental del Igarapé das Lajes, 01°58'S, 50°02'W, ca. 100 m, 29–30 June 1985, *O. Huber & Luíz O. Adao Teixeira 10652* (INPA, NY, VDB). PARÁ: Mun. Oriximiná, Campos do Ariramba, campinas inundaveis da margem do Rio Jaramacarú; afloramento arenitoco; 80 m, 8 June 1980, *G. Martinelli 6847* (INPA, NY, VDB).

This species most closely resembles *X. stenocephala* Malme, differing from it primarily in its longer, narrower leaf blades, these less strongly bordered and more inconspicuously nerved. The spikes are very different, being mostly narrowly cylindric and blunt (rather than ellipsoid and acute). The

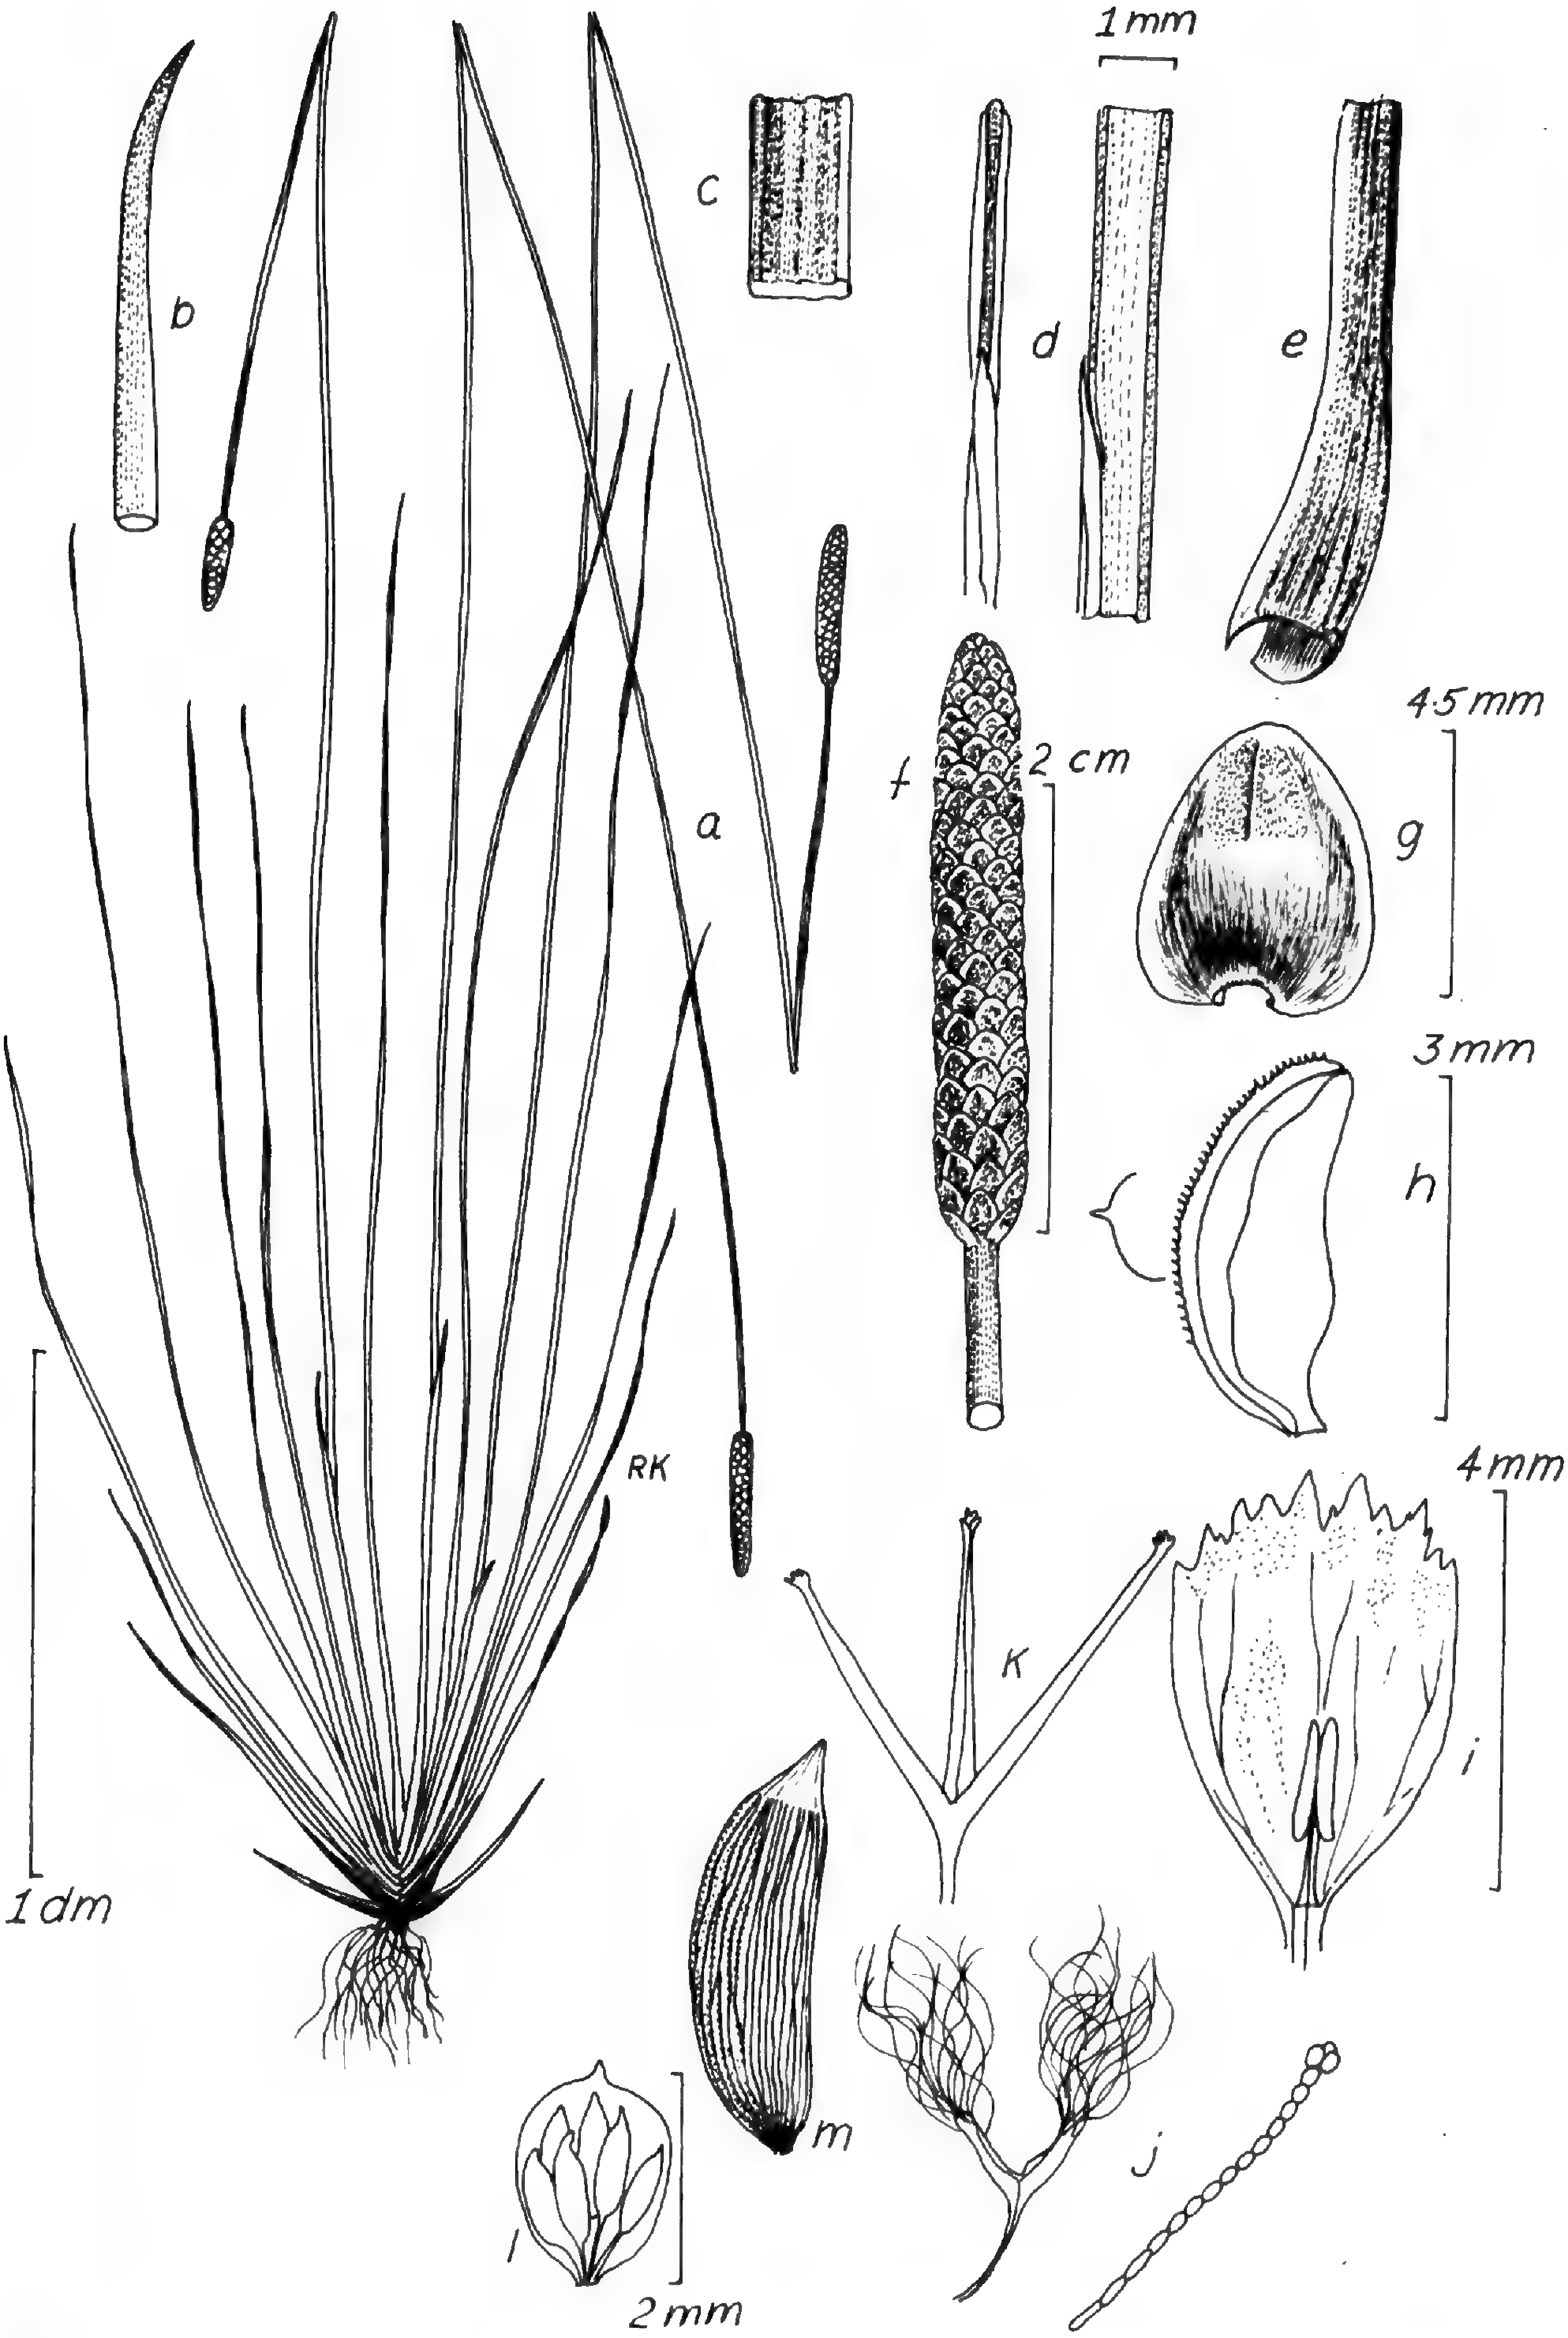

FIGURE 55. Xyris cylindrostachya *(from the type)*.—*a. Habit sketch.*—*b. Leaf apex.*—*c. Leaf midblade sector.*—*d. Two views of leaf blade–sheath junction.*—*e. Leaf base.*—*f. Spike.*—*g. Fertile bract.*—*h. Lateral sepal.*—*i. Petal blade and stamen.*—*j. Staminode and enlarged beard hair.*—*k. Stylar apex.*—*l. Capsule outline, placentation.*—*m. Seed.*

lateral sepals are somewhat shorter and the seeds are significantly shorter (0.6–0.7 mm long vs. 1.2–1.7 mm long). These two species, along with the varieties of *X. paraensis*, *X. savannensis*, *X. uleana*, and *X. mima*, appear to provide an abundant (and perhaps sometimes intergrading) display on the white-sand campinas of the Amazonian savannas. Dense stands are often depauperate and mixed, escaping standard measures and aggravating the taxonomic problem.

56. Xyris brachysepala Kral, sp. nov. TYPE: Brazil. Pará: Serra dos Carajás, 2 km W of AMZA camp N-5, 6°04′S, 50°08′W, ca. 700 m, scrubby vegetation on ferric rock outcrops, moist low areas, 13 May 1982, *C. R. Sperling, R. S. Secco, M. Condon, A. L. Mesquita, B. G. S. Ribeiro & L. R. Marinho 5641* (holotype, INPA; isotypes, MG, NY, VDB). Figure 56.

Planta humilis, annua, glabra. Radices filiformes. Folia linearia, solum basalia, (2–)8–12 cm longa, erecta vel leviter expansa, vulgo vaginis scaporum longiora. Laminae folia principalium vaginis 3–4-plo longiores, spongiosae, tortae, a basin leviter compressae, alter teretes, ca. 0.5 mm crassae, viridulae, ad apicem abrupte contractae, obtusatae; vaginae subcarinatae, roseolae, integrae, in laminas gradatim convergentibus aut ad apicum ligulam scariosam curtam latam fascientibus, infime gradatim expansae. Vaginae scaporum laxae, plerumque apertae, rectae, carinatae, sine laminis aut laminis brevis. Scapi subteretes, subfiliformes, plus minusve spiraliter torti, ca. 0.5 mm crassi, striati. Spicae lanceoloideae vel anguste ellipsoideae, 1–2 cm longae, anguste acutae, pluriflorae, bracteis arcte spiraliter imbricatis, tenuibus, pallide rufobrunneolis, marginibus tenuissimis, latis, pallidis, integris; bracteae steriles 4, oblongae vel anguste ovatae, 2–4 mm longae, acutae vel obtusae, obscure carinatae, fertilibus leviter breviores; bracteae fertiles ovatae, 5–7 mm longae, ad apicem carinatae, acutae; area dorsalis anguste triangulati, subapicales, virides, tum brunneolae, 2–3 mm longae. Sepala lateralia libera, curvata, aequilatera, lanceolata, 2–2.3 mm longa, acuta; ala carinali angusta, integra. Laminae petalorum obovatae, ca. 2 mm longae, luteolae, ad apicem erosae. Antherae oblongae, profunde bifidae et sagittatae, ca. 0.5 mm longae; filamenta plana, ca. 0.5 mm longa. Staminodia parce penicillatis. Capsula leviter dorsali-ventraliter compressa, obovoidea, ca. 3 mm longa; placenta basalis. Semina numerosa, ellipsoidea, 0.6 0.8 mm longa, pallide rufobrunneola, longitudine subtiliter multistriata, translucida.

The plant low, annual, smooth. Roots filiform. Leaves linear, strictly basal, (2–)8–12 cm long, erect to slightly spreading, mostly longer than the scape sheaths. Blades of the principal leaves 3–4 times longer than the sheaths, spongy, twisted, slightly compressed at base, otherwise subterete, ca. 0.5 mm thick, greenish, abruptly narrowed at apex, obtuse; sheaths subcarinate, roseate, entire, narrowing gradually to blades or producing a broad short scarious ligule at apex, gradually dilating below. Scape sheaths lax, commonly open, straight, carinate, without blades or with short blades. Scapes subterete, subfiliform, ± spirally twisted, ca. 0.5 mm thick, striate. Spikes lanceoloid to narrowly ellipsoid, 1–2 cm long, narrowly acute, several-flowered, with bracts tightly spirally imbricate, thin, pale red-brown, the margins very thin, broad, pale; sterile bracts 4, oblong to narrowly ovate, 2–4 mm long, acute to obtuse, obscurely carinate, slightly shorter than the fertile bracts; fertile bracts ovate, 5–7 mm long, carinate at apex, acute; dorsal areas narrowly triangular, subapical, green then (later) brown, 2–3 mm long. Lateral sepals free, curvate, subequilateral, lanceolate, 2–2.3 mm long, acute; keel narrow, entire. Petal blades obovate, ca. 2 mm long, yellow, erose at apex. Anthers oblong, deeply bifid and sagittate, ca. 0.5 mm long; filaments plane, ca. 0.5 mm long. Staminodia sparsely penicillate. Capsule slightly compressed dorsiventrally, obovoid, ca. 3 mm long; placentation basal. Seeds numerous, ellipsoid, 0.6–0.8 mm long, pale red-brown, longitudinally finely lined, translucent.

Distribution. Known only from grassy, rocky, acid savannas in Pará, Brazil.

Additional specimens examined. BRAZIL. PARÁ: Marabá, N$_5$, arredores do lago, canga, 14 May 1982, *R. S. Secco, C. Sperling, M. Condon, A. Mesquita, B. Gilberto R. & L. Marinho 155* (MG, NY, VDB); Marabá, Serra dos Carajás, N-4, proximo a transição para a mata, campo rupestre, solo de canga e na mata de terra firme, 20 Mar. 1984, *A. S. L. da Silva, N. A. Rosa, R. P. Bahia & M. R. Santos 1920* (MG, NY, VDB); Marabá, arredores estrada p/N$_1$ transição campo natural/veg. canga, 17 May 1982, *R. S. Secco, C. Sperling, M. Condon, A. Mesquita, B. Gilberto R. & Lucival Marinho 226.*

This little annual bears a strong resemblance to longer-spiked forms of *X. paraensis* Poeppig ex Kunth, but its leaves differ by

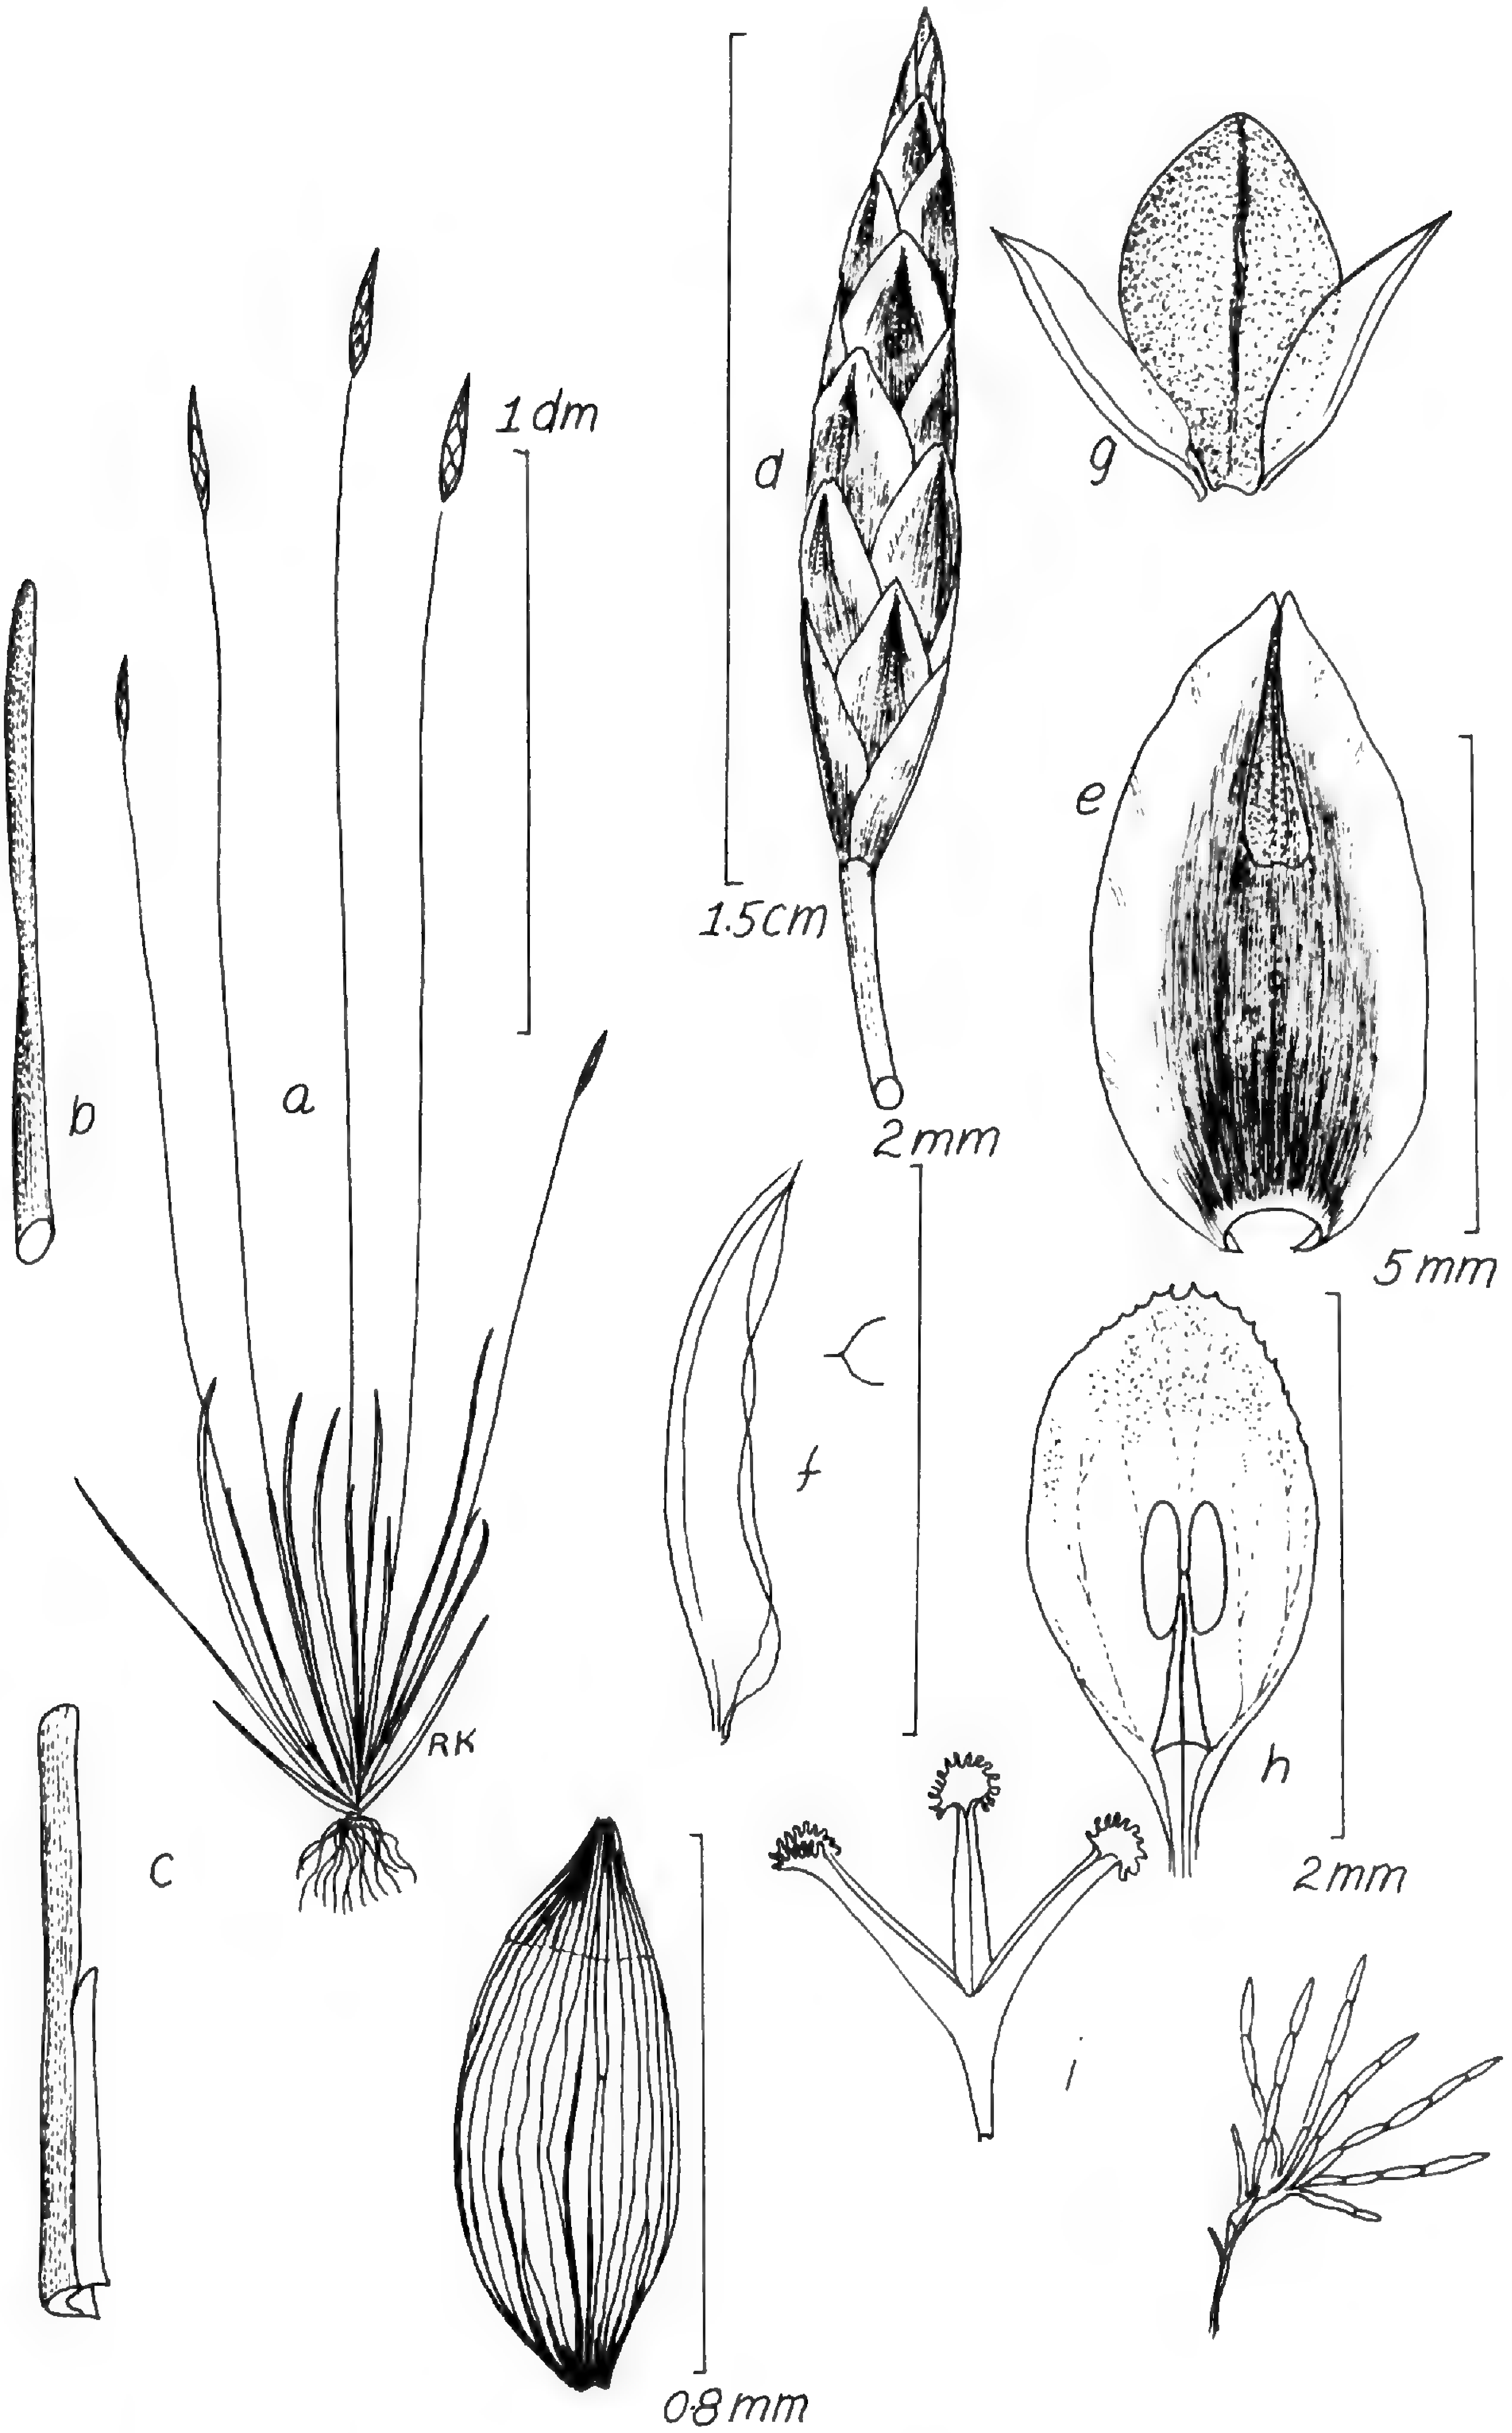

FIGURE 56. Xyris brachysepala (Sperling et al. 5641).—*a. Habit sketch.—b. Leaf apex.—c. Leaf blade-sheath junction.—d. Spike.—e. Fertile bract.—f. Lateral sepal.—g. Capsule, showing length relative to lateral sepals.—h. Petal blade, stamen.—i. Stylar apex.—j. Staminode.—k. Seed.*

being distinctly terete apically; the fertile bracts are larger but distinctly thinner with distinctive broad, pale thin borders and with narrower dorsal areas, these forming a carina subapically on the bract. The lateral sepals are much more reduced than is typical in most *Xyris*.

57. **Xyris paraensis** Poeppig ex Kunth, Enum. Pl. 4: 9. 1843. TYPE: Brazil. Pará: "Rio Para, *Poeppig, 1832*" (lectotype, B; phototype, US).

Three varieties are delimited by Smith & Downs (Arq. Bot. Estado São Paulo, nov. ser. 4(2): 28. 1966) for this complex whose greatest diversity appears to be in Pará, Brazil. The varieties *paraensis* and *longiceps* are thus far the only two collected within the area of my concentration, so, while the key below is to three, I am putting down full descriptions only of those two.

KEY TO VARIETIES OF *XYRIS PARAENSIS*

1a. Lateral sepals as viewed from the side broadly oblong and blunt; spikes predominantly ovoid to nearly round, mostly 5 mm long or less .... 57A. *X. paraensis* var. *paraensis*

1b. Lateral sepals as viewed from the side lanceolate and acute; spikes ellipsoid to cylindric, at maturity predominantly 1–2 cm long.

  2a. Spikes less than 5 mm thick, mostly cylindric, the bracts spiraled in 3–4 ranks .... 57B. *X. paraensis* var. *longiceps*

  2b. Spikes 5 mm thick, mostly ellipsoid, the bracts spiraled in 5–6 ranks .... 57C. *X. paraensis* var. *polystachya*

57A. **Xyris paraensis** var. **paraensis.** Figure 57A.

Cespitose or solitary, mostly low and slender, mostly annual plants 0.5–4 dm high, the roots fine, the stems short. Leaves erect to spreading flabellately, the principal leaves 2–15(–20) cm long, the sheaths eciliate, stramineous to brown or red-brown, narrowing gradually from base to blade, with or without a narrowly triangular ligule to 1 mm long; blades flattened, slightly if at all twisted, 1–2.5 mm wide, narrowly linear, tapering gradually to an acute, usually calloused apex, the margins thin, unbordered, usually smooth, the surface green to maroon, very finely nerved and smooth. Scape sheaths shorter than principal leaves, the base tubular, multicostate, keeled, distally open and with a prominent leaflike blade, or the blade short, erect, fleshy. Scapes straight or slightly flexuous, twisted, distally terete, 0.3–0.8 mm thick, mostly ecostate but finely striate, smooth. Spikes ovoid to subglobose, 0.3–0.5 mm long, mostly acute, the several to many bracts in a spiral, tightly imbricate, with strong, unicostate dorsal areas, the few sterile bracts grading slightly larger into the fertile bracts, these obovate, low-auriculate, ca. 2–4 mm long, the apex broadly to narrowly rounded, entire or erose, the backs rounded, convex, ecarinate. Lateral sepals free, inequilateral, 3–4 mm long, strongly curvate, broadly acute to obtuse, the wide keel coarsely and irregularly ciliate to ciliolate. Petal blades broadly to narrowly obovate, 2–4 mm long, yellow, the broadly rounded apex lacerate. Staminodia bibrachiate, the flat, narrow branches sparsely penicillate terminally. Anthers broadly oblong, 0.5–0.7 mm long, the parallel sacs separated by wide connective, the filaments 0.5–0.7 mm long. Capsules broadly obovoid, somewhat compressed dorsiventrally, ca. (1–)2 mm long, the placentation basal, the valves without septa. Seeds ellipsoid or fusiform on long funicles 0.5–0.9 mm long, apiculate, amber, longitudinally distinctly but finely ribbed.

Distribution. Sandy savannas of mostly white sand, locally abundant, rare in Belize; rare in southern Venezuela; frequent to common eastward across Guyana to French Guiana and contiguous northern Brazil.

Additional specimens examined. BELIZE: pure sand savanna, Hattieville, 7 May 1972, *Dwyer & Pippin 10981* (MO); wet sand, Manatee Lagoon, 5 Jan. 1906, *Peck 269* (GH); All Pines, *Schipp S-131* (BM, F, GH, MO, NY). BRAZIL. This variety is the most often misidentified as *X. savanensis*, which may produce smooth-leaved forms (var. *glabrata*). Careful examination should solve the problem in that *X. savanensis* produces no staminodial beard. If flowers are lacking, then seed characters help in that the shorter seed of *X. savanensis* has the typical truncate and apiculate apex. On the other hand, *X. mima* would pose a problem except for its uniquely comose seed tips.

57B. Xyris paraensis var. longiceps (Malme) Lyman B. Smith & Downs, Ark. Bot. Estad. São Paulo 4(2): 28. 1966. *Xyris longiceps* Malme, Rec. Trav. Bot. Neerl. 9: 131. 1912. TYPE: "in arenosis inundatis Para (Suriname), *Splitgerber 978*" (lectotype, U). Figure 57B.

Xyris leptostachya Malme, Rec. Trav. Bot. Neerl. 9: 132. 1912.

Leaf blades often longer and wider than in the typical variety, the leaf tips tending to be less thickened, sharper, the habit sometimes perennial or the plants harder-based, more strongly tufted. Spike outline narrower, mostly narrowly ellipsoid, or fusiform-cylindric, mostly 1–2 cm long, rarely wider than 0.4 cm. Lateral sepals predominantly lance-ovate, acute, the narrow keels rather uniformly ciliolate. Seeds mostly 0.5–0.6 mm long.

Distribution. Sandy savanna of mostly low-elevation, southeastern Colombia and eastward (occasionally) into Surinam (abundantly) and northern Brazil (Amapa, Pará).

Selected specimens examined. Colombia. amazonas: frequent in Araracuara savannas, Rio Caquetá, 400 m, 6 Sep. 1959, *Maguire et al. 44162* (NY). vaupés: Río Vaupés, cachivera de Yuruparí, 400 m, 24–26 Oct. 1952, *García-Barriga 14936* (NY); Río Kudujarí: Cerro Yapoboda, ca. 450 m, 5–6 Oct. 1951, *Schultes & Cabrera 14379-a* (GH); Río Negro, San Felipe & vic., *Schultes & Cabrera 18116* (GH); Circasia: savanna, ca. 800 ft., Nov. 1951, *Schultes & Cabrera 19647*. Teresita de Kavanayen, 1,220 m, *Steyermark 60823A* (US).

The petiolelike constriction of old bracts in this and in var. *polystachya* is created by infolding of the auriclelike bract base. The closest affinity of this variety, other than to var. *polystachya*, is to *Xyris cuatrecasana*, which may turn out to be merely a part of the latter.

58. Xyris mima Lyman B. Smith & Downs, Proc. Biol. Soc. Wash. 73: 250, fig. 4. 1960. TYPE: Brazil. Pará: campo arenoso artificial, Missão Nova, Rio Cururu, região do Alto Rio Tapajos, 12 July 1959, *Egler & Raimundo 791* (holotype, US). Figure 58A, B.

Xyris trisperma Kral & Lyman B. Smith, Phytologia 53: 433–434, fig. 1a–i. 1983. TYPE: Venezuela. Bolívar: cumbre de Cerro Guaiquinima, Salto del Río Szczerbanari (Río Carapo), 1–2 km río arriba del Salto Szczerbanari, 750 m, 20–25 Jan. 1977, *J. A. Steyermark et al. 113149* (holotype, VEN; isotypes, US, VDB).

Solitary or cespitose, slender, mostly low annual (0.5–)1–3 dm high, the stems contracted. Leaves erect or spreading flabellately, 0.5–2.5 dm long; sheaths entire, strongly keeled, less than ½ as long as blades, gradually narrowing from the dilated base to the blade, there producing a narrowly triangular erect ligule to 0.5 mm long or eligulate, the surfaces tuberculate-rugose (rarely smooth); blades narrowly linear to linear-gladiate, strongly flattened, sometimes slightly twisted, apically incurved-acute, the margins tuberculate-scabrid (rarely entire), the surfaces verrucose-scabrid (rarely smooth), strongly nerved, deep reddish green to maroon. Scape sheaths slightly to much shorter than principal leaves, reddish brown below, multicostate, tubular, twisted, opening distally, strongly keeled, producing a short blade. Scapes straight or slightly flexuous, twisted, papillate or rugoscabrid, dull green, subterete to slightly compressed distally, thus oval or elliptic in cross section, bicostate, the costae strong, usually strongly tuberculate-scabrid or papillate. Spikes ovoid to short-cylindric or narrowly ellipsoid, 3–15 mm long, mostly acute, of few–several tightly spirally imbricate bracts with narrow but distinct, usually greenish dorsal areas, the sterile bracts mostly 4–6, the lowest the smallest, slightly shorter than the fertile bracts, ovate, keeled or carinate, grading into the fertile bracts, these mostly broadly ovate to broadly obovate, 4–4.5 mm long, the apex broadly rounded, sometimes emarginate, the margins entire, the backs ecarinate, convex. Lateral sepals free, slightly inequilateral, oblong-curvate, ca. 3–3.5 mm long, the broad, thin keel ciliate mostly from just below middle to the blunt apex. Petal blades broadly obovate, ca. 4 mm long, yellow, the broadly rounded apex lacerodentate. Staminodia bibrachiate, the narrow, flat branches penicillate-ciliate distally with clavate hairs. Anthers broadly oblong, ca. 0.5 mm long, shallowly bifid, deeply sagittate, on filaments ca. 0.6–0.7 mm long. Capsules broadly obovoid, planoconvex, ca. 2.5 mm long, the placentation basal, the valves lacking septa. Seeds numerous, mostly ellipsoid to fusiform, ca. 1 mm long, pale amber, the tip with a cone of pale bristles, the body finely longitudinally lined.

Distribution. Low, mostly white-sand savanna, Amazonian Brazil and contiguous Venezuela (Bolívar), locally abundant. Known in 1960 but only from the type collection.

Selected specimens examined. BRAZIL. AMAZONAS: Transamazon Highway, 9 km W of Rio dos Pombos, ca. 1.5 km E of Igarapé dos Oombos and ca. 64 km E of the Aripuanã, 19 June 1979, *Cleofé Calderón et al. 2577* (INPA, US, VDB); base of Serra Araca, 0–3 km south of Central Massif, 3 km E of Rio Jauari, 7 Feb. 1984, *Prance et al. 28870* (INPA, NY, US). MATO GROSSO: R. Juruena, Cachoeira São Simaõ, 21 May 1977, *Rosa & Santos 1959* (INPA, US, VDB). PARÁ: Mun. Itaituba, arredores da Base Aerea do Cachimbo, proximo ao destacamento km 6 da estrada que vai para o aeroporto km 794, 25 Apr. 1983, *Silva et al. 82* (INPA, NY, VDB). VENEZUELA. BOLÍVAR: topotype of *X. trisperma* Kral & Smith, 20–25 Jan. 1977, *Steyermark et al. 113222, 113445* (VDB, VEN).

This species very much resembles *X. savanensis* and *X. paraensis* var. *paraensis*. From the former it differs in its strongly bicostate scape, staminodia with beards, and longer and scaly-comose seeds. From the latter it usually differs in being much more scabrid of foliage and in its bicostate scape and longer, comose-tipped seeds.

In the Venezuelan locality the Steyermark discovery, found in a mixed population with *X. savanensis*, seemed to depart enough from

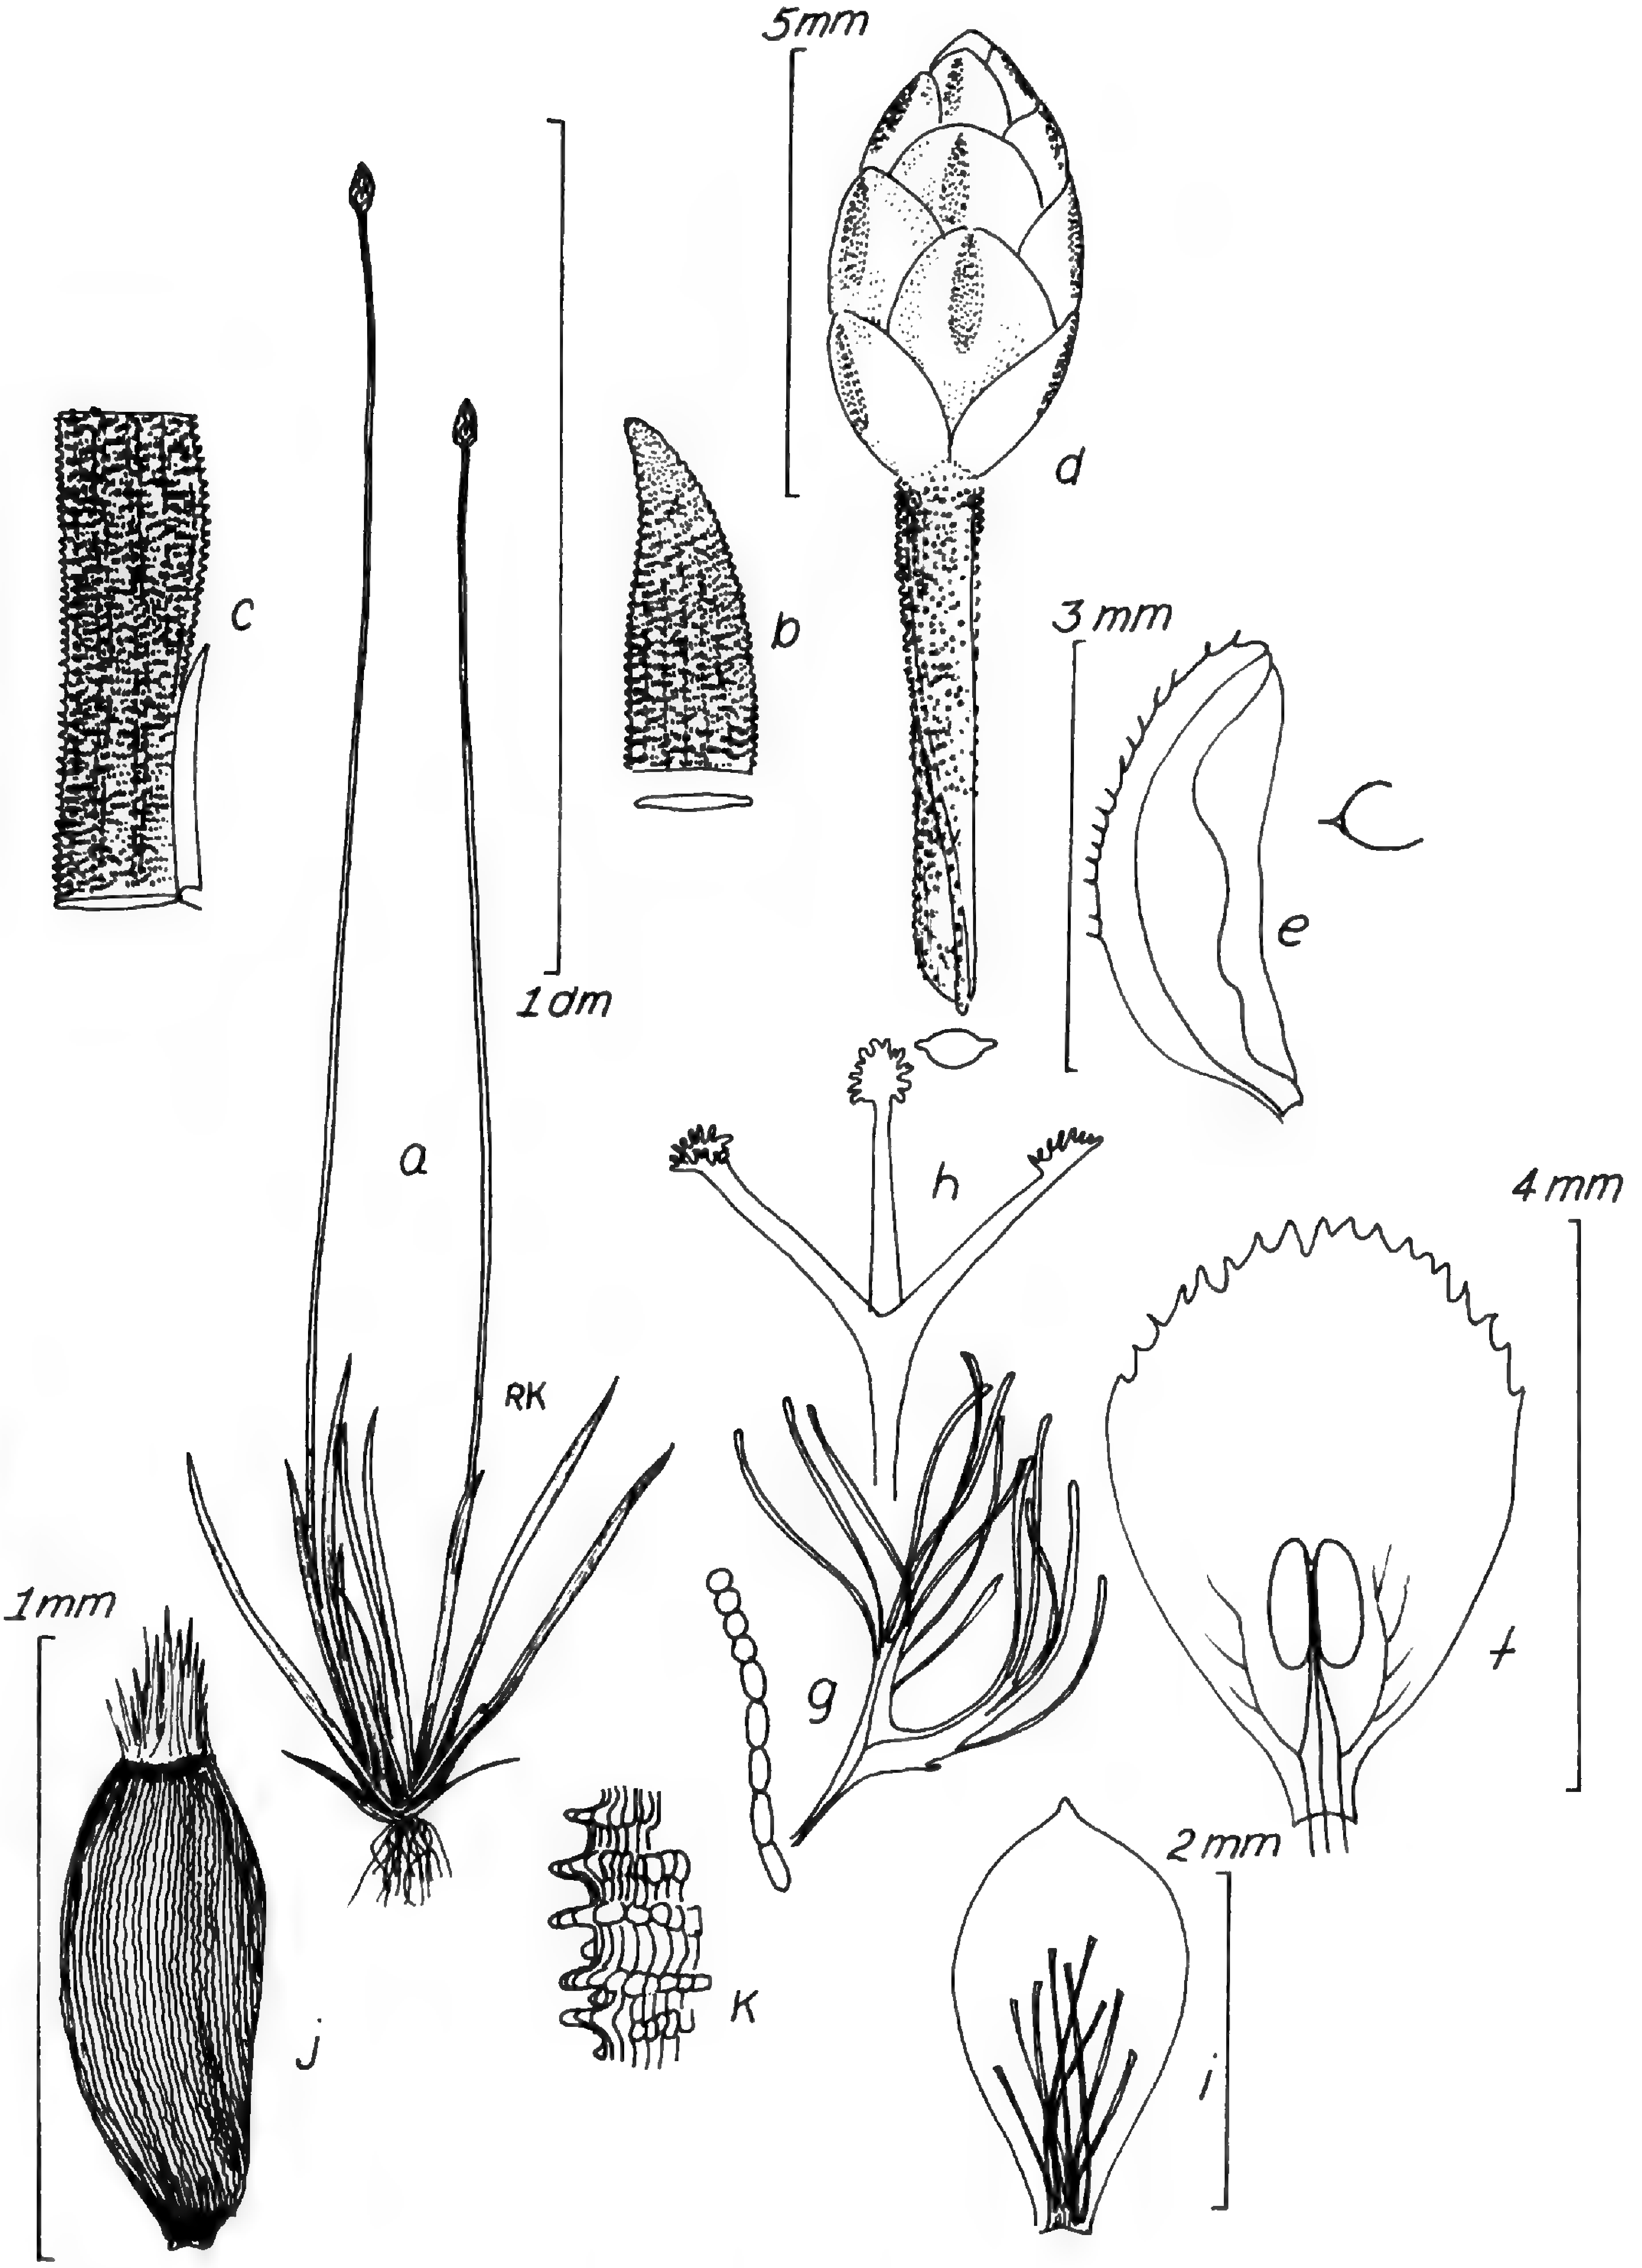

FIGURE 58A. Xyris mima (Steyermark & Dunsterville 113445).—*a. Habit sketch.—b. Leaf tip.—c. Leaf sheath–blade junction.—d. Spike, upper scape.—e. Lateral sepal.—f. Petal blade, stamen.—g. FIGURE 58B. Xyris mima *(from type of* X. trisperma*)*.—*a. Habit sketch.—b. Leaf tip.—c. Leaf blade, sector at midblade.—d. Leaf sheath–blade junction.—e. Leaf base.—f. Spike, upper scape.—g. Midscape sector.—h. Lateral sepal.—i. Seed.*

the original Smith and Downs description in regard to seed and sepal characters to warrant description. Cryptic species are not rare in *Xyris*, should be looked for, and at least for now deserve some place in the literature if only to acquaint readers with the "motion" in such a genus. However, it now appears, on consultation with a larger series of *X.*

mima, that *X. trisperma* fits within the former.

59. Xyris rubrolimbata Heimerl, Ann. k. k. Naturh. Hofmus. Wien 21: 70, pl. 4, figs. 4–6. 1906. TYPE: Colombia. Vaupés: moist sandy woods, Lomo, 100 km northwest of mouth of Casiquiare, Vaupés, Colombia, *Spruce 2994* (lectotype at W destroyed; isolectotype, K). Figure 59.

Low, cespitose, small but stiff annual mostly 0.5–1 dm high, the stems contracted, the roots capillary. Leaves spreading flabellately, 2–8 cm long, the sheaths from nearly as long as blades to longer, soft, strongly keeled, strongly nerved, entire, tapering gradually from the dilated base to the blades, there producing a narrowly triangular, erect, scarious ligule to 2 mm long; blades flattened, straight or rarely slightly twisted, linear-gladiate, narrowly acute, the margins cartilaginous-incrassate, usually forming a distinct, reddish brown band, the surfaces greenish gray or maroon, strongly and palely multinerved, smooth. Scape sheaths slightly shorter than principal leaves, tubular and twisted at base, striate, open toward apex, keeled, producing a short, flat, linear-triangular blade. Scapes straight or slightly flexuous, slightly twisted, terete distally, ca. 0.7 mm thick, greenish brown, striate, smooth. Spikes obovoid at maturity ca. 5 mm long, blunt, of several subdecussately arranged brown bracts with thin, usually fimbriolate margins and distinctly papillose dorsal areas; sterile bracts narrowly to broadly ovate, usually 4, the lowest pair ca. ½–⅔ as long as the spike, keeled, navicular; fertile bracts broadly obovoid, 3–3.5 mm long, the shallowly rounded or subtruncate apex aging erose, the backs slightly convex, the dorsal areas bisected by a single strong nerve. Lateral sepals strongly curvate, free, subequilateral, 2.5–3 mm long, blunt, yellow-brown, the firm, wide keel ciliolate-scabrid from ca. the middle to the apex. Petal blades obovate, ca. 3 mm long, the broadly rounded apex lacerate. Staminodia slightly bibrachiate, the broad, flat branches distally penicillate-ciliate. Capsule planoconvex, broadly obovoid, ca. 1.5 mm long, the placentation basal, the valves without septa. Seeds numerous, ellipsoid, 0.6–0.7 mm long, pale-apiculate, dark, translucent red-brown, longitudinally finely and spirally ribbed, the ribs finely beaded.

Distribution. Low Amazon caatinga, wet sand in southeastern Colombia and southwestern Venezuela, apparently rare.

Additional specimens examined. COLOMBIA. VAUPÉS: Río Guainía, Puerto Colombia (opposite Ven. Town of Maroa) and vic., ca. 800–850 ft., 31 Oct.–2 Nov. 1952, *Schultes et al. 18195* (GH). VENEZUELA. T. F. AMAZONAS: Río Negro at base of Cerro Cucuy, 2 Mar. 1944, *Baldwin 3212* (US); Maroa–Yavita rd., between Río Guianía and Caño Pimichin, at edge of bana (low Amazon caatinga) on wet white sand, 8 Oct. 1978, *Clark 6875* (NY); Maroa, 127 m, Guainía Alto Río Negro en malezas de terreno arenoso, 11 Feb. 1942, *Ll. Williams 14280* (F, US, VEN).

This little but uniformly distinctive annual xyris is so small as to be overlooked easily. It should be looked for in areas of Amazonian Brazil in places along the upper Rio Negro.

60. Xyris cuatrecasana Idrobo & Lyman B. Smith, Caldasia VI(29): 244–245, fig. 30a–d. 1954. TYPE: Colombia. Vaupés: Comisaria del Vaupés. Circasia; margenes del Vaupés, sobre granitos, 200 m, 9 Oct. 1939, *J. Cuatrecasas 7155* (holotype, COL; isotype, F). Figure 60.

Solitary or cespitose, soft-based annual to 3.5 dm high, the stem contracted. Leaves erect or slightly spreading flabellately, 8–12 cm long; sheaths ca. ½ or less as long as blades, entire, dull at base, pale red-brown or stramineous, tapering gradually to blade, there with a scarious, erect, narrow, acute ligule to 2 mm, the blades flat, ensiform-linear, 1.5–2.5 mm wide, tapering to narrowly acute apex, the margins subentire, the surfaces smooth and finely multinerved, green with strong maroon tints. Scape sheaths loose, shorter than leaves, carinate, short-bladed. Scapes lineal, straight or flexuous, slightly twisted, distally terete, ca. 1 mm thick, finely striate, ecostate, smooth. Spike ovoid-ellipsoid, ca. 1 cm long, acute, the numerous bracts tightly spirally

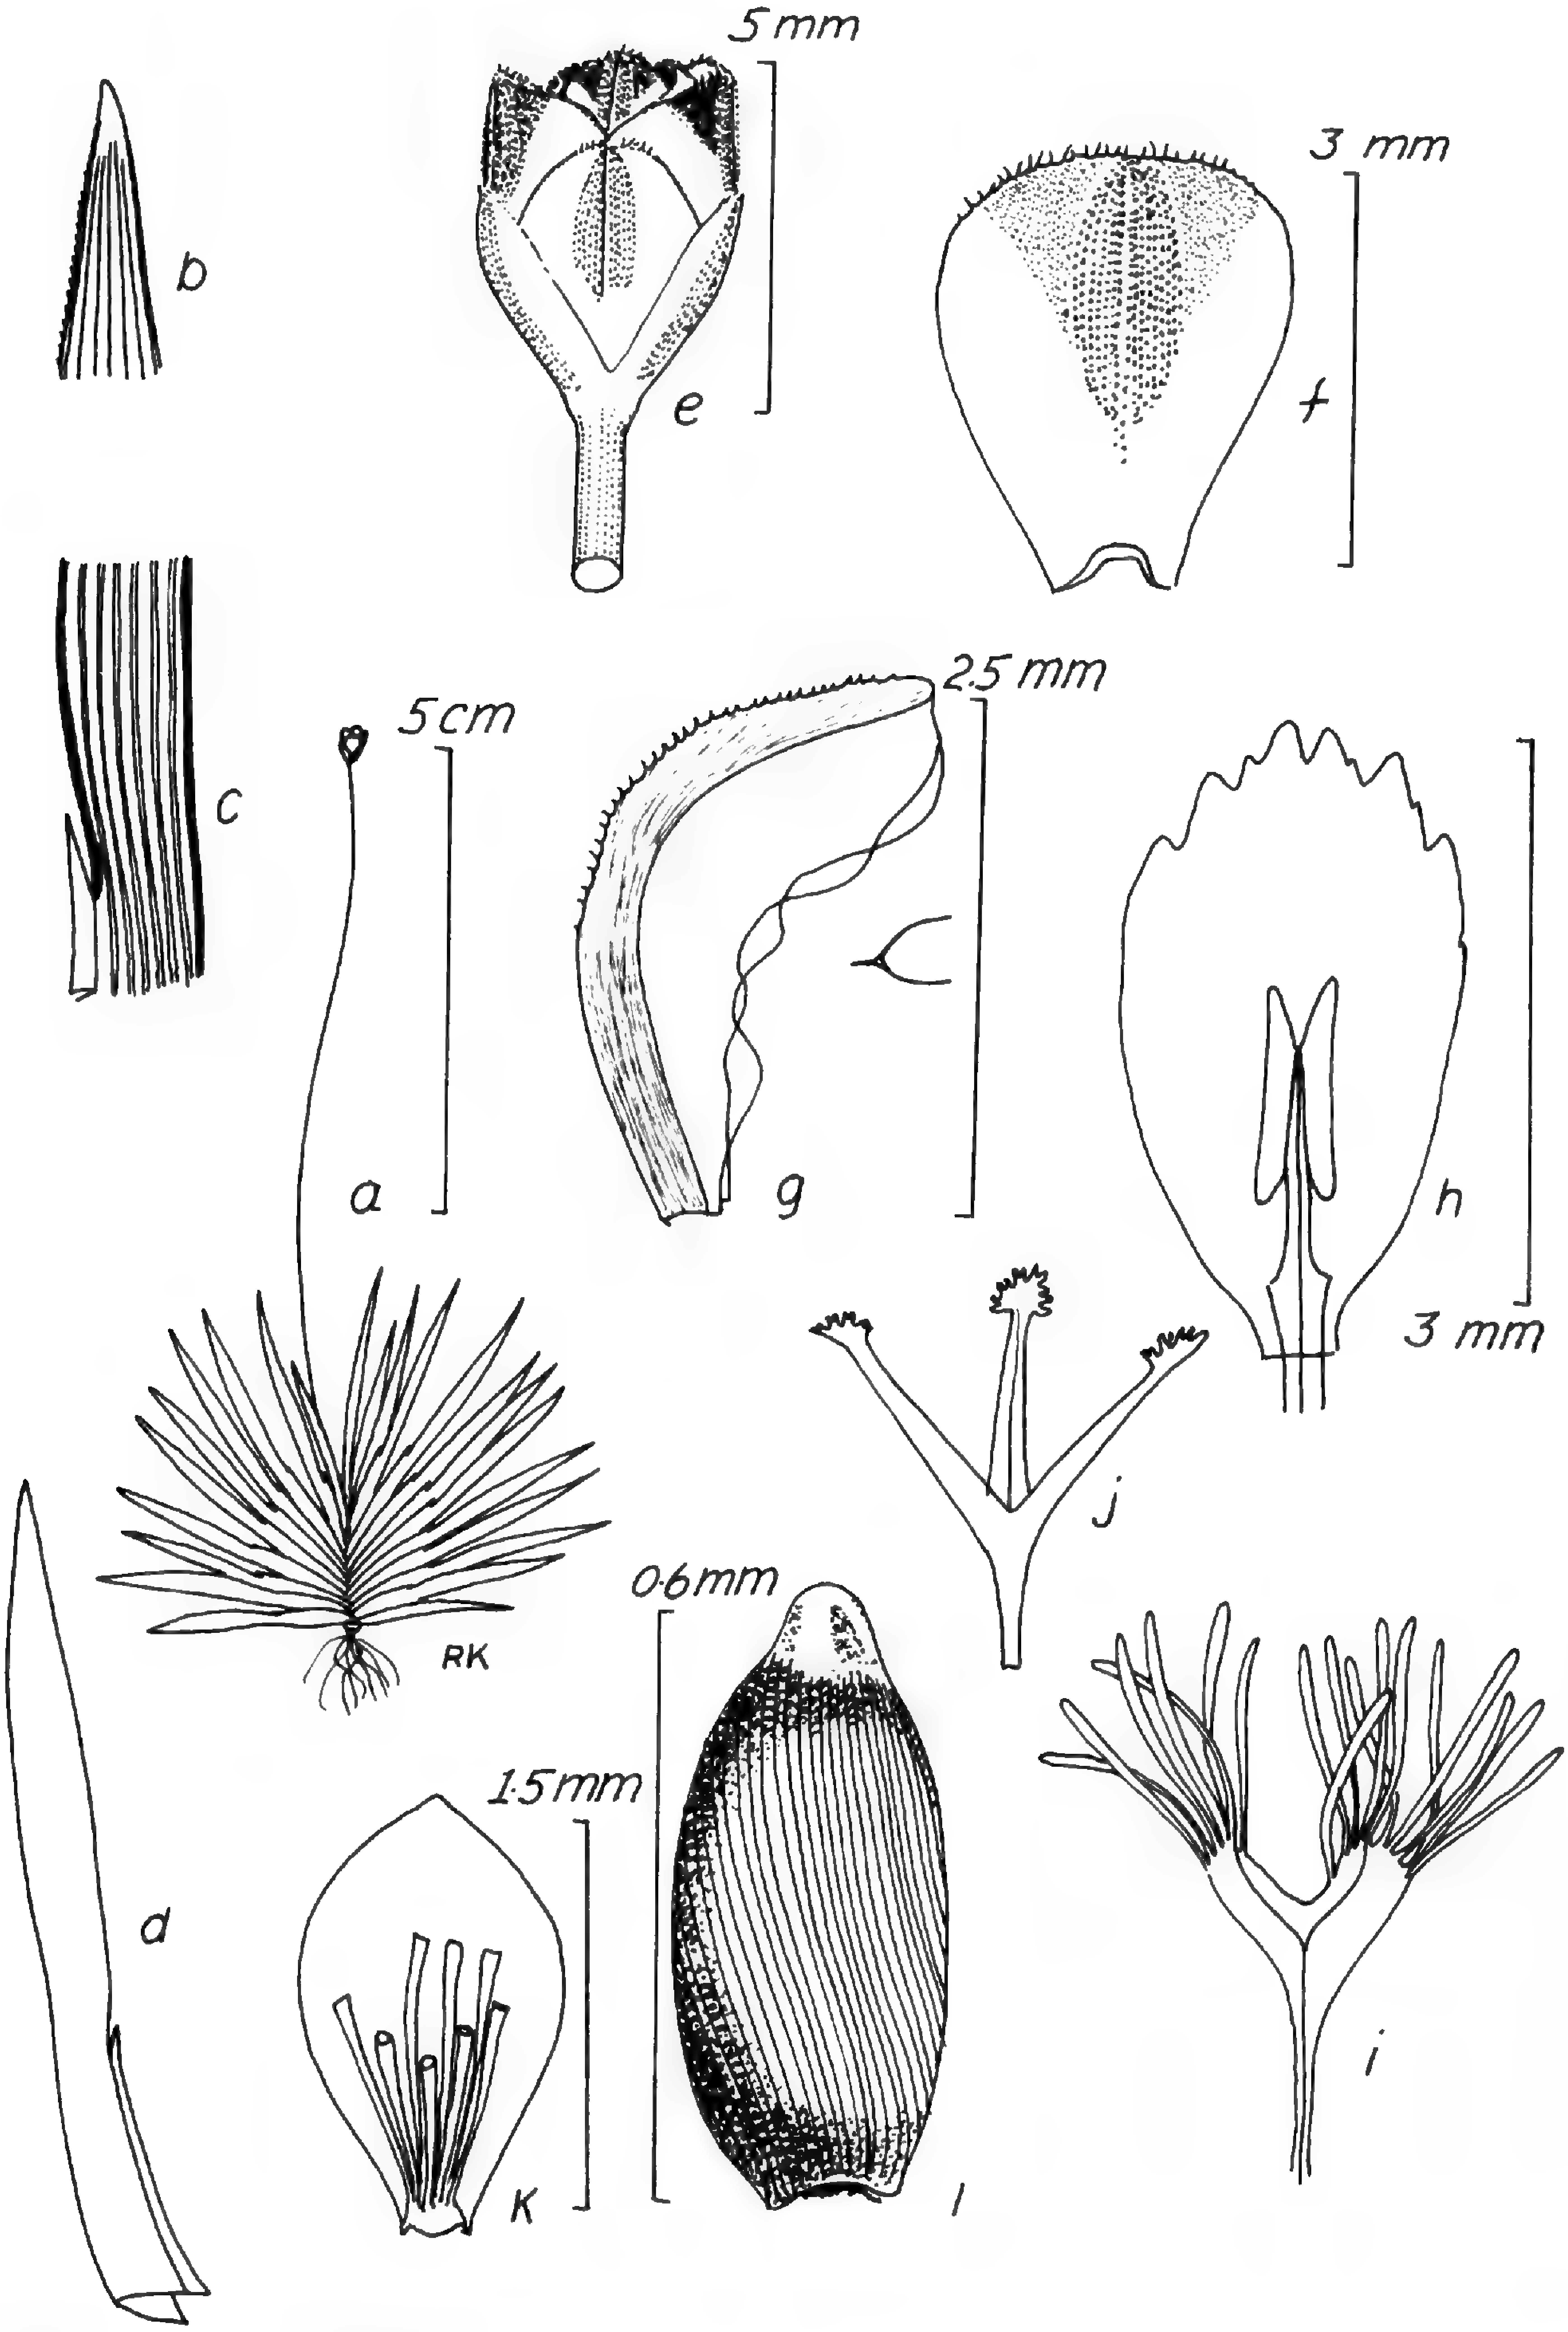

FIGURE 59. Xyris rubrolimbata (J. T. Baldwin 3212).—*a. Habit sketch.—b. Leaf apex.—c. Leaf blade-sheath junction.—d. Leaf, outlined.—e. Spike.—f. Fertile bract.—g. Lateral sepal.—h. Petal blade, stamen.—i. Staminode.—j. Stylar apex.—k. Capsule, two valves removed to show placentation.—l. Seed.*

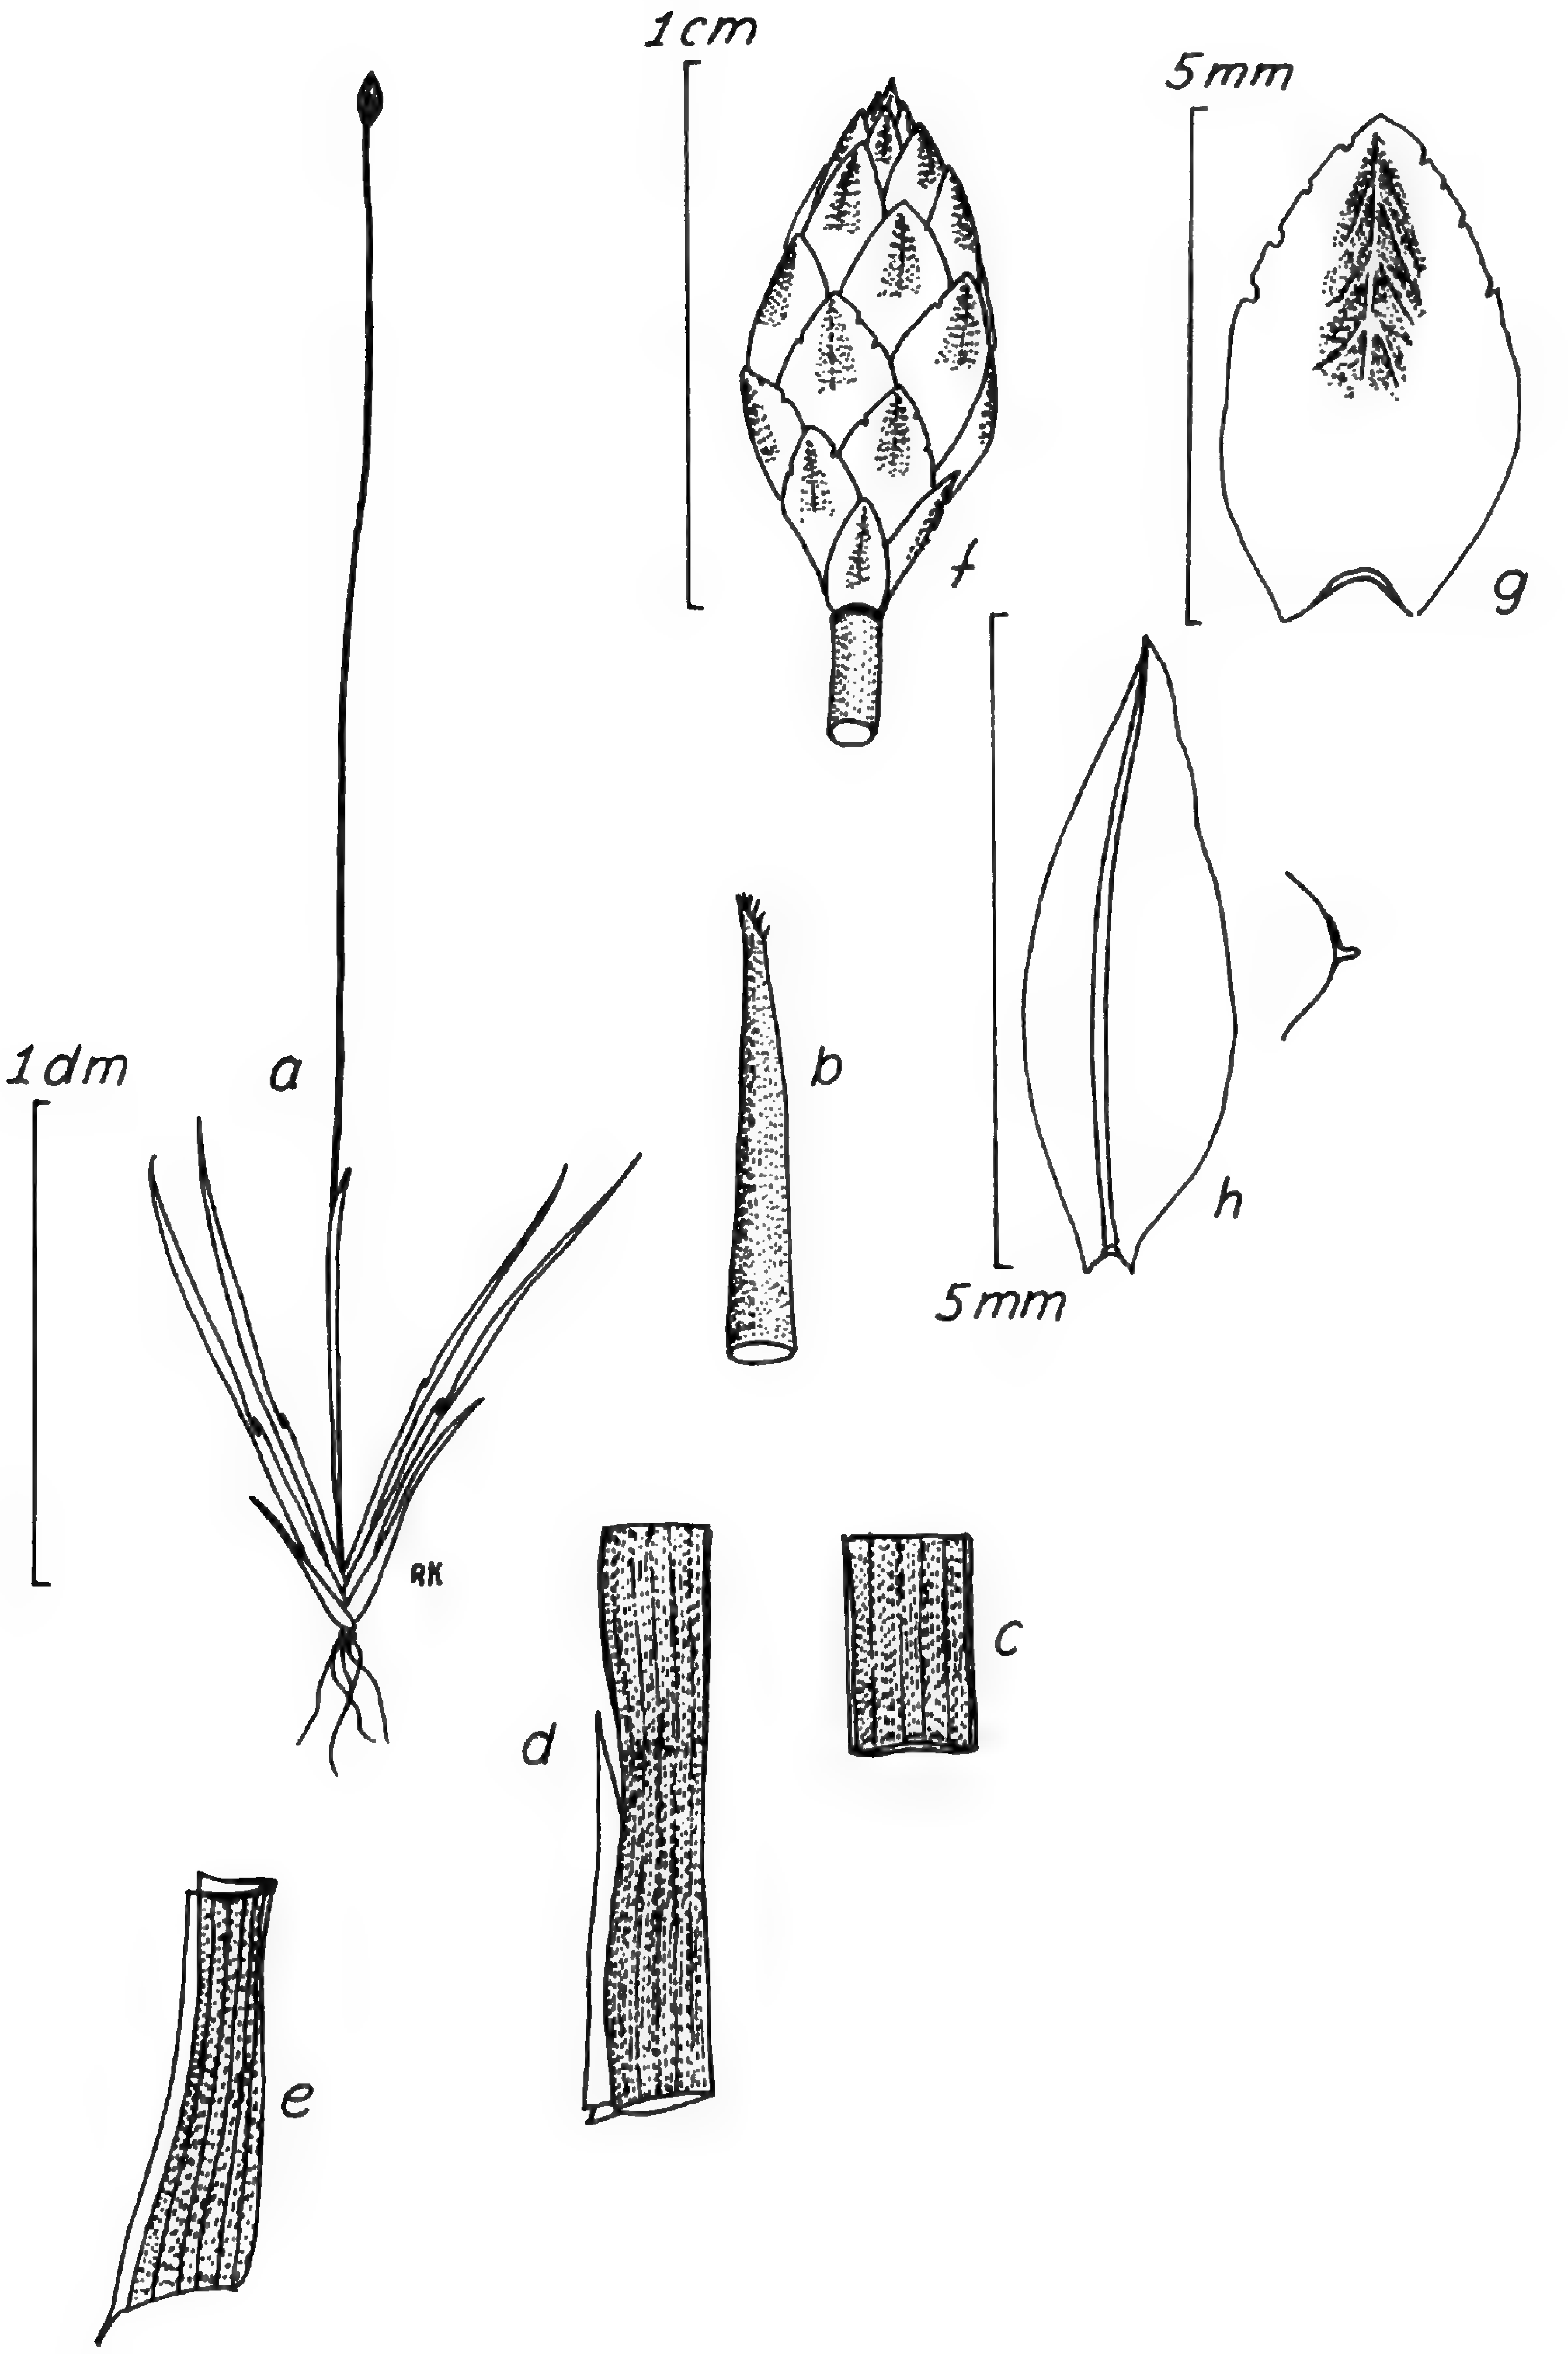

FIGURE 60. Xyris cuatrecasana *(from the isotype).—a. Habit sketch.—b. Leaf apex.—c. Sector of blade at midblade.—d. Leaf sheath–blade junction.—e. Leaf base.—f. Spike and upper scape.—g. Fertile bract.—h. Lateral sepal.*

imbricate, thin, the sterile bracts several, smaller than the fertile bracts and grading into them, these ovate, ca. 5 mm long, acute, ecarinate, with strong, dark, lanceolate, venose dorsal areas and scarious, subentire to erose edges. Lateral sepals free, subequilateral, ca. as long as bracts, very thin, lanceolate, narrowly acute, the firm, narrow keel subentire. Corolla, staminodes, and stamens not seen. Immature capsule ellipsoid, ca. 4

mm long, the valves eseptate, the placentation basal. Immature seeds ellipsoid, ca. 1 mm long.

Distribution. Known only from the type.

This is perhaps not distinguishable from *Xyris paraensis* and except for the equilateral sepals could be considered a disjunct collection of var. *polystachya* of that species. However, until more information (seeds, flowers) becomes available, it seems best to retain the taxon.

61. Xyris pectinata Kral, Lyman B. Smith & Wanderley, sp. nov. TYPE: Brazil. Amazonas: Estrada Transamazônica–Capim, campina aberta, terreno arenoso, Proj. RADAM, 1 June 1976, *T. R. Bahia 35* (holotype, INPA; isotypes, US, VDB). Figure 61.

Herba perennis densicaespitosa, tenella, glabra; radices graciles. Folia linearia, 4–6 cm longa, erecta vel leviter expansa, vaginis scaporum longiora. Laminae planae vel leviter tortae, 0.9–1.2 mm latae, vaginis 3–5-plo longiores, longitudine distincte multinervosae, ferrugineae vel olivaceae; apices contracti, incurvato-acuti; margines incrassati, minute ciliati; vaginae carinatae, carinibus persaepe minute rufociliatis, incrassatis, lateribus valde longitudine multicostatae, pallide vel intense ferrugineae, marginibus in laminas gradatim convergentibus, ad apicem ligulam acutam 0.5 mm longam fascientes, infime gradatim dilatatae. Vaginae scaporum laxae, plerumque apertae, tortae, basin versus nitidae, a medio carinatae, laminis aut similibus laminis foliorum aut brevibus. Scapi subteretes, filiformes, plus minusve spiraliter torti, 1.2–2 dm alti, ca. 0.4–0.5 mm crassi, olivacei, distaliter acute bicostati, costis laevibus. Spicae subglobosae vel late obovoideae, 4.5–6 mm longae, pluriflorae, breviter attenuatae; bracteae steriles 2(–4), paro infimo oblongo, 2–2.5 mm longo, areis dorsalibus linearibus bracteam aequantibus; bracteae fertiles arcte spiraliter imbricatae, late ovatae, obovatae, suborbiculatae, aut reniformes, ca. 3 mm longae, convexae et leviter carinatae, obtusae vel subtruncatae, ad apicem utrinque erosae et ciliatae, scariosae, minute tuberculato-rugulosae, a medio ad basim multo crassiores, nitidae, brunneolae, marginibus effuse et pectinate rigofimbriatis; area dorsali ovata, ca. 2–2.5 mm longa, glauca. Sepala lateralia ca. ½ connata, ca. 2 mm longa, inaequilateralia, lobis acutis scariosis, ala carinali angusta, integra. Laminae petalorum anguste obovatae, ca. 1.5 mm longae, ad apicem rotundatae, laceratae, luteolae. Staminodia aliquantum redacta, bibrachiata, brachiis ad apicem breviplumosis, pilis moniliformibus. Antherae oblongae, ca. 0.3–0.4 mm longae, loculis parallelis distinctis; filamenta ca. 0.5 mm longa. Capsula dorsali-ventraliter compressa, oblongo-cylindrica, tenuissima, 1.2–1.3 mm longa; placenta basalis. Semen solitarium, lenticulariter oblongo-ellipsoideum, 1–1.2 mm longum, translucidum, pallide luteo-brunneolum, longitudine subtiliter striatum.

Delicate, smooth, cespitose perennial; roots slender. Leaves linear, 4–6 cm long, erect or somewhat spreading, longer than the scape sheaths; blades 3–5 times longer than the sheaths, plane or slightly twisted, 0.9–1.2 mm wide, longitudinally distinctly multinerved, strongly flattened, ferrugineous to olive green; apices contracted, incurved-acute; margins thickened, minutely ciliate; sheaths carinate, with carinae minutely red-ciliate, incrassate, the sides strongly longitudinally nerved, pale to deep red-brown, the margins gradually converging into the blade, at apex producing an acute ligule 0.5 mm long, gradually dilating below. Sheaths of scales lax, mostly open, twisted, shining toward the base, carinate at the middle, with blades either similar to those of principal leaves or shorter. Scapes subterete, filiform, ± spirally twisted, 1.2–2 dm high, ca. 0.4–0.5 mm thick, olivaceous, sharply costate distally, the costae smooth. Spikes subglobose to broadly obovoid or short-cylindric, 4.5–6 mm long, several-flowered, short-attenuate; sterile bracts 2 (–4), the lowest pair oblong, 2–2.5 mm long, with dorsal areas linear and equal to them in length; fertile bracts tightly spirally imbricate, broadly ovate, obovate, suborbicular, or reniform, ca. 3 mm long, convex and slightly carinate, obtuse to subtruncate at apex on either side, erose, scarious, minutely rugulose-tuberculate, much thicker from the middle to the base, shining, brownish, with margins effusely and pectinately rigidly fimbriate; dorsal area ovate, ca. 2–2.5 mm long, gray-green. Lateral sepals ca. ½ connate, ca. 2 mm long, inequilateral, the lobes acute, scarious, the carinal keel narrow, entire. Petal blades narrowly obovate, ca. 1.5 mm long, apically rounded, lacerate, yellow. Staminodia somewhat reduced, bibrachiate, the branches at apex short-plumose with moniliform hairs. Anthers oblong, ca. 0.3–0.4 mm long, the locules parallel, distinct; filaments ca. 0.5 mm long. Capsule dorsiventrally compressed, oblong-cylindric, very thin, 1.2–1.3 mm long;

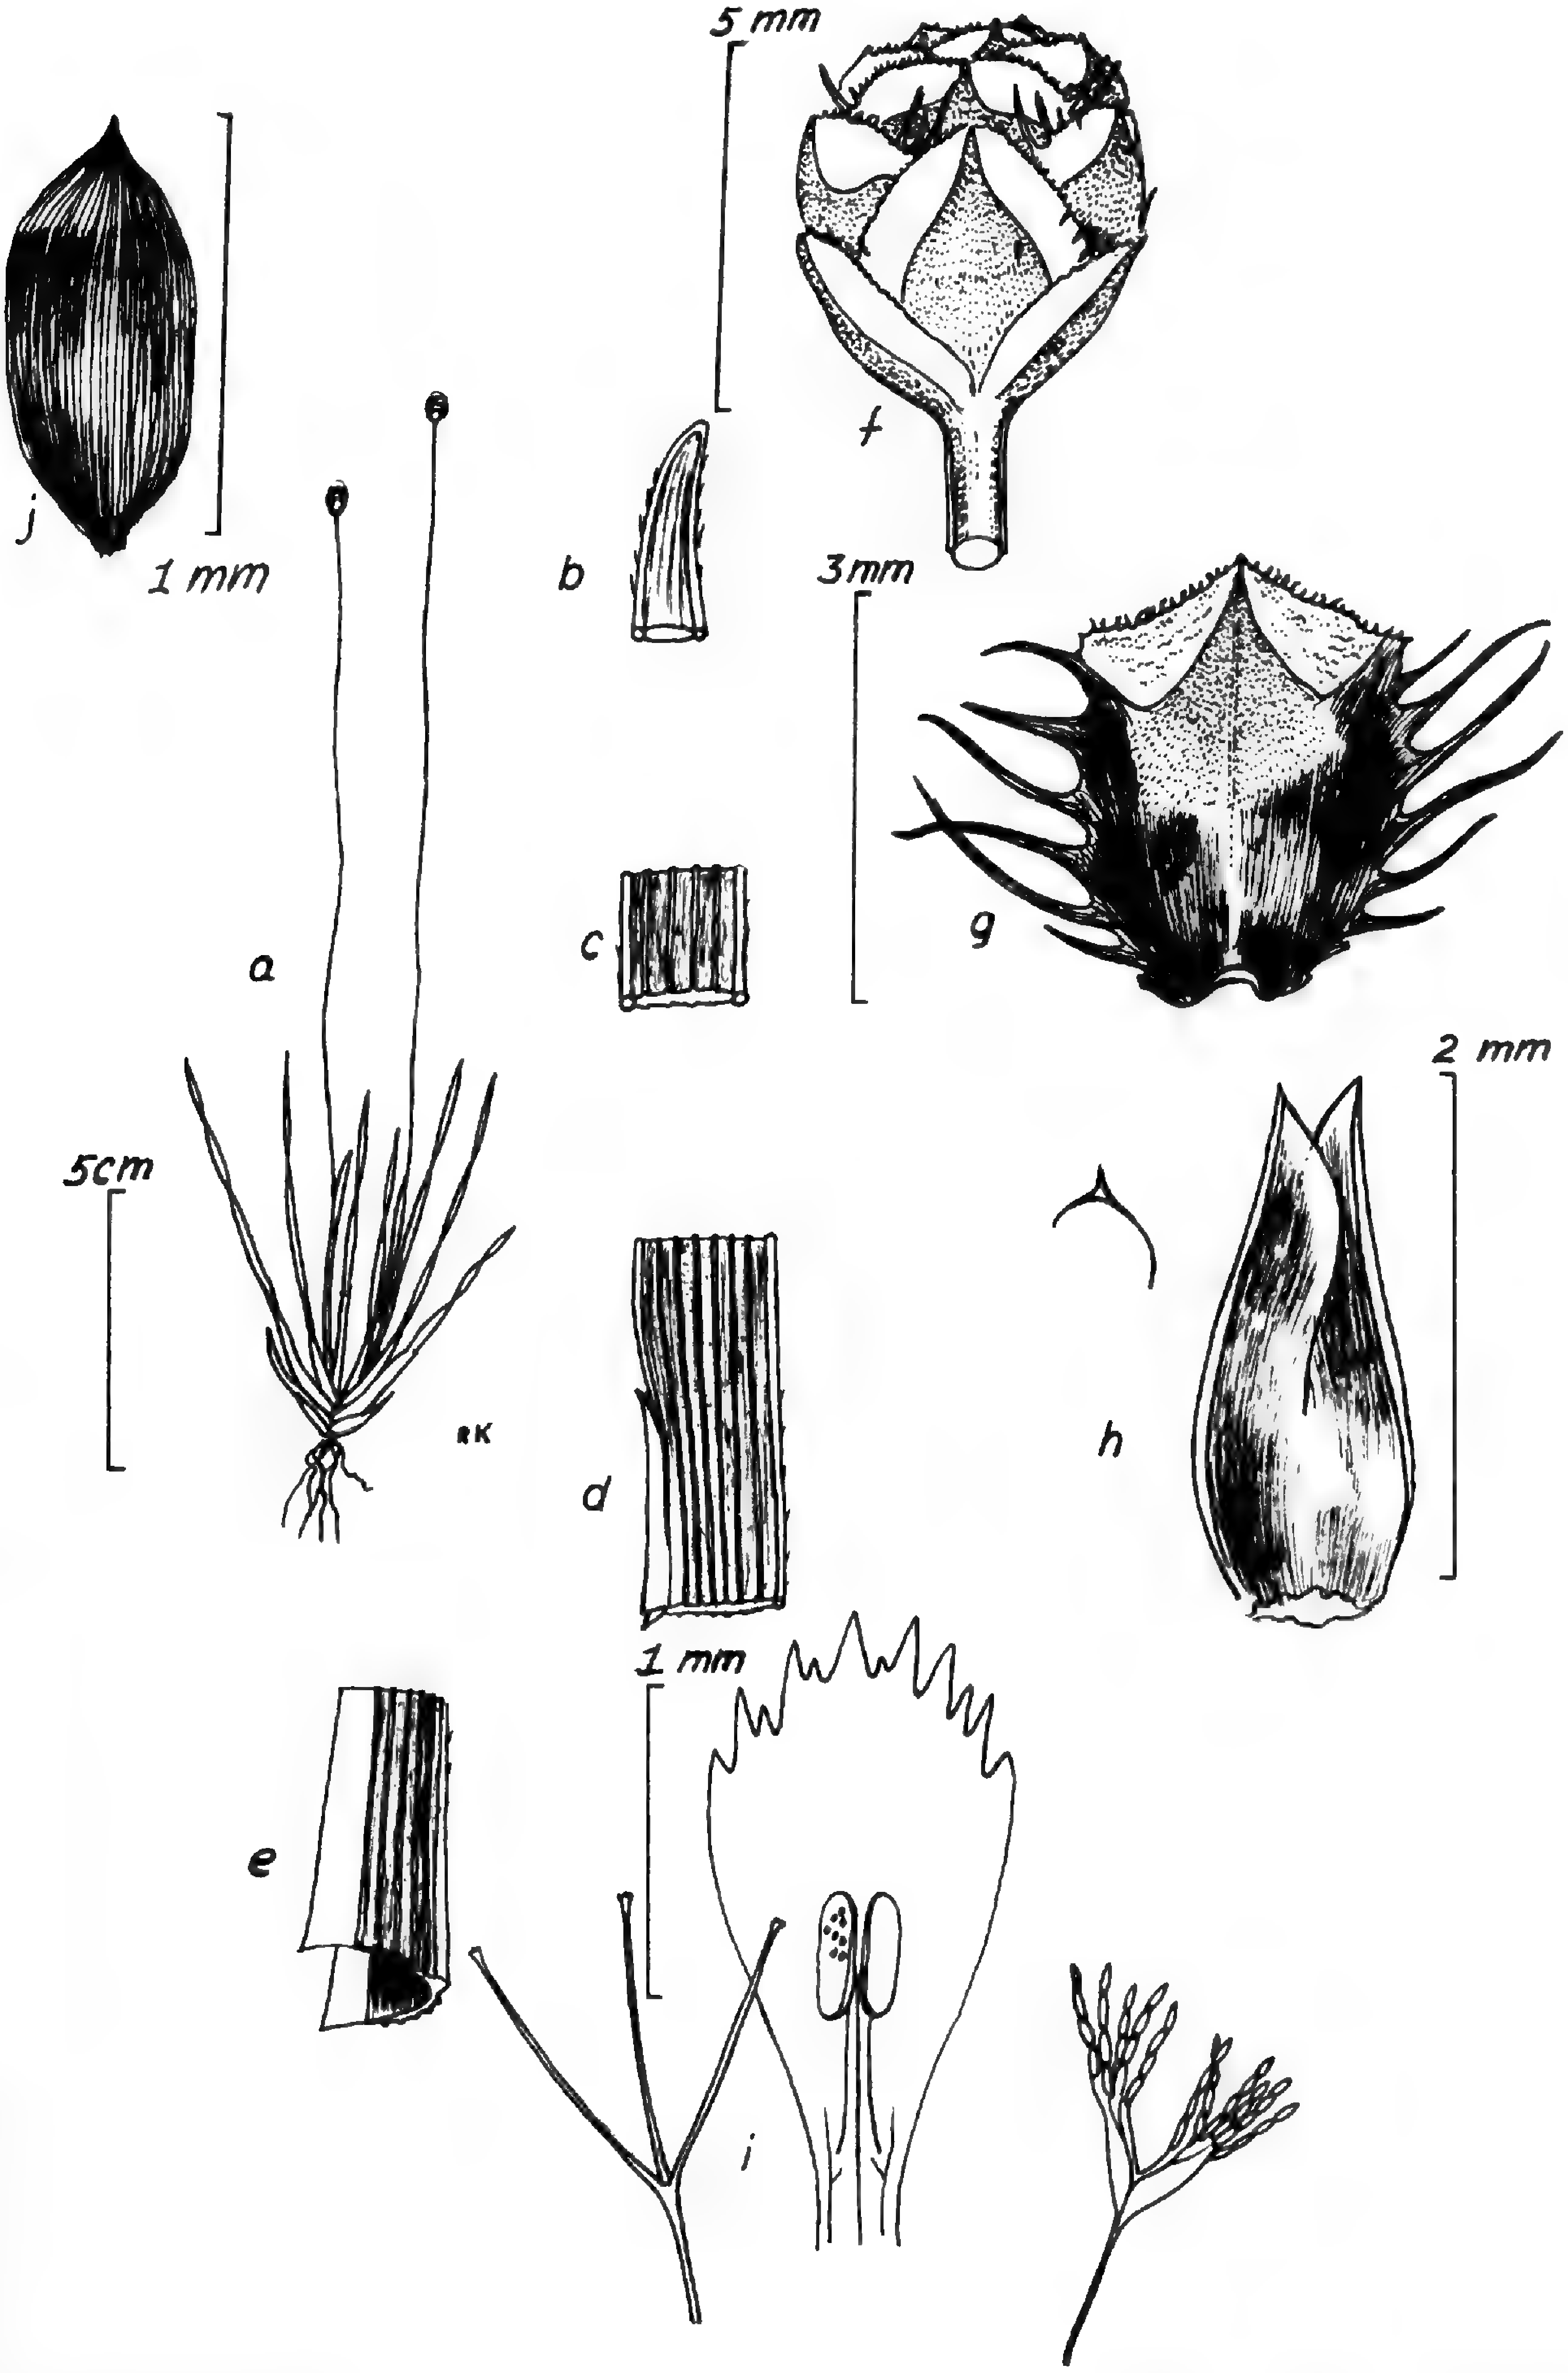

FIGURE 61. Xyris pectinata (T. R. Bahia 35).—*a. Habit sketch.—b. Leaf tip.—c. Sector of midblade.—d. Blade-sheath junction.—e. Leaf base.—f. Spike.—g. Fertile bract.—h. Lateral sepals.—i. Stylar apex, petal blade, stamen, staminodial apex.—j. Seed.*

placenta basal. Seed solitary, lenticularly oblong-ellipsoid, 1–1.2 mm long, filling capsule, translucent, pale yellow-brown, finely longitudinally striate.

Additional specimens examined. BRAZIL. AMAZONAS: Transamazona Highway, 53 km W of Aripuaná River; "campina" region, common in open campina of white sandy soil, 27 June 1979, *C. E. Calderón, O. P. Monteiro & J. Guedes 2696* (INPA, US, VDB); Município de Borba, acima de Terra Preta, campina do Rio Surubím, afluente do Rio Abacaxis, 4°29'S, 58°33'W. Campina aberta, areia branca. Erva de 10 cm de altura; flores amarelas, 4 July 1983, *C. A. Cid 4026* (INPA, NY, VDB).

This species is easily distinguished by its fringe of strong though slenderly tapering rigid bristles on the margins of the fertile bracts, nearly separate anther locules, and reduced staminodial condition. It is unusual in its particularly small and thin-walled capsule, this tightly filled by a single large seed.

62. **Xyris savanensis** Miq., Linn. 18: 605. 1844. TYPE: "Surinam, Berlyn, *Focke 1022*" (holotype, U). Figure 62.

Solitary or cespitose, soft-based annual 1–5 dm high; stem contracted. Leaves spreading flabellately to erect, (2–)5–20(–25) cm long; sheaths ½ or less as long as blades, entire, red-brown to tan or brown, papillose-rugulose, narrowing gradually from wide base to blade, there with an erect, narrowly triangular ligule to 0.5 mm long, or eligulate; blades flat, slightly twisted, gladiate-linear, 1–5 mm wide, narrowing gradually above middle to a narrowly acute apex, the margins slightly thickened or not thickened, papillose to scabrid, surfaces mostly rugose-scabrid. Scape sheath shorter than leaves, multicostate and tubular, keeled, open and short-bladed above. Scapes straight or flexuous, twisted, terete or subterete distally, 0.5–1 mm thick, ecostate to tricostate or striate, the costae and surfaces scabridulous or papillose (rarely nearly smooth). Spikes ovoid to cylindric, ellipsoid or subglobose, 0.3–0.7(–1) cm long, with many spirally imbricate bracts, these tan or reddish brown with darker green or maroon dorsal areas; sterile bracts smaller than fertile bracts, grading into them, the fertile bracts broadly obovate to suborbicular, 3–5 mm long, the apex broadly rounded, entire, backs strongly convex-rounded, ecarinate. Lateral sepals free, very inequilateral, elliptic, ca. 3 mm long, acute to obtuse, the strong, curvate keel irregularly ciliate and/or ciliolate. Petal blades broadly obovate, yellow, 2–2.5 mm long. Staminodia bibrachiate, the lance-linear branches beardless. Anthers oblong, ca. 0.5 mm long, deeply emarginate and sagittate on filaments about as long. Capsule broadly obovoid, 1.5–2.5 mm long, placentation basal. Seeds numerous, ellipsoid or ovoid, 0.4–0.5 mm long, apically truncate and minutely apiculate, the body pale yellow-brown or red-brown, translucent, faintly 20–24-ribbed and indistinctly cross-lined.

Distribution. South America, from the Andean foothills eastward, mostly at low to medium elevations, south into Argentina. Records of this species from Mesoamerica have all turned out to be *X. paraensis.* It is so commonly collected that even a partial citation of records (as in the case of the equally common *X. jupicai, X. laxifolia, X. fallax*) is better done separately.

It is not surprising that a widespread, common, and weedy xyris would show considerable variation in habit and in character of indumentum, pigmentation, and other features. Thus two additional varieties, *X. savanensis* var. *glabrata* Seubert, (Fl. Bras. 3(1): 217. 1855) and var. *procera* (Malme) Malme (Ark. Bot. 13(3): 53. 1913), have been described along with some forms. The former variety, as the name suggests, has totally smooth foliage, while the latter assumes (sometimes?) a perennial habit. The species nearest it taxonomically is *X. paraensis*, and here would be a great difficulty were it not for a pair of characters that, regardless of variety, appear to hold throughout the range. All specimens of *X. savanensis* lack bearded staminodes; all have seed uniformly truncate at apex, there with a short but distinguishable apiculus.

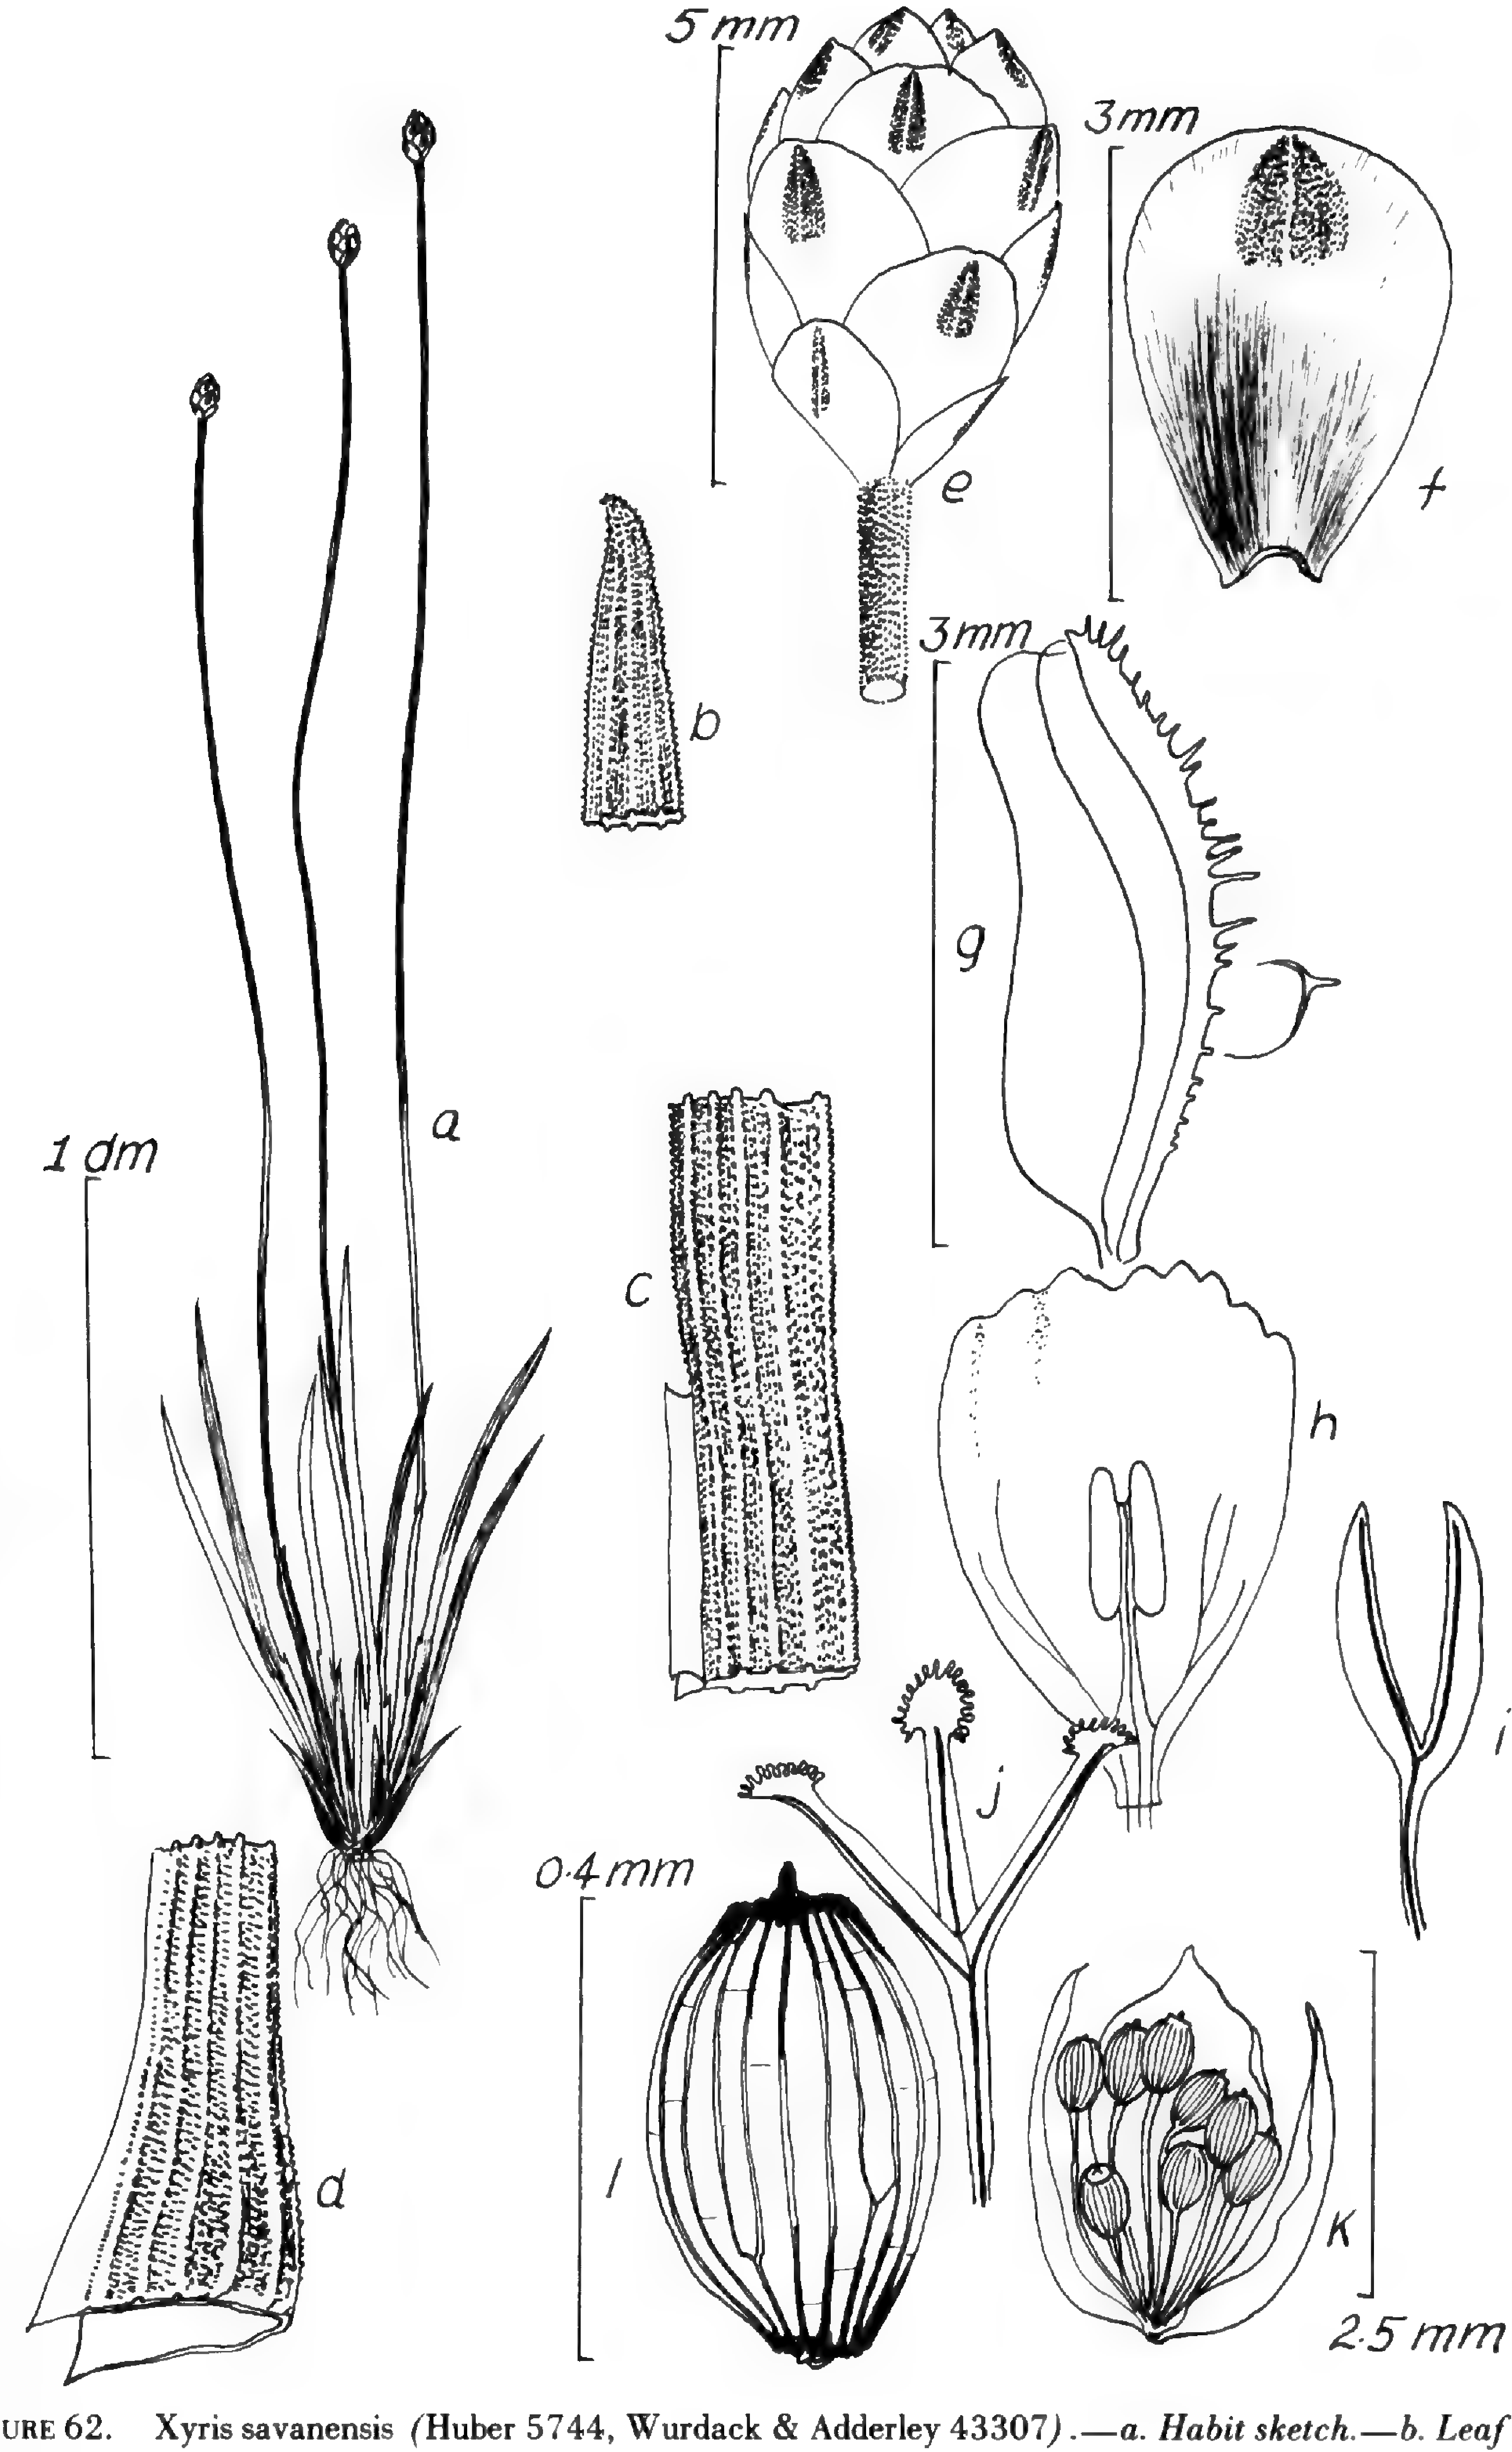

FIGURE 62. Xyris savanensis (Huber 5744, Wurdack & Adderley 43307).—*a. Habit sketch.—b. Leaf apex.—c. Leaf at junction of sheath and blade.—d. Leaf base.—e. Spike.—f. Fertile bract.—g. Lateral sepal.—h. Petal blade, stamen.—i. Staminode.—j. Stylar apex.—k. Dehiscing capsule.—l. Seed.*

63. Xyris surinamensis Sprengel, Tent. Suppl. Syst. Veg. Linn. 2. 1828. TYPE: "Suriname, *Weigelt*, 1827" fide J. Lanjouw, Rec. Trav. Bot. Neerl. 34. 1937. Possibly (fide Lanjouw) based on same material as *X. eriophylla* Reichenb., but still a problem, the marked type not found. Figure 63A, B.

X. eriophylla Reichenb., Pl. Excic. Weigelt, 1827 (?). TYPE: Surinam, Leg. & Exc. *Weigelt 1827* (?lectotype at Delessert Herbarium; isolectotype, MO; phototype, GH).

Cespitose, hard-based, often bulbous, stocky perennial 2.5–4 dm high. Leaves often nearly as long as scapes, ascending or slightly spreading, 1.5–3 dm long; sheaths long-ciliate, usually with brownish hairs, the dilated base ecarinate, red to purple or deep brown, rugose, gradually narrowing to leaf blade, mostly eligulate; blades linear, flattened, 2–4 mm wide, often twisted, dull green, abruptly blunt-tipped or incurved-acute to incurved-narrowly rounded, the margins mostly pale, incrassate, ciliate or scabrociliate, rarely papillate; surfaces rugulose, strongly nerved, the strongest nerves often pale-incrassate, often hirtellous or scabridulous. Scape sheaths highly variable, keeled, from much shorter than leaves and elaminar to nearly as long and similar in blade. Scapes flexuous, twisted, flattened, distally 2–3 mm wide with strong costae comprising edges, often with one or both costae pale pilose-ciliate or scabrid, the sides pale yellow-green, strongly rugose, sometimes with additional lower costae. Spikes subglobose or broadly turbinate, 0.8–1 cm long, of many spirally imbricate or subdecussate, stiff, dull brown or red-brown, ciliolate or entire bracts with large, ovate dorsal areas. Sterile bracts ovate-triangular, slightly keeled, lower bracts much smaller than the fertile bracts and grading into them, the fertile bracts oblong to obovate, 6–8 mm long, slightly carinate, apically obtuse-angled or narrowly rounded, the dorsal area of lower ones venose and sometimes white pilose. Lateral sepals free, subequilateral to inequilateral, lance-linear, curvate, 5–7 mm long, acute, the firm keel lacerate, villosulous or ciliolate from middle to apex. Petal blades broadly obovate, 5–6 mm long, yellow, the broadly rounded apex erose-denticulate. Staminodia bibrachiate, the slender branches densely long penicillate-ciliate. Anthers oblong, ca. 2 mm long, deeply bifid and sagittate, on filaments ca. 1.5 mm long. Capsule narrowly to broadly obovoid, 4–5 mm long, the placentation appearing basal-central, but the valves dehiscing to reveal strong septa. Seeds few, cylindric-fusiform, ca. 1 mm long, pale amber, faintly longitudinally striate and cross-lined, often additionally with a few, conspicuous, irregular, dark red-brown ribs.

Distribution. Locally abundant in low- to high-elevation savanna from southeastern Colombia eastward across southern Venezuela into French Guiana, southward into Amazonas and Pará, Brazil.

Selected specimens examined. BRAZIL. AMAZONAS: Serra Aracá, 10 Feb. 1975, *Pires 15000* (MG, US, VDB); margens de um riacho da serra Aracá, 1 Nov. 1978, *Rosa & Lira 2343* (US). COLOMBIA. Sabana Grande, NE of Esmeralda, 6 Sep. 1944, *Steyermark 58405* (F, NY); Grand Savanna, Esmeralda, ca. 325 ft., 1 Nov. 1928, *Tate 304* (C, NY). BOLÍVAR: cerca de San Rafael de Camoiran, ca. 1,240 m, 8 Jan. 1982, *Cordero y Utrera 5* (PORT); ca. 17 km al NE de Ikabaru, ca. 1,100 m, *Huber et al. 6723* (MYF, VDB, VEN); cerca de la ribera Norte del Río Carrao medio, ca. 8–10 km al NNE de la confluencia Carrao–Churun, 31 Aug. 1983, *Huber et al. 8270* (NY); al E del Churí-tepui en el Vallé del Río Karuay inferior, 18 Nov. 1984, *Huber*

9794 (MYF, VEN, VDB); ca. 5 km al norte del Poblado San Francisco de Yuruaní, 19 Jan. 1985, *Huber 9949* (MYF, VDB); el piedemonte septentrional del Cerro Zumbador, *Huber 10271* (MYF, VDB); ca. 35 km al W del caserio de Chiguao, 23 Mar. 1985, *Huber 10354* (MYF, VDB); 1.5 km E of Kavanayen in Gran Sabana, bog, 27 July 1983, *Kral 70536* (BM, F, L, MO, NY, SP, U, US, VDB, VEN, and others); Salto Yuruani, 28 July 1983, *Kral 70568* (BM, F, K, L, MO, NY, SP, U, US, VDB, VEN, and others); El Pauji, savanna E of town, 2 Nov. 1985, *Liesner 19357* (MO, VDB, VEN); savanna vic. Uriman, 300 m, 30 Apr. 1953, *Steyermark 75265* (C, F, NY, VEN).

As one might suspect from such a wide geographic distribution, the species is highly variable in stature, leaf dimensions, and in indumentum of scapes, leaves, and sepals. Its pale yellow blooms with broad petals expand in morning.

64. Xyris pratensis Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 34, fig. 19A–E. 1963. TYPE: Venezuela. T. F. Amazonas: pubescent, frequent in wet hummocks, Camp Savanna, Campo Grande, 1,500 m, Cerro Sipapo (Paraque), 10 Dec. 1948, *Maguire & Politi 27581* (holotype, NY; isotypes, GH, US). Figure 64.

Cespitose, slender, hard-based perennial 4–5.5 dm high, the stems short, ascending, covered by chaffy bases of old leaves. Leaves erect, 2–4 dm long; sheaths sparsely pilose-ciliate, as long as blades or longer, abruptly constricted above the dilated, deep red-brown base, then narrowing upward and keeled to blade, the margins intermittently pilose-ciliate; blades narrowly linear, flat, 2–3 mm wide, slightly narrowing above middle then abruptly incurved-acute or obliquely acute, the thickened tip often white bristly-ciliate, the margins thin, pale ciliate, the surfaces green with streaks of red, strongly multinerved. Scape sheaths somewhat shorter than leaves, above with strong blades like leaves but narrower. Scapes somewhat compressed distally, ca. 1–1.5 mm wide, elliptic in cross section, with the two costae making edges, strongly pale ciliate or with one costa smooth. Spikes ellipsoid, becoming obovoid, 8–10 mm long, the several bracts subdecussate, rather loosely imbricate, dark red-brown with distinct and usually paler dorsal areas, firm, the sterile bracts narrower and shorter than the fertile bracts, the lowermost keeled, sometimes pilosulous-ciliate, grading into fertile bracts, these oblong, bluntly acute or narrowly rounded, entire or apically villosulous, 6–7.5 mm long, the backs convex, ecarinate but with dorsal areas bisected by a strong costa. Lateral sepals equaling bracts or slightly longer, free, subequilateral, linear-oblanceolate, 7–8 mm long, acute, the dark, firm keel entire or above middle low-lacerate and also often minutely ciliate. Petal blades obovate, ca. 5.5 mm long, yellow, apically broadly acute. Staminodia bibrachiate, the flat branches densely penicillate-pilose. Anthers lance-oblong, deeply bifid, sagittate, 1.5 mm long, on filaments 1 mm long. Capsule ellipsoid, 3–3.5 mm long, placentation central, the valves with strong septa toward base, thus actually placentation axile there. Seeds several, narrowly ellipsoid, ca. 1 mm long, pale amber with a conic white apiculus, the body longitudinally finely but distinctly ribbed.

Distribution. High savanna, cerros Sipapo (Paraque) and Marahuaca, southern Territorio Federal Amazonas, Venezuela, infrequent.

Additional specimens examined. VENEZUELA. T. F. AMAZONAS: summit Cerro Marahuaca, 2,685 m, 15 Jan. 1981, *Maguire 65635* (NY, VDB); cumbre del Cerro Paraque, 1,600 m, alto Orinoco, *Phelps 20* (US); Cerro Sipapo, 17 Feb. 1981, *Steyermark 124532* (NY, VDB, VEN).

This species is very evidently closely related to *X. bicostata* Maguire & Lyman B. Smith of Cerro Huachamacari in Amazonas, which differs only in that the plants are (mostly) lower, with smaller and fewer-flowered spikes, and narrower scapes and leaves.

65A. Xyris bicostata Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 30, fig. 14A–F. 1963. TYPE: Venezuela. T. F. Amazonas: frequent on mossy rocky banks, dense woodlands along right fork of Caño de Dios, 1,800 m, Summit Camp, Cerro Huachamacari,

Río Cunucunuma, 13 Dec. 1960, *B. Maguire, R. Cowan & J. J. Wurdack 30169* (holotype, NY; isotypes, NY, US, VEN). Figure 65.

Cespitose slender perennial 2–3 dm high, the stems short, with base sometimes forming a short, stout rhizome. Leaves erect, 1–2 dm long; sheaths over ½ as long as blades, at very base red-brown ciliate, medially and distally pilose-ciliate with red-brown hairs, tapering gradually to blade, eligulate, the surfaces smooth or papillose-rugulose toward base; blades flat, narrowly linear, 0.8–1 mm wide, the apex abruptly conic-acute or terete-rounded, the margins finely ciliate to scabrociliate, the surfaces smooth and punctate, few-nerved, smooth or papillose toward base. Scape sheaths loose, as long as leaves, with long, strong blades. Scapes straight or slightly flexuous, lineal, 0.8–1 mm wide, oval distally in cross section, strongly bicostate, costae pale-ciliate or scabrociliate. Spikes narrowly obovoid, ellipsoid, aging obconic, 9–10 mm long, red-brown, few flowered; bracts subdecussate, the sterile bracts ca. 6, the lowest ones narrowly triangular, strongly keeled, grading into fertile bracts, these oblong or lance-ovate, 7.5–8 mm long, broadly acute or rounded, entire, carinate and keeled apically and with paler, linear-elliptic dorsal areas, often also with faint but evident arcuate lateral nerves. Lateral sepals free, subequilateral, ca. 6–7 mm long, lance-linear, narrowly acute, firm, pale red-brown, the narrow, firm keel entire. Petal blades narrowly obovate, ca. 6 mm long, yellow, the broadly acute apex irregularly dentate. Staminodia bibrachiate, the narrow flat branches penicillate pubescent toward and at apex. Anthers oblong, ca. 1.5 mm long, deeply bifid and auriculate, on filaments ca. 0.5 mm long. Capsule narrowly ellipsoid, ca. 4 mm long, the placentation appearing free-central, but capsule valves with shallow septa at base. Seeds numerous, ellipsoid, ca. 1 mm long, both ends acute, the body amber, finely longitudinally ribbed.

Distribution. A high-tepui endemic, thus far found on Cerro Marahuaca and on Cerro de La Neblina, along the Brazil–Venezuela border, as well as at the type locality, Cerro Huachamamacari. The specimens from Marahuaca and Neblina are uniformly different enough from the type to have been recognized as a species by Smith, who related them more to *X. tatei* Malme and named them *X. tillettii.* The material seems, however, to represent a varietal extreme of *X. bicostata,* particularly in its prominent, sharp and prominent, scabrociliate pairs of scape costae, and in its general spike and sepal dimensions. Yet the leaves are narrower than in the type, also slightly thicker and blunter, and the spike scales are less prominently keeled (though evidently costate) and are less spreading at maturity. Thus, the following is proposed:

65B. Xyris bicostata var. **tillettii** (Lyman B. Smith) Kral, stat. nov. *Xyris tillettii* Lyman B. Smith, Ernstia 9: 3–4. 1982. TYPE: Venezuela. T. F. Amazonas: Cerro Marahuaca, al NE de, y casi contigua con, Cerro Duida, este inmediatamente al N de La Esmeralda 3°10′N, 65°31′W, en el Río Orinoco, ca. 2,750 m, 2 & 9 Feb. 1975, *S. S. Tillett, P. Colvee et al. 752-332* (holotype, VEN; isotype, US).

Additional specimens examined. VENEZUELA. T. F. AMAZONAS: plateau of Cerro de Marahuaca above Salto Los Monos on trib. headwaters of Río Iguapo, 3°37′N, 65°23′W, 2,555 m, 25 Feb. 1985, *Liesner 17962* (MO, VEN, VDB); Cerro Marahuaca, parte central de la Meseta Sur-este, 10–12 Oct. 1983, *Steyermark 129442* (VDB, VEN); Cerro de La Neblina, Planicie de Zuloaga, Río Titirico, 2,300 m, 10–15 Oct. 1970, *Steyermark 103845* (NY, VDB); Valle de Titirico N of Pico Phelps in Cerro Neblina, ca. 2,200 m, bog, 1 Dec. 1984, *Kral et al. 71920, Kral 71927* (NY, VDB, VEN, and to be distributed).

66. Xyris globosa Nilsson, Bih. Kongl. Svenska Vetensk.-Akad. Handl. 24(14): 57, pl. 3. 1892. TYPE: Venezuela. T. F. Amazonas: "prope Esmeralda ad flumen orinoco, Dec. 1853, *R. Spruce 3244*" (lectotype, S; possible isolectotype, NY). Figure 66.

Solitary or cespitose, slender but stiffish, bulbous-based perennial 3–7 dm high, the

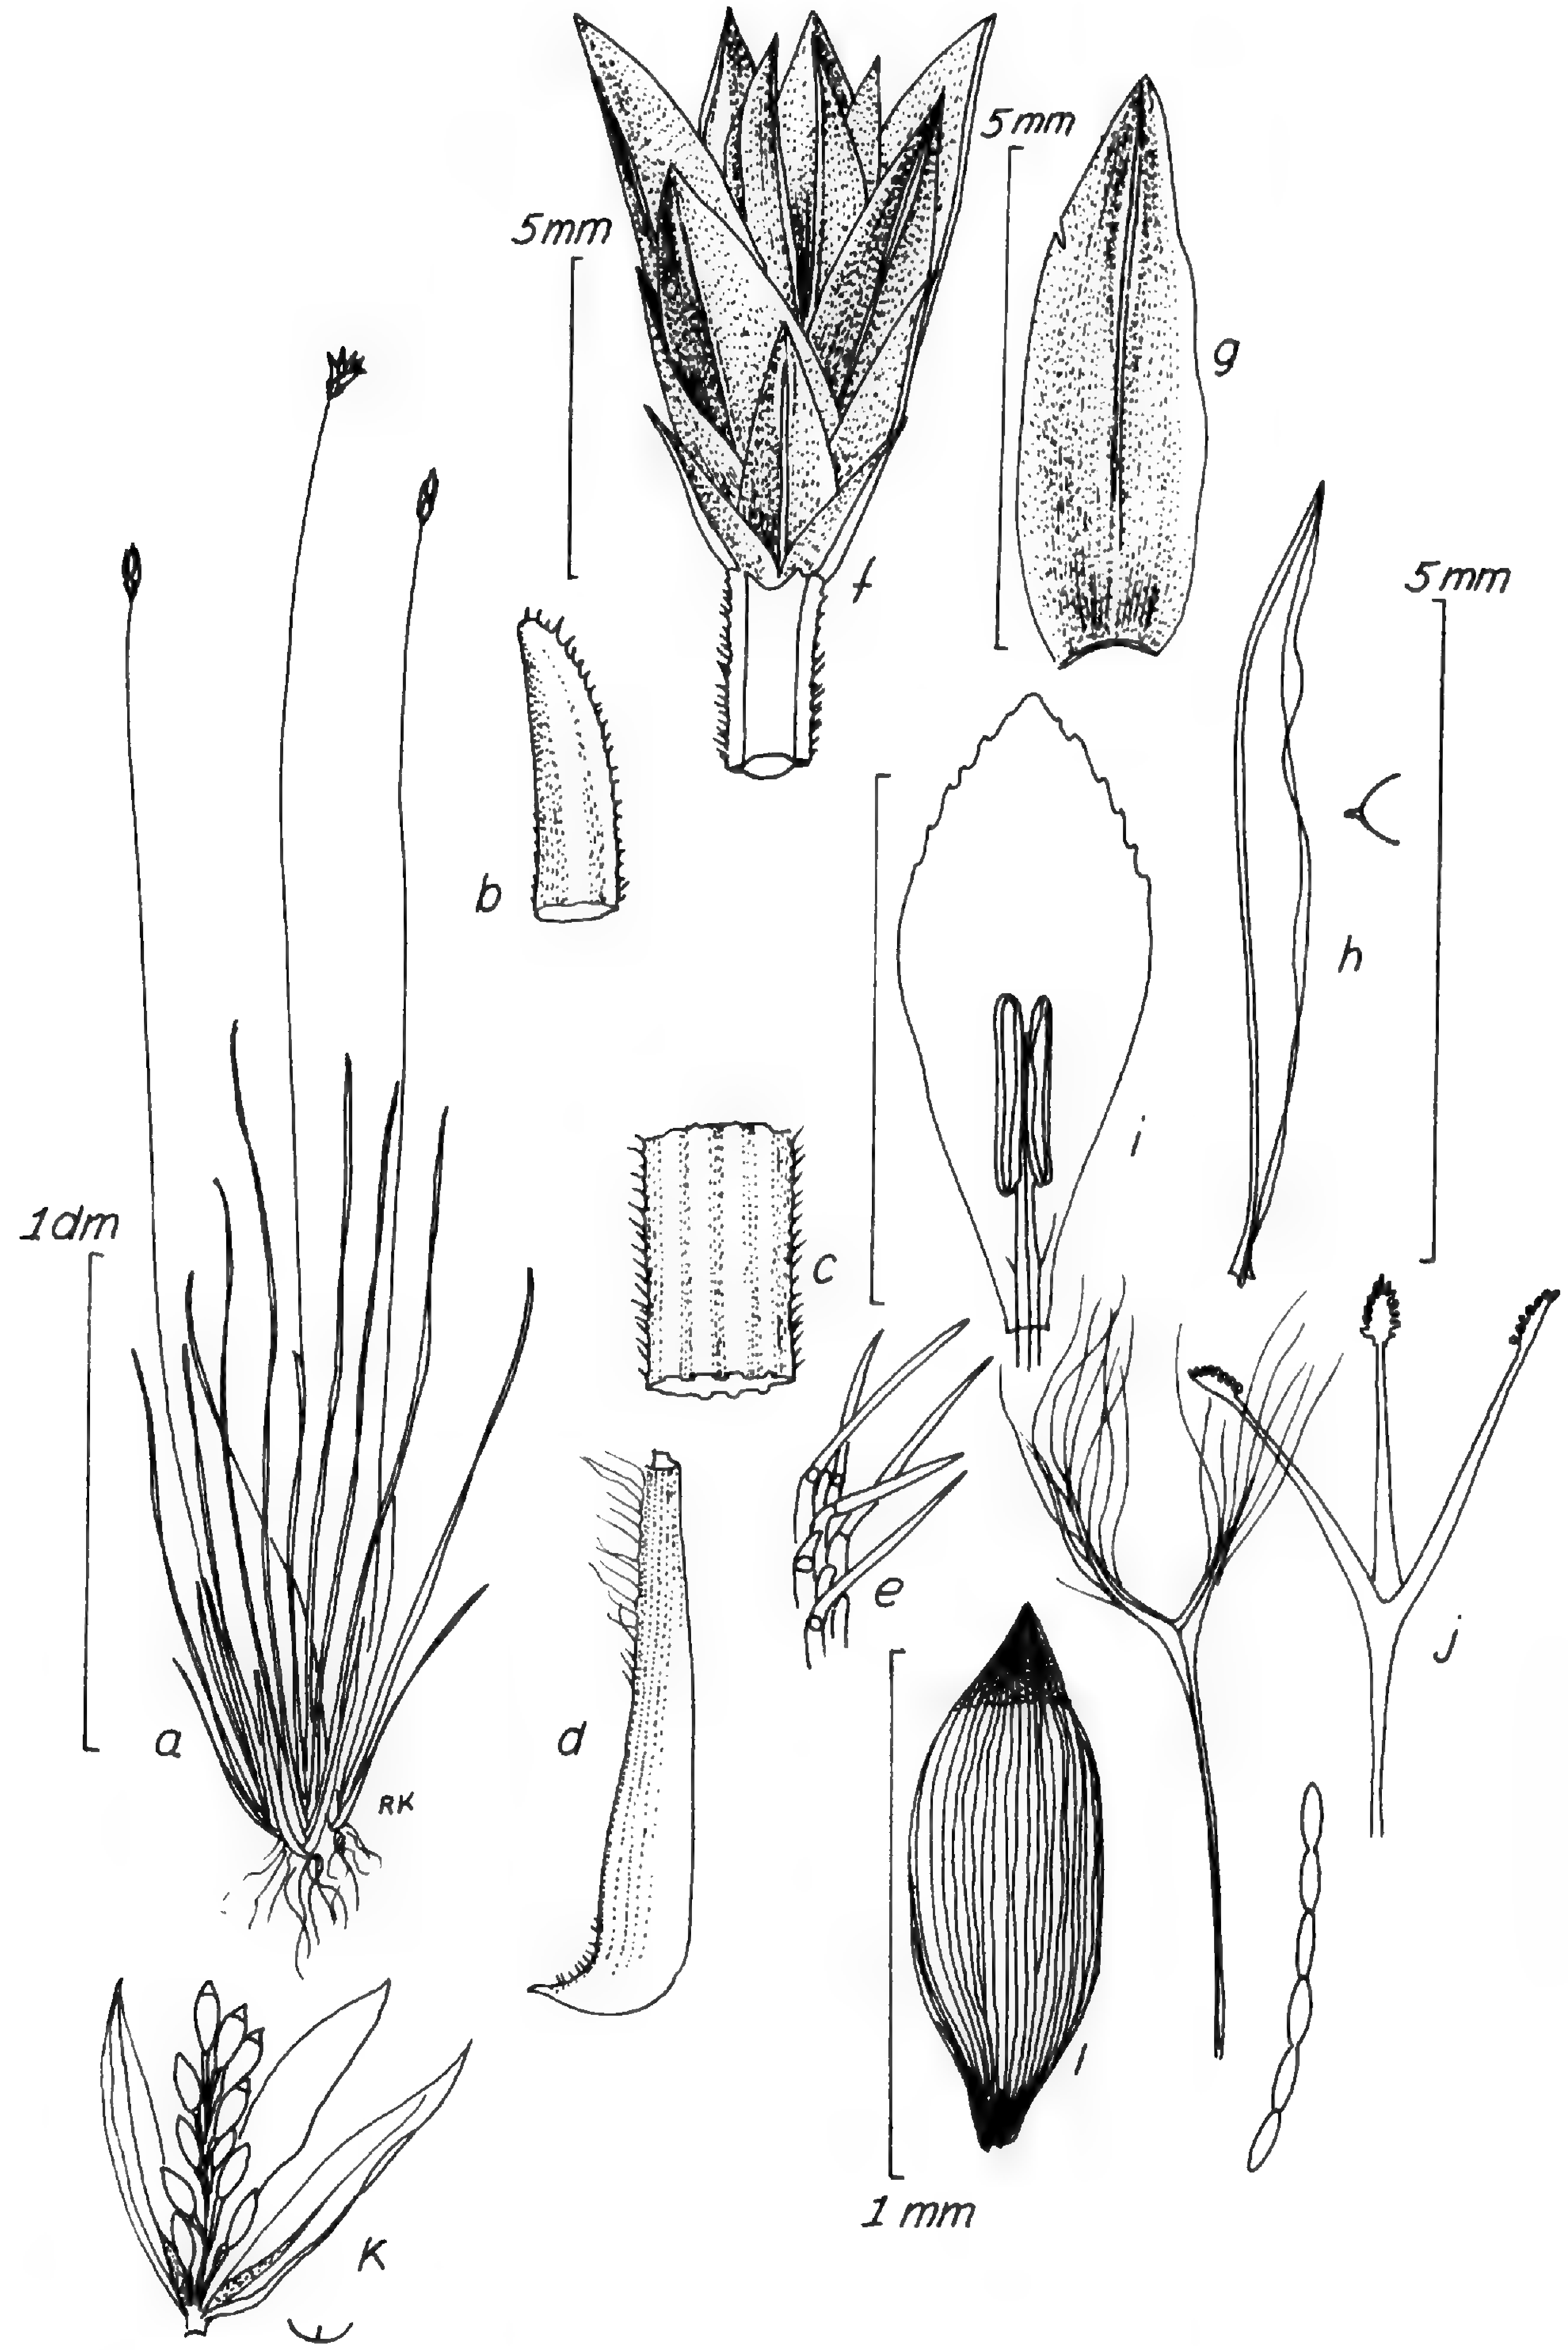

FIGURE 65. Xyris bicostata *(from the type).—a. Habit sketch.—b. Leaf apex.—c. Leaf blade, midsector.—d. Leaf base.—e. Enlarged small sector of leaf blade edge.—f. Spike.—g. Fertile bract.—h. stems contracted. Leaves erect, outermost scalelike, castaneous, the principal ones with sheath ⅛ or less the length of the blade, the base orbicular-dilated, villous-ciliate, castaneous, narrowing abruptly above, then tapering gradually into blade, this narrowly lineal, twisted, ca. 1 mm broad, slightly compressed with rounded-incrassate edges, the apex abruptly or narrowly conic, the surface smooth, longitudinally few ribbed, green. Scape sheaths much shorter than leaves, loosely convolute, multicostate, essentially bladeless. Scapes twisted, flexuous, terete, 0.7–1 mm thick, green, smooth, shallowly multiribbed or striate. Spikes broadly ovoid to subglobose or hemispherical, 5–10(–15) mm long, blunt, dull red-brown or tan, of many loosely and spirally imbricate bracts, these with pale-scarious borders, lacerate, white villous-ciliate, with distinct, narrow dorsal areas. Sterile bracts numerous, the lowest much the smallest, grading gradually to fertile bracts, these oblong to obovate, ca. 5(–7) mm long, broadly rounded, ecarinate or slightly carinate, the backs slightly convex-rounded. Lateral sepals free, subequilateral, linear-oblanceolate or oblong, ca. 5 mm long, obtuse, the sharp, alate keel pale-villous fimbriate or fimbriociliate with pale hairs from middle to apex. Petal blades narrowly obovate or elliptic, ca. 4.5–5.5 mm long, yellow, the apex broadly acute, the margins subentire. Staminodia bibrachiate, the broadly rectangular branches glabrous. Anthers narrowly oblong, deeply bifid and sagittate, ca. 1 mm long, on filaments ca. 0.7–1 mm long. Capsules deep brown, broadly obovoid, 2.5–3 mm long, the placentation basal-central, the valves lacking septa. Seeds numerous, oblong-ellipsoid, ca. 0.5–0.6 mm long, pale amber, apiculate, longitudinally with fine but distinct and anastomosing ribs.

Distribution. Mostly in low-elevation white-sand savanna in southwestern Venezuela (Territorio Federal Amazonas), particularly along the middle and upper Orinoco and tributaries; possibly in Colombia.

Selected specimens examined. VENEZUELA. T. F. AMAZONAS: La Esmeralda, Alto Orinoco, Jan.–Feb. 1969, *Farinas et al. 571* (VEN); Canaripo, bajo Río Ventuari, 11 Oct. 1977, *Huber 1064* (US); a unos 30 km al SE de la confluencia Orinoco–Ventuari, 30 Nov.–1 Dec. 1978, *Huber & Tillett 2819* (US); SSE de Sta. Barbara del Orinoco, ca. 100 m, 4 Dec. 1978, *Huber & Tillett 2852* (US); bajo Río Ventuari, ca. 10 km al E del Caserio de Carmelitas, 20 Feb. 1979, *Huber 3241* (US); W del Caño Pimichín un poco al sur del caserio Pimichín, 24 Feb. 1979, *Huber 3395* (US); also Caño Yagua, a unos 30 km al W de la Serranía El Tigre, 29 Feb. 1980, *Huber 4846* (VEN); 15 km N de Esmeralda, 8 Mar. 1980, *Huber 5059* (VEN); 20 km al NW Yavita, cabeceras Caño Pimichín, 11 Feb. 1981, *Huber & Medina 5948* (VDB, VEN); Savana el Venado, left bank Caño Pimichín above Pimichín, 23 Nov. 1953, *Maguire et al. 36360* (NY, US); Cerro Moriche, Río Ventuari, base Cerro Moriche, 17 Jan. 1951, *Maguire et al. 30992* (GH, NY, US, VEN); Cerro Moriche, cumbre, 4,500 ft., 15 Jan. 1951, *Maguire et al. 30936* (NY, US); Yapacana, Savanna III, 31 Dec. 1950, *Maguire et al. 30475* (NY, US, VEN); Cerro Moriche, 800 m, 14 Jan. 1951, *Maguire et al. 30897* (NY, US); Canaripo, 125 m, 28 Dec. 1976, *Steyermark & Redmond 112801* (MO, US, VDB, VEN); Cerro Yapacana, 8–9 Nov. 1979, *Thomas & Rogers 2610* (NY). BOLÍVAR: Cerro de Auyantepui, *Cardona 262* (US, VEN); morichal 2 km E of Río Orinoco between Río Horeda and Cerro Gavilan (Cerro Carighang), 100 m, 17 Dec. 1955, *Wurdack & Monachino 39952* (NY, US).

This, fuzzy-spiked plant, common in the Orinoco savannas, appears closest to *X. lacerata* Pohl and *X. lanulobractea* Steyerm., with the lacerate bract of the former but having villose-ciliate borders, and with the villose-ciliate border of the latter, yet with leaf bases villose-ciliate and more bulbous. It appears to be rare in low-altitude savanna in western Estado Bolívar. The leaf blades, if at all compressed, are thickened so that they have no sharp edge, something hard to reflect in key construction.

67. **Xyris arachnoidea** Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 28, fig. 12A–E. 1963. TYPE: Venezuela. T. F. Amazonas: flowers yellow, occasional, Savanna III, northwest base of Cerro Yapacana, 150 m, alto Río Orinoco, 17 Mar. 1953, *B. Maguire & J. J. Wurdack 34570* (holotype, NY; isotype, US). Figure 67.

Cespitose, hard- and fibrillose-based, subbulbous perennial 2.5–4 dm high, the stems contracted. Leaves erect, 1–2 dm long; sheaths dull brown, the very base abruptly

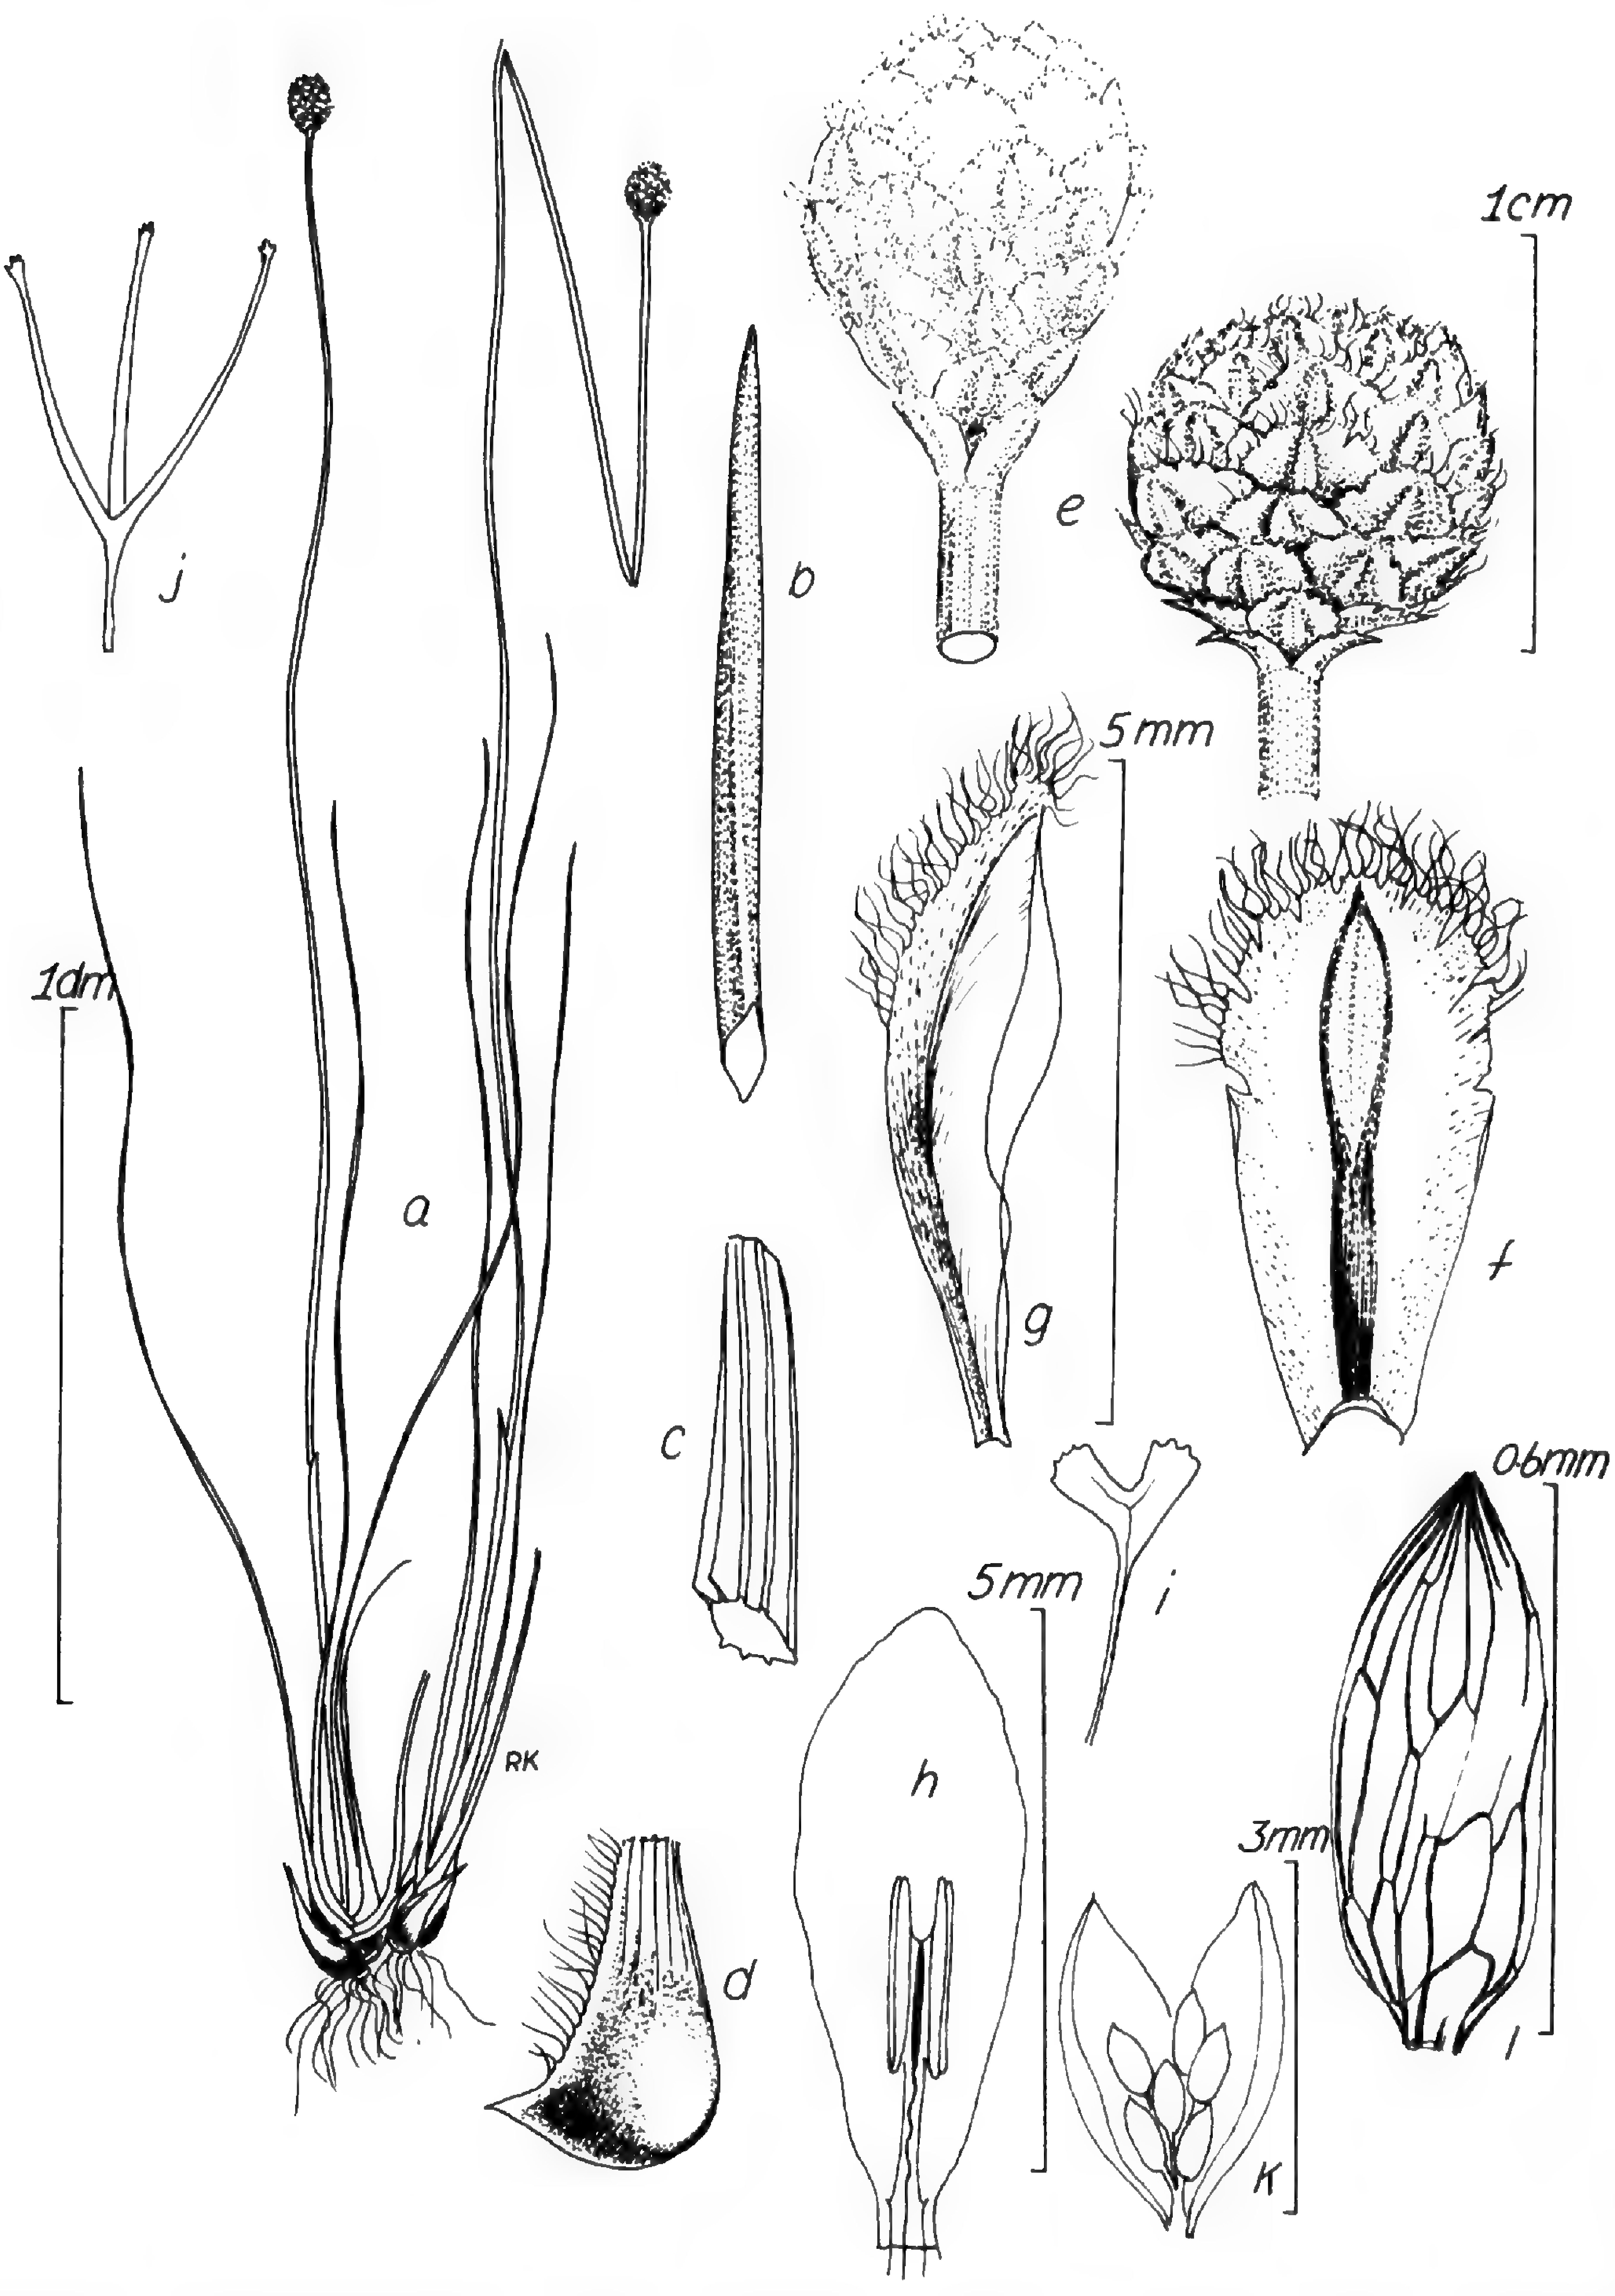

FIGURE 66. Xyris globosa (Huber 3395).—*a. Habit sketch.—b. Leaf tip.—c. Leaf at sheath–blade junction.—d. Leaf base.—e. Spikes, two types.—f. Fertile bract.—g. Lateral sepal.—h. Petal, stamen.—i. Staminode.—j. Stylar apex.—k. Capsule, one valve removed showing placentation.—l. Seed.*

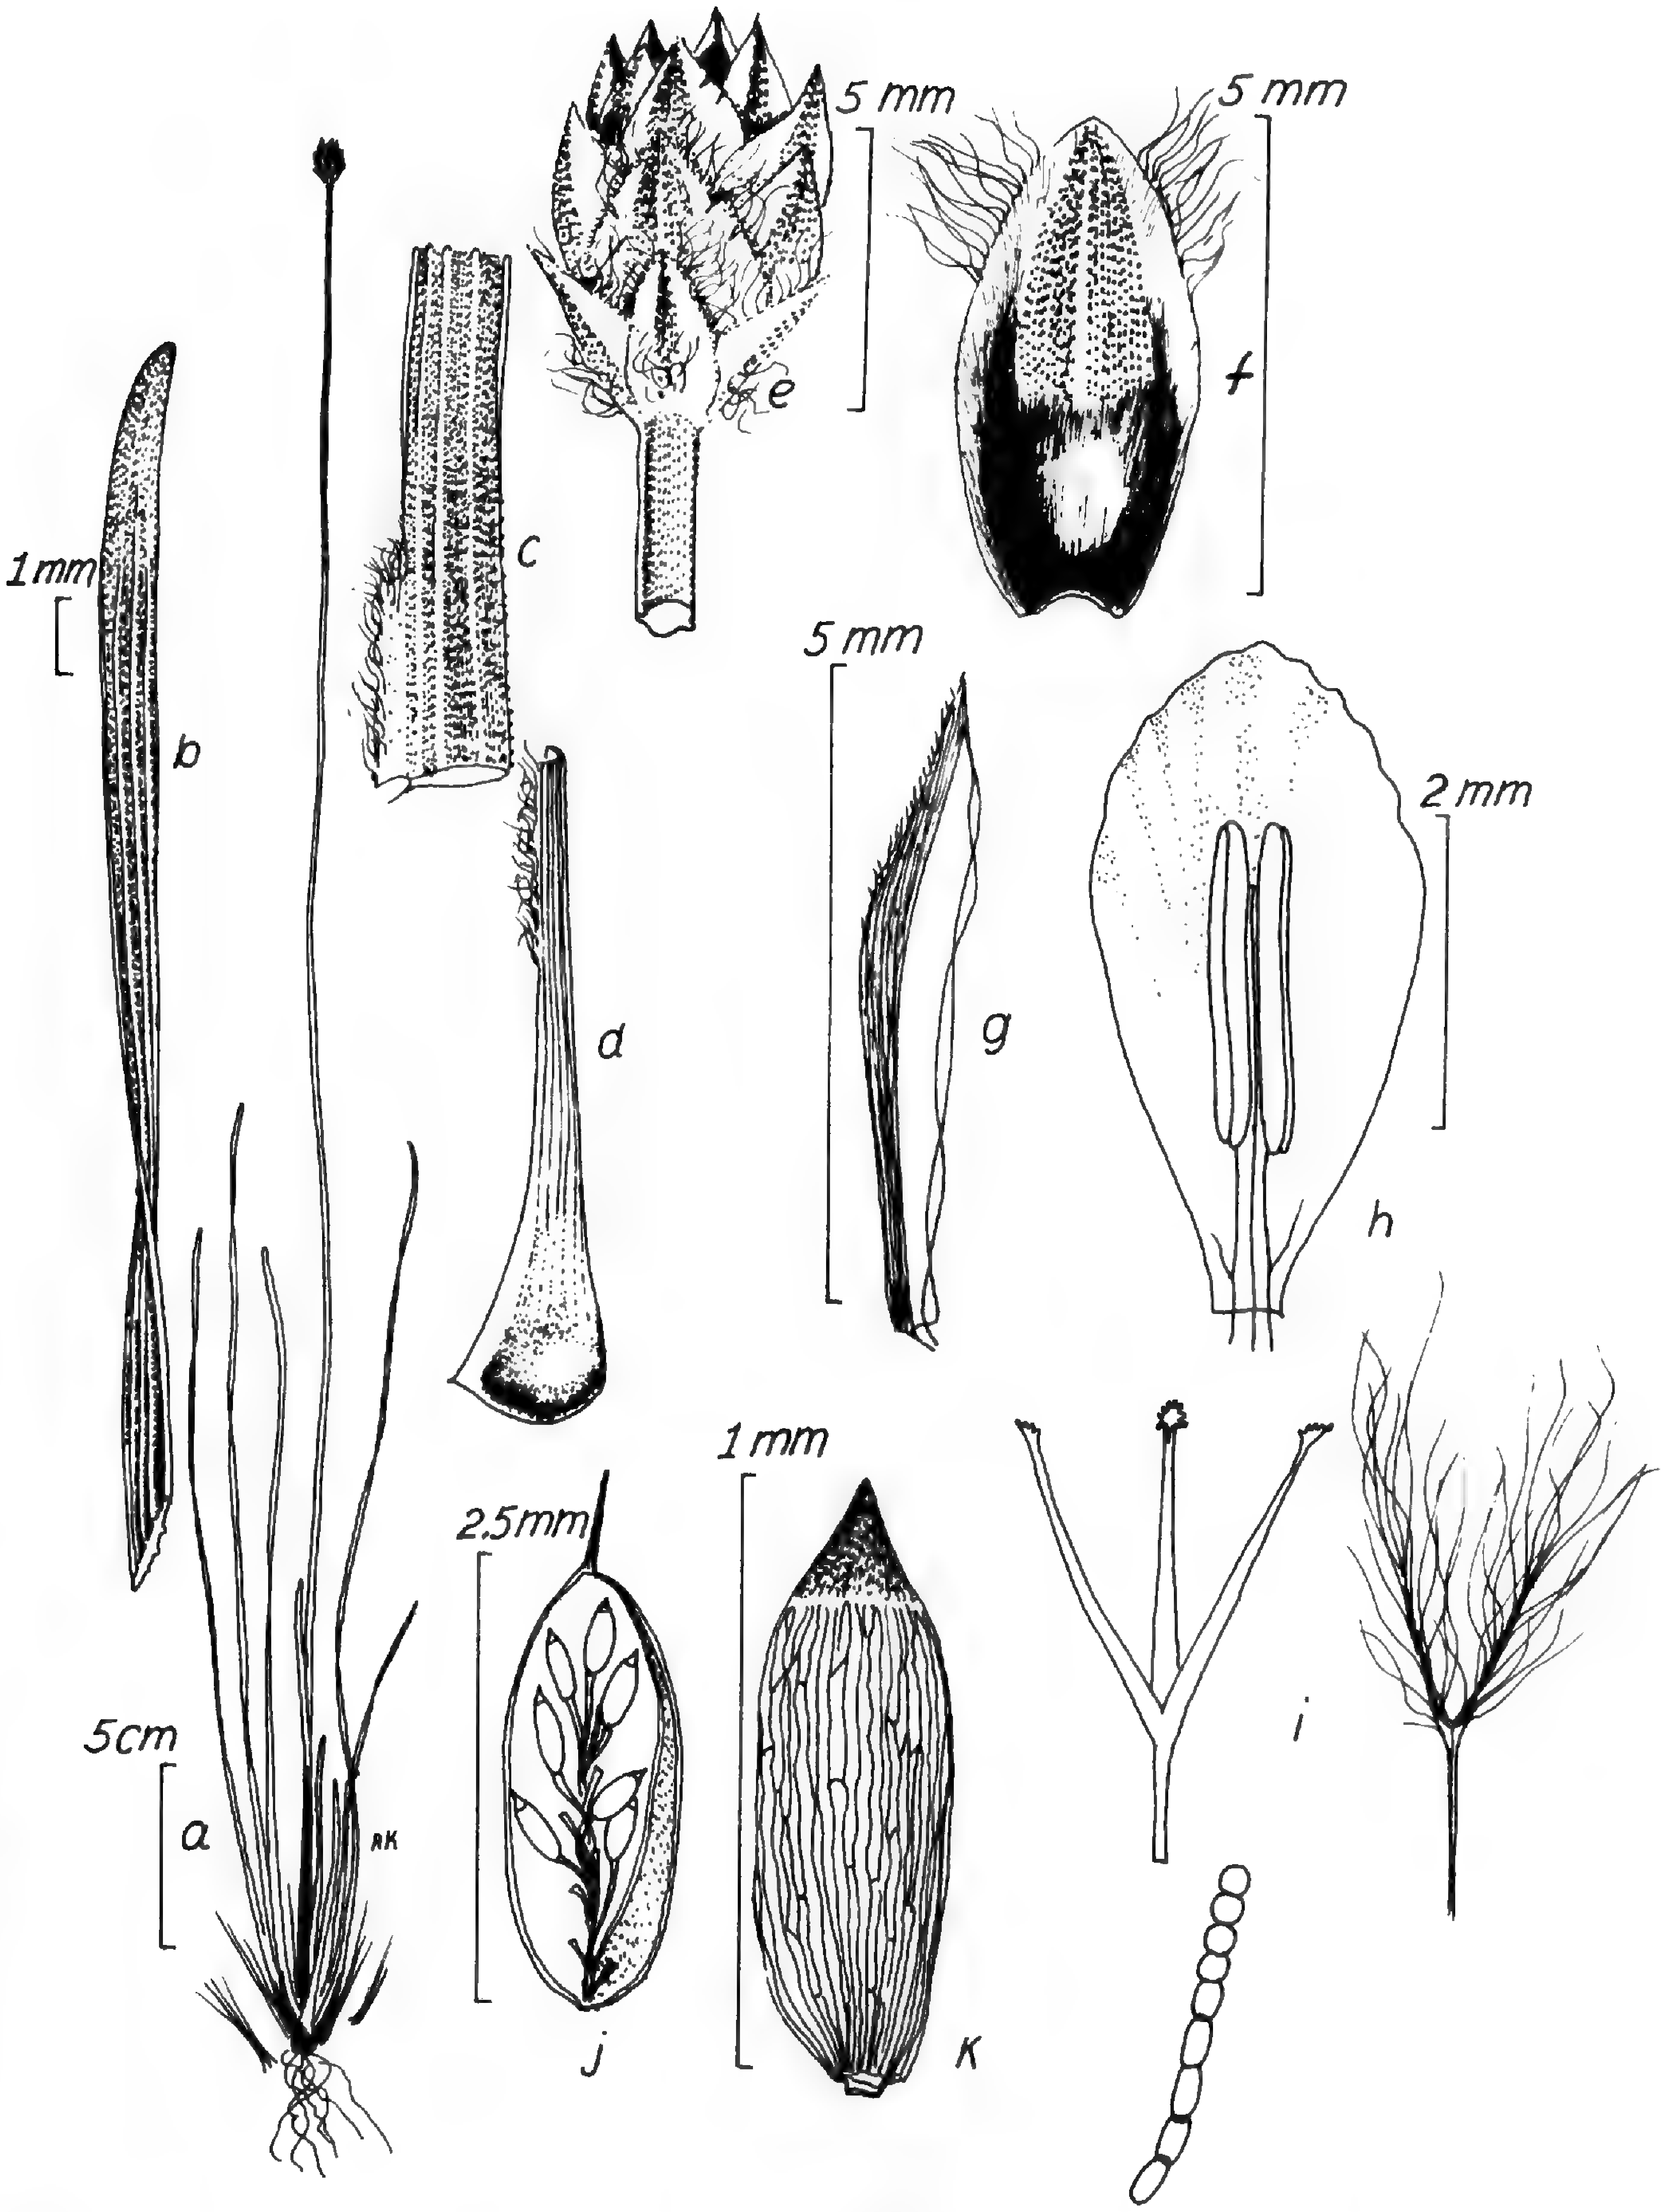

FIGURE 67. Xyris arachnoidea *(a–e from type, f–k from* Kral 70710*).—a. Habit sketch.—b. Leaf tip and upper blade.—c. Leaf sheath–blade junction.—d. Leaf base.—e. Spike.—f. Fertile bract.—g. Lateral sepal.—h. Petal blade and stamen.—i. Staminode, style branches, enlarged staminodial hair.—j. Capsule, side view of one septum (shaded), placentation.—k. Seed.*

dilated, castaneous, above tapering gradually into blades and white-villous- or lanate-margined, the ligule concealed by cottony hairs; blades evenly linear, at least 5 times as long as sheaths, flattened, ca. 1 mm wide, abruptly narrowed to a callused, narrowly rounded apex, the margins entire or scabrid toward base, rather thick, sometimes pale and contrasting, sometimes with 1 edge double, the surfaces smooth or papillose-scabrid or rugulose toward base, sometimes with a few strong, yellowish nerves, otherwise dull green or maroon. Scape sheaths much shorter than leaves, thin, keeled and open, apically with short, erect, stiff blades. Scapes flexuous and twisted, apically subterete or oval in cross section, ca. 1 mm thick, 2–4-costate, the costae yellowish, low, smooth. Spikes ovoid, drying obovoid, 7–8 mm long, blunt, dull brown, of several spirally imbricate, firm but loose bracts, the sterile bracts narrowly to broadly triangular, grading slightly larger into fertile bracts, these ovate, 4–5 mm long, acute with margins (sometimes also backs) white villose and with strong, red-brown triangular dorsal areas. Lateral sepals free, subequilateral, curvate-lanceolate, 4.5–5 mm long, acuminate, lustrous red-brown, thin, the darker, wide, firm keel with a sparse fringe of villosulous or scalelike ascending hairs, villosulous at tip, aging subentire. Petal blades obovate, ca. 5 mm long, yellow, the narrowly rounded tip erose. Staminodia bibrachiate, the branches long, slender, long-penicillate from tip to base. Anthers oblong, ca. 2 mm long, ca. 2.5–3 mm long, the placentation free-central, the capsule valves septate. Seeds numerous, narrowly ellipsoid or cylindrical, ca. 1 mm long, apiculate, translucent pale brown with numerous, very fine, wavy, longitudinal ribs and some fine cross-lines.

Distribution. Locally abundant in sandy low-elevation savanna along the upper Orinoco, Territorio Federal Amazonas, Venezuela.

Additional specimens examined. VENEZUELA. T. F. AMAZONAS: SE bank of mid part of Caño Yagua at Cucurital de Yagua, ca. 120 m, *Davidse et al. 17403* (MO), *17435* (MO, US); Cerro Yapacana, 22 May 1981, *Guánchez 1164* (TFAV, VDB); el pie occidental del Cerro Yapacana, 14–28 Feb. 1978, *Huber 1617* (US); alrededores de Canaripo, 30 May 1978, *Huber 1914* (US, VEN); Savanna III, Cerro Yapacana, 3 June 1978, *Huber 2029* (VEN), *2040* (US); entre el medio Caño Yagua y el bosque al N del Cerro Cucurito, 18 Jan. 1979, *Huber 3136* (US); Caño Caname, ca. 18 km arriba (al E) de la boca, 29 May 1979, *Huber et al. 3749* (US); alto Caño Yagua, a unos 30 km al W de la Serranía El Tigre, 29 Feb. 1980, *Huber 4846a* (VEN); Savanna II, W base Cerro Yapacana, ca. 100 m, 10 Aug. 1983, *Kral & Huber 70710* (F, K, L, MO, NY, SP, US, VDB, VEN); Cerro Yapacana en la sabana grande el Caño Cotua, 7 May 1970, *Steyermark & Bunting 103243* (US, VEN).

This species is fairly common in the savannas around Cerro Yapacana and much resembles the more widespread and associated *X. subglabrata* Malme (*X. garcia-barrigae* Idr. & Smith). It differs, however, in having much more copious white villous or arachnoid pubescence on the bracts and in having distinctly flattened (rather than terete) leaf blades. The flowers are open in the morning, closed by mid afternoon.

68. Xyris malmeana Lyman B. Smith, Bol. Inspet. Fed. Obras Contra Secas, Rio 10: 126. 1939. TYPE: Brazil, Pará: open sandy soil 2 km S of Vigia, *Drouet 2136* (holotype, GH). Figure 68.

Xyris glabrata (Seub.) Griseb. sensu Griseb., Fl. Brit. W. Ind. 525 (Trinidad), not as to basionym *X. savanensis* Miq. var. *glabrata* Seub.

Slender, solitary or cespitose, glabrous perennial 4–6 dm high, the stems contracted. Leaves erect, 1–3 dm long; sheaths ciliate, pink to deep brown, the abruptly dilated base gradually narrowed, strongly ribbed and ecarinate into the blade, this flattened, narrowly linear, twisted, 1.5–3 mm wide, gradually narrowed above middle to a narrowly acuminate or subulate apex, the margins thin, smooth, the surfaces pale green, finely nerved. Scape sheaths much shorter than principal leaves, strongly ribbed, twisted, also keeled, with a cusplike blade apically. Scapes slenderly linear, straight or flexuous, twisted, subterete at apex, ca. 0.5 mm thick, with 3 or more low but sharp and distinct, smooth or papillose costae. Spikes broadly ellipsoid or ovoid, 5–8 mm long, acute, pale red-brown or dull brown, of several spirally imbricate, convex, ecarinate, entire to lacerate bracts with distinct dorsal areas, the sterile bracts slightly smaller than the fertile bracts, grading into them, the fertile bracts 4–6 mm long, broadly elliptic to obovate, broadly or narrowly rounded apically, sometimes the inner ones slightly keeled, all with a short, narrow,

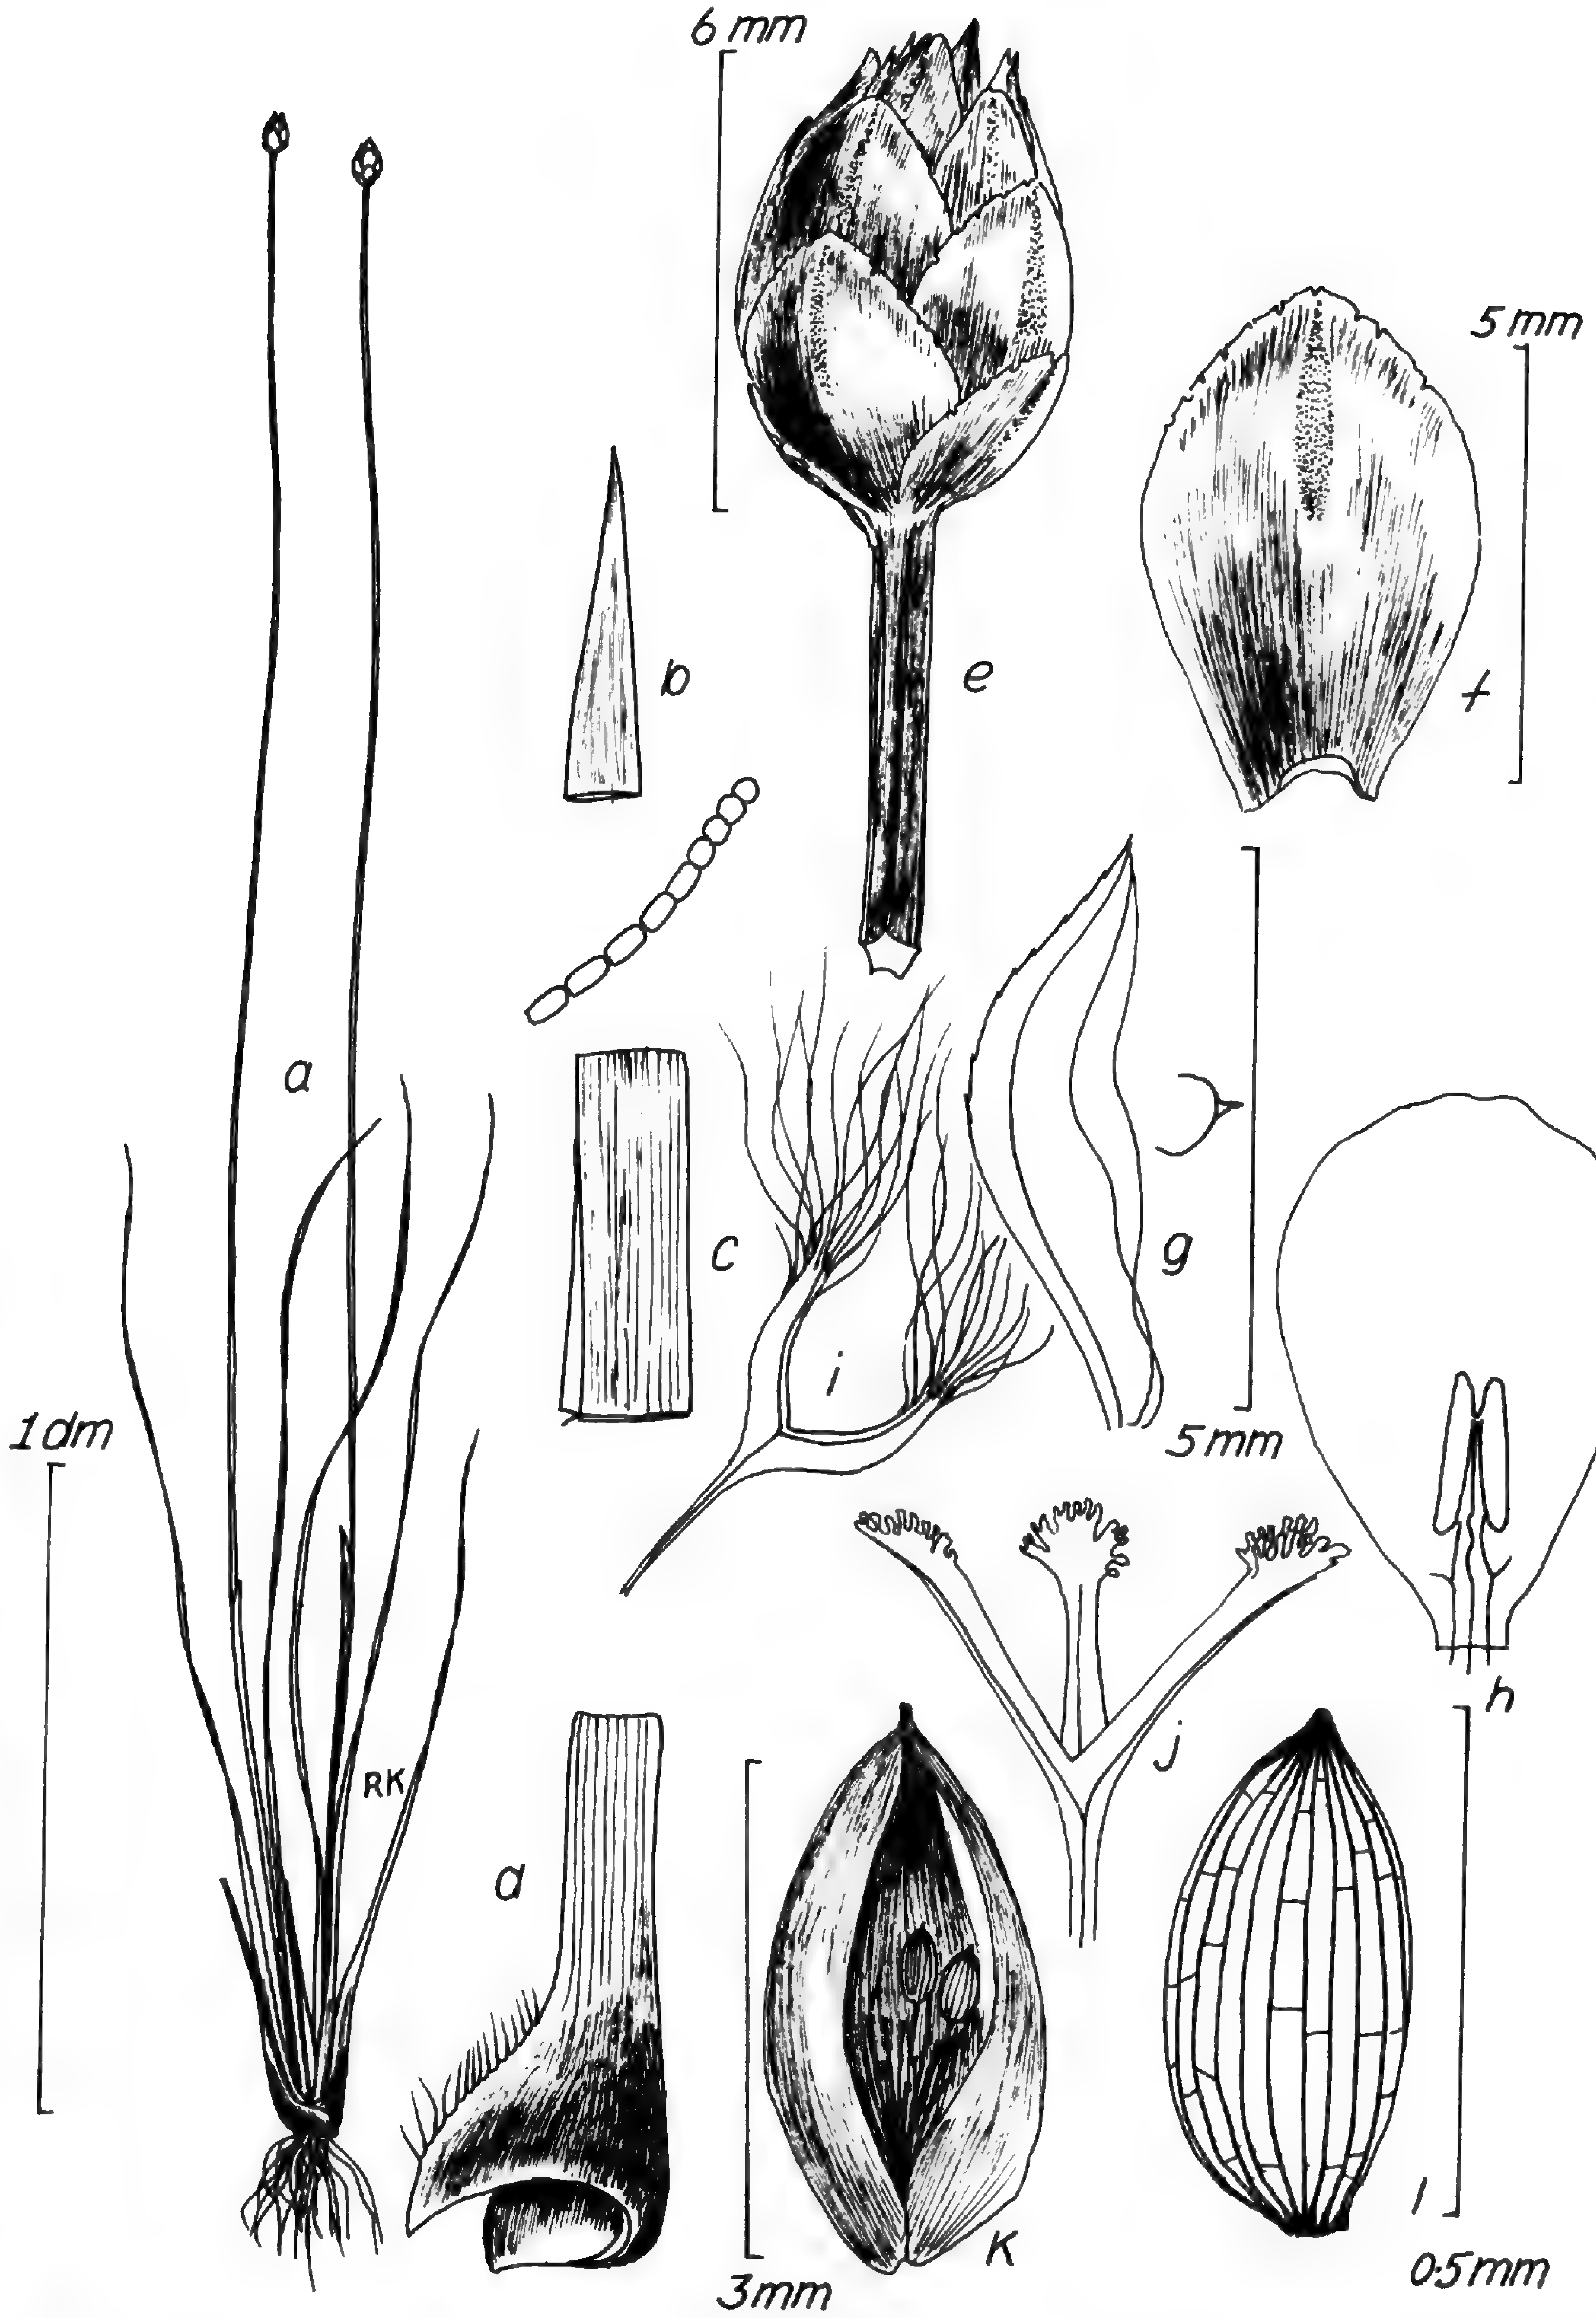

FIGURE 68. Xyris malmeana (Steyermark & Dunsterville 113285).—*a. Habit sketch.*—*b. Leaf tip.*—*c. Leaf sheath–blade junction.*—*d. Leaf base.*—*e. Spike.*—*f. Fertile bract.*—*g. Lateral sepal.*—*h. Petal blade, stamen.*—*i. Staminode.*—*j. Stylar apex.*—*k. Capsule.*—*l. Seed.*

usually greenish dorsal area. Lateral sepals free, slightly inequilateral, thin, elliptic-curvate, ca. 5 mm long, acute, the broad, firm keel lacerate-ciliolate from middle to apex, or nearly entire. Petal blades obovate, ca. 4 mm long, yellow, the broadly rounded apex subentire. Staminodia bibrachiate, the narrow, flat branches distally penicillate-ciliate. Anthers ca. 1 mm long, lance-oblong, deeply bifid and sagittate, on filaments 0.3–0.4 mm long. Capsule obovoid, firm-valved, 3.5–4 mm long, the placentation basal, the valves without septa. Seeds numerous, broadly ellipsoid, ca. 0.5 mm long, 2-apiculate, deep lustrous amber, finely ribbed longitudinally.

Distribution. Sandy, low- to high-elevation savanna, northern South America from Territorio Federal Amazonas, Venezuela, eastward to French Guiana and in contiguous northern Brazil in Amapá, Amazonas, Guapore, and Pará; Trinidad.

Selected specimens examined. BRAZIL. AMAPÁ: Camp 27.VI.1904, *A. Ducke s.n.* (MG, US). AMAZONAS: estrada Humaita–Lábrea, km 17, 10 June 1982, *Teixeira et al. 1059* (INPA, NY, VDB). AMAZONAS: 20–25 km W de San Juan de Manapiare, 8 Oct. 1979, *Huber 4491* (US); Esmeralda, 9 Oct. 1928, *Luetzelburg 22498* (US). BOLÍVAR: SE base Auyan-tepui, 24 Nov. 1982, *Davidse & Huber 22565* (MO, VDB); 3 km S of El Pauji, 1,050 m, 19 Oct. 1985, *Holst & Liesner 2630* (MO, VDB, VEN); sabanas al SW de Kamarata, 23 Nov. 1982, *Huber et al. 6810* (MYF, VDB, VEN); Caserio de Kukenan, ESE de la punta SE del Churí-tepui, *Huber 9768* (MYF, VDB); flats above Río Yuruani at Salto Yuruani, 28 July 1983, *Kral 70572* (MO, NY, US, VDB, VEN); 1.3 km N of Río Yuruani Ferry, ca. 750 m, 29 July 1983, *Kral 70619* (NY, US, VDB, VEN); above Ven. 10, ca. 800 m, and N of Ferry, Puente Kumerepa, 17 Dec. 1984, *Kral 72189* (MYF, VDB, VEN—a large set to be distributed); cumbre de Cerro Guaiquinima, salto del Río Szczerbanari, 20–25 Jan. 1977, *Steyermark & Dunsterville 113285* (NY, US, VEN); Auyan-tepui, 1,100 m, Dec. 1937–Jan. 1938, *Tate 1316* (NY).

This species most resembles *X. lacerata* Pohl ex Seub. However, *Xyris malmeana* is usually lower, is more slender, and is less bulbous based. Its scapes are more sharply costate, its dorsal areas are narrower, and its lateral sepals are less ciliate.

69. Xyris araracuare Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 34, fig. 20A–F. 1963. TYPE: Colombia. Amazonas: frequent in scrub savanna, Araracuará, Río Caquetá, 5 Sep. 1959, *B. Maguire, C. K. Maguire & A. Fernandez 44132* (holotype, NY; isotype, US). Figure 69.

Slender, somewhat cespitose, bulbous-based perennial 2–3 dm high. Older leaves short, scalelike, covering "bulb." Main foliage leaves few, ascending, 10–20 cm long; sheaths ciliate, much shorter than blades, abruptly flaring at base, castaneous, ligule absent, tapering gradually above into blade, this green, subterete, fluted, lineal, twisted, 0.7–0.8 mm wide, smooth or scaberulous along lateral ribs, abruptly bluntly conic. Scape sheaths shorter than leaves, loose, blade short, cusplike. Scape straight or flexuous, twisted, terete and slightly grooved or fluted, punctate distally, proximally ribbed and scaberulous. Spike broadly obovoid, 7–8 mm long, blunt, many-flowered, pale dull brown, the bracts loosely spirally imbricate; sterile bracts mostly 6, broadly ovate or triangular, the lowest smallest, narrowly scarious-lacerate-bordered, grading gradually to fertile bracts, these ovate, ca. 5.5 mm long, the tips narrowly rounded, lacerate-bordered, the backs rounded with darker, lance to linear dorsal areas; innermost bracts more navicular, more acute, subentire,

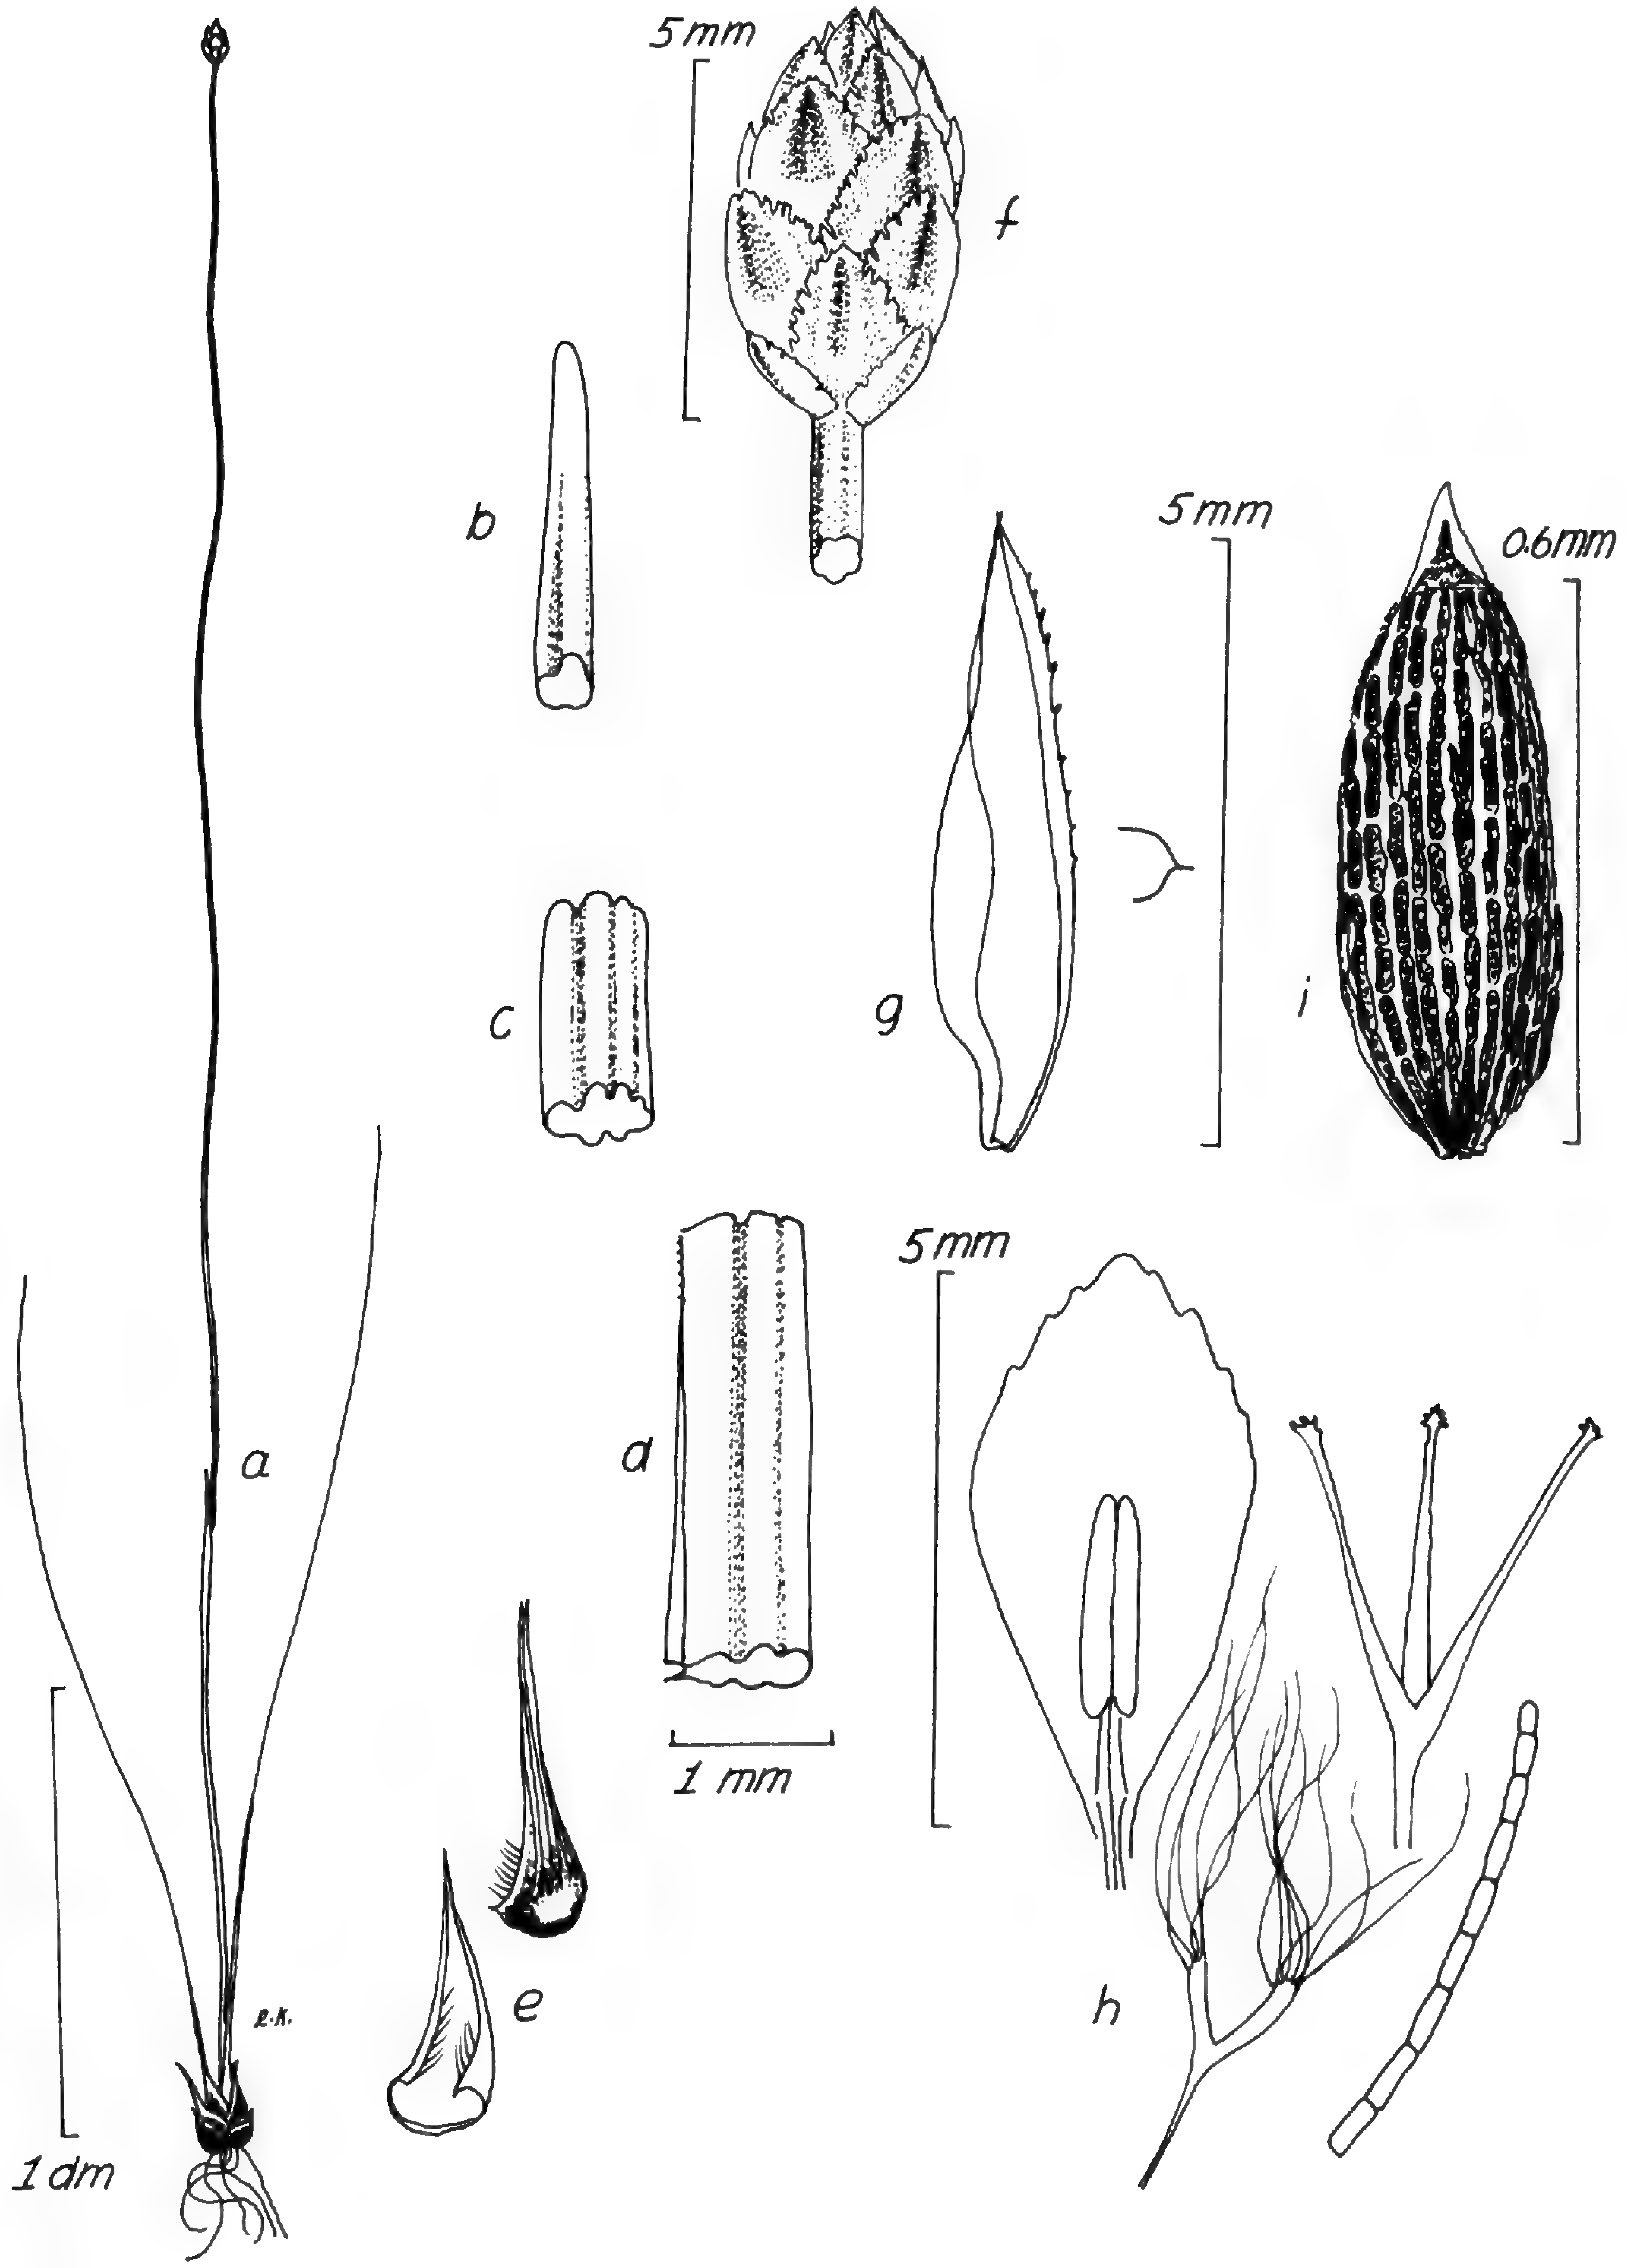

FIGURE 69. Xyris araracuare *(from the type).—a. Habit sketch.—b. Leaf apex.—c. Sector of lead mid-blade.—d. Leaf at junction of sheath.—e. Two views of leaf base.—f. Spike.—g. Lateral sepal.—h. Petal blade, stamen, staminode, style branches, enlarged beard hair.—i. Seed.*

to 6 mm long. Lateral sepals free, subequilateral, elliptic-linear, ca. 4.5(–5.5) mm long, narrowly acute, pale brown except for darker, narrow, firm keel, this ciliate-scabrid from ca. middle to apex. Petal blades yellow, obovate, ca. 5 mm long, narrowly rounded apically, sparsely dentate. Staminodia bibrachiate, the branch apices sparsely long-penicillate. Anthers oblong, ca. 2 mm long, on filaments 0.5 mm long. Capsule narrowly obovoid, 2.5 mm long; placentation basal, funiculi long. Seeds numerous, narrowly lance-ovoid to ellipsoid, 0.6 mm long, translucent, longitudinally with several broad, wavy, distinct ribs.

Distribution. Sandy scrub savanna, known only from the type collection.

Evidently this species is very close to the widespread *X. lacerata* Pohl ex Seub., as the descriptions and illustrations show. It is best to include it now with that perspective until the entire genus is revised for South America.

70. Xyris lacerata Pohl ex Seub. in Martius, Fl. Bras. 3(1): 26, pl. 26. 1855. TYPE: Brazil: "Goias, *Pohl*" (isolectotype, BR; phototype, US no. *5752*). Figure 70.

Tall, bulbous-based, solitary or cespitose perennial 4–6 dm high, the stems contracted, the outer leaves scalelike, castaneous. Principal leaves 1.5–3 dm long, erect or ascending; sheaths less than ¼ length of blades, at base abruptly dilated, ciliate, cochleariform, usually castaneous, papillose-rugulose; above paler, entire, gradually tapering to blade, papillose-rugulose, eligulate; blades narrowly linear, flattened, or rarely thickened, subterete, twisted, 1.5–3 mm wide, acute to narrowly acuminate, often subulate, the edges thin or cartilaginous-incrassate, smooth or papillose, the surfaces dull green, smooth or papillose-rugulose, multinerved. Scape sheaths much shorter than leaves, tight, proximally twisted and multicostate, opening and keeled distally, producing a cusplike blade. Scapes twisted, straight or flexuous, terete distally, 0.5–1 mm thick, striate, ecostate or with 1 low costa, smooth to papillose. Spikes globose, broadly ovoid or hemispherical, 0.5–1 cm long, dull brown, of very many spirally imbricate, convex-rounded, lacerate and scarious-edged bracts having distinct, green to red-brown dorsal areas; sterile bracts several, distinctly smaller than and grading into fertile bracts, these oblong to obovate, 6–7 mm long, broadly rounded, ecarinate, and with broadly lacerate scarious borders (innermost fertile bracts narrower, frequently keeled). Lateral sepals free, slightly inequilateral, oblong-curvate, ca. 5.5–6 mm long, blunt, lustrous red-brown, the firm, narrow keel ciliolate from near base to tip. Petal blades obovate, 5.5–6 mm long, yellow, the rounded apex erose. Staminodia bibrachiate, the narrow flat branches long-penicillate from near base to tip. Anthers lance-oblong, ca. 2 mm long, shallowly bifid, deeply auriculate, on filaments ca. 0.5 mm long. Capsule narrowly ellipsoid, ca. 5 mm long, the placentation densely central, the valves lacking septa. Seeds numerous, broadly to narrowly ellipsoid or fusiform, 5–6 mm long, deep amber, 15–20-ribbed with much fainter crosslines.

Distribution. Sandy or sandy-silty or rocky campos and savannas, eastern Colombia eastward across southern Venezuela and probably into Guyana but with no official record; to the south, from the Andean foothills eastward from northern Brazil south into Argentina.

Selected specimens examined. Only northern records are listed. COLOMBIA. META: E of Río Zanza, 2 km above jct. with Río Cuejar, ca. 500 m, 22 Aug. 1950, *Idrobo & S. This common plant of low- to medium-elevation savanna bears a considerable resemblance to *X. tortula* C. Martius of the planalto of Brazil and may indeed intergrade with it. I have seen the phototype of *X. fallax*, the type supposedly still at M, and am surprised to see that it is comprised of two good specimens of *X. lacerata*.

71. Xyris oblata Kral & Lyman B. Smith, sp. nov. TYPE: Venezuela. T. F. Amazonas: en la sombrede arboles pequenos; fls. amarillas; en las sabanetas periodicamente enegadas cerca de la margem del Caño Temi, Yavita, 128 m, 31 Jan. 1942, *Llewelyn Williams 14121* (holotype, F; isotypes, F, US). Figure 71.

Planta solitaria vel caespitosa, tenuis, annua aut perennis, 3–4 dm alta, caulibus contractis. Folia principalia vulgo flabellate expansa, 1–2 dm longa; vaginae brunneociliatae, laminas ca. 2-plo breviora, brunneolae vel atroporphyreae, sursum in laminas gradatim contractae, eligulatae; laminae gladiatolineares, complanatae, 1–3.5 mm latae, a medio ad apicem gradatim contractae, ad apicem abrupte incurvatae vel erectae, acutae, leviter incrassatae; margines tenues, scabriduli; paginae leviter stratonervosae, marroninae, dense scabrido-rugosae. Vaginae scaporum foliis breviora, proxime contortae, carinatae et costatae, carinatis scabridis, ad apicem apertae, laminis curtis, ciliatis, erectis. Scapi recti vel flexuosi, torti, ad apicem teretes vel in sectione transversali ovales, papillati, ecostati, plani vel leviter striati. Spicae oblatae, ca. 5 mm altae, 6–7 mm latae, interdum proliferatae, brunneolae, bracteis numerosis integris, spiraliter imbricatis, area dorsalis distinctis; bracteae steriles plures, fertilibus leviter breviores et angustiores, fertiles gradatim profluentes; bracteae fertiles late obovatae, ca. 5 mm longae, subintegrae, ecarinatae, leviter convexae; area dorsalis ovata vel elliptica, pallide punctata. Sepala lateralia libera, inaequilatera, ca. 4 mm longa, obtusa, pallide spadiceae; ala carinali valde curvata, a medio ad apicem fimbriatolacerata. Lamina petalorum obovata, ca. 4.5 mm longa (est.), luteola. Staminodia bibrachiata, brachiis dense longipenicillatis. Antherae lanceolatae, 1.5 mm longae; filiis ca. 0.5 mm longis. Capsula ellipsoidea vel subrotunda, ca. 2.5 mm longa, planoconvexa, placentae axiales. Semina numerosa, ellipsoidea, ca. 0.8 mm longa, atrosuccinea, longitudine valde et anguste 28–30-costatae.

Solitary or cespitose, slender annual or short-lived perennial 3–4 dm high, the stems contracted. Leaves mostly spreading flabellately, 1–2 dm long; sheaths soft, ca. ½ as long as blades, carinate, brown ciliate, dull brown to deep red-brown, rugoscabrid, narrowed gradually to blades and eligulate; blades gladiate-linear, flat, 1–3.5 mm wide, tapering gradually from midblade to an erect or slightly incurved, bluntly acute, slightly thickened tip; margins thin, scabridulous; surfaces striate-ribbed, maroon, densely scabridulous-rugose. Scape sheath shorter than leaves, proximally twisted, carinate and costate, the keel scabrid, open at apex, with short, ciliate, erect blade. Scape straight or flexuous, twisted, distally terete or oval in cross section, papillate, ecostate, level or striate. Spikes depressed-globose, ca. 5 mm long, 6–7 mm broad, sometimes proliferous, dull brown, of many firm, entire, spirally imbricate bracts with distinct dorsal areas; sterile bracts several, the lowest narrower and slightly shorter than the fertile bracts, scabrid-ciliate, grading into fertile bracts; these obovate, ca. 5 mm long, broadly rounded, subentire, the backs shallowly convex, ecarinate, papillate, the dorsal area oval to elliptic, pale punctate. Lateral sepals free, inequilateral, ca. 4 mm long, obtuse, tan, the thin, strongly curvate keel fimbriolacerate from middle to apex. Petal blades obovate, ca. 4.5 mm long (estimate), yellow. Staminodia bibrachiate, the branches densely long-

penicillate. Anthers lanceolate, ca. 1.5 mm long, planoconvex, the placentation axile at base. Seeds ellipsoid, ca. 0.8 mm long, dark amber, with 28–30 strong, narrow, irregular longitudinal ribs.

Distribution. So far known only from the type collection.

Material of this distinctive species in general character of leaves and aspect of plant much resembles some *X. savanensis.* It differs markedly in that the leaf sheaths are conspicuously ciliate, the spikes distinctively oblate, and the ornamentation of lateral sepals different. Also, the staminodial branches are densely long-penicillate, a character lacking in *X. savanensis.*

72. Xyris tenella Kunth, Enum. Pl. 4: 9. 1843. TYPE: Brazil. São Paulo: Sul do Estado, *Sellow s.n.* (lectotype, B; phototype, US). Figure 72.

Synonyms given below are only for Venezuelan material.

Xyris steyermarkii Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 30, fig. 15A–E. 1963. TYPE: Venezuela. Bolívar: Caño Mojado between base of upper falls and drop to escarpment, 1,985–1,910 m, summit, Chimantá Massif, Torono-tepui, 23 Feb. 1955, *J. A. Steyermark & J. J. Wurdack 1096* (holotype, NY; isotype, US).

Xyris yutajensis Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 36, fig. 19A–F. 1963. TYPE: Venezuela. T. F. Amazonas: small savanna and along left fork of Caño Yutaje, 1,250 m, Serranía Yutaje, Río Manapiare, 12 Feb. 1953, *B. Maguire & C. K. Maguire 35206* (holotype, NY; isotype, US).

Cespitose, delicate, low smooth annual, 0.5–2 dm high, the stems contracted. Leaves mostly erect, 2–8 cm long; sheaths soft, scarious, long-ciliate, stramineous or pale brown, less than ½ blade length, finely costate, evenly narrowed from dilated base to blade, eligulate; blades linear-filiform, slightly twisted, somewhat flattened, ca. 0.5 mm wide, narrowed at apex to an incurved-apiculate, callused tip; margins entire, smooth, or ciliolate; surfaces very finely nerved, green to maroon. Scape sheaths shorter than leaves, at base tubular, multicostate, brown, distally open and slightly dilated, keeled, with short, erect blades. Scapes filiform, terete, 0.3–0.4 mm thick, finely striate distally, sometimes unicostate with a low costa, or low-costate, costae papillate to finely scabrid. Spikes ellipsoid or lance-ovoid, drying narrowly obovoid, ca. 5–6 mm long, of a few thin, brown to tan bracts with prominent but narrow or streaklike dorsal areas; sterile bracts few, lance-ovate or oblong, navicular, smaller than the fertile bracts, grading into them; fertile bracts few, lanceolate, rounded-folded (navicular), ca. 5–5.5 mm long, acute, subentire or lacerate, the keel darker brown. Petal blades broadly obovate, 3 mm long, yellow, the broadly or narrowly rounded apex with sinuate-erose margin. Staminodia lacking or blade broadly bilobed, beardless (in the Guayanas). Anthers lance-oblong, ca. 1 mm long, deeply bifid and sagittate, on broad filaments 0.6–0.7 mm long. Capsule narrowly ovoid, ca. 3 mm long, acuminate, the placentation basal. Seeds ovoid to ellipsoid, ca. 0.5 mm long, deep amber, finely lined longitudinally.

Distribution. Low- to high-elevation savanna from southeastern Venezuela eastward to French Guiana; southward through the planalto of Brazil, thence south into Paraguay.

Selected specimens examined. Citations are selected from Venezuelan material only. VENEZUELA. T. F. Some insight into the *X. tenella* situation was given me by examination of a *Tate* specimen (*810*) from the gorge of Caño Negro, Savanna Hills, Mt. Duida. Malme, working when that part of Venezuela was hardly explored, did see this specimen, annotating it at first *X. tenella* Kunth var. *subtenella,* a taxon he later (Ark. Bot. 13(3): 44. 1913) changed to a form of the type variety. This led me to examine a rather large series of materials from Brazil and Paraguay. From these it appears that if transplants of *X. tenella* from Paraná or Mato Grosso were put in suitable habitat in Venezuela, such would be indistinguishable from forms named *X. steyermarkii* and *X. yutajensis.* The variety from French Guiana (var. *leprieurii* Malme, "Cajenne legit Le Prieur" isolectotype at L) is taller than the Venezuelan material, has flat, ciliolate-edged leaf blades, and narrowly ovoid spikes.

The dorsal area character in this species varies troublesomely. Sometimes it appears only on some bracts. In Brazil are specimens named other species that, if given the pencil-thin dorsal area, would again be placeable in *X. tenella.* The only constant, apart from the low and annual or short-lived perennial habit, seems to be the long brush of ciliae on the leaf-sheath edges. The dorsal area when present is very narrow, a ready means of distinguishing this from extremes of *X. guianensis,* which always has a broad dorsal area.

73. Xyris byssacea Kral, sp. nov. TYPE: Venezuela. T. F. Amazonas: Dpto. Río Negro, Valle de Titirico N of Pico Phelps in Cerro Neblina, ca. 0°56′N, 65°58′W, ca. 2,200 m; peat bog interspersed with shrub and low rocky but wet ridges, flowers opening in the A.M., 1 Dec. 1984, *R. Kral et al. 71926* (holotype, VEN; isotypes, MO, NY, US, VDB). Figure 73.

Planta perennis, densicaespitosa, glabra, delicatula. Caules breves; radices graciles. Folia principalia arcte disticha, suberecta, 8–15 cm longa, vaginis scaporum longiora; vaginae elongatae, laminis multi-plo longiores, byssaceociliatae, pallide brunneolae, nitidae, ad basin gradatim dilatatae, in laminas gradatim decrescentes, eligulatae; laminae compressae, 0.3–0.4 mm latae, leviter tortae, ferrugineae, nitidae, subcapillaceae, in apicem gradatim decrescentes, ad apicem conico-subulatae, plerumque setaceae. Scapi tenues, 20–30 cm longi, brunnei, apicem versus teretes, ecostati vel leviter striati, ca. 0.5 mm crassi. Spicae pauciflorae, ellipsoideae, tum curtocylindricae, pallide brunneolae, ca. 6 mm longae; bracteae leviter expanse, integrae, decussatae, area dorsali lineare, infimae 4 steriles, par inferiora lanceolata, ca. 3–4 mm longa, acuta, valde carinata, par intima ovata, ca. 4 mm longa, ad apicem curto-carinata, area dorsali redacto; bracteae fertiles 2–4, oblongae, 4.5–5 mm longae, subconduplicatae, anguste rotundatae, a medio ad apicem carinatae, area dorsali lineari. Sepala lateralia libera, inaequilateralia, anguste-elliptica, ca. 4.5–5 mm longa, acuta, leviter curvata, ala carinali angusta sed crassa, integra. Laminae petalorum anguste obovatae, luteolae, ca. 4 mm longae, integrae. Staminodia bibrachiata, brachiis anguste triangulatis, longipenicillatis. Antherae lanceolatae, vadose bifidae et sagittatae, ca. 1.5 mm longae, filiis ca. 0.5 mm longis. Capsula matura anguste ellipsoidea, ca. 3 mm longa; placenta basalis, funiculis elongatis. Semina ellipsoidea vel cylindrica, ca. 1 mm longa, translucentia, pallide ferrugineobrunneola, subtiliter longitudine spiraliter lineata.

Densely cespitose, smooth, delicate perennial. Stems short; roots slender. Principal leaves tightly distichous, suberect, 8–15 cm long, longer than the scape sheaths; sheaths elongate, many times longer than the blades, cobwebby-ciliate, pale brown, shining, gradually dilated toward base, gradually narrowing into blades, eligulate; blades flattened, subcapillary, 0.3–0.4 mm wide, slightly twisted, entire, red-brown, lustrous, gradually tapering, conic-subulate at apex, often setaceous. Scapes slender, 20–30 cm long, brown, terete toward apex, ecostate to slightly striate, ca. 0.5 mm thick. Spikes few-flowered, ellipsoid, later short-cylindric, pale brown, ca. 6 mm long; bracts spreading slightly, decussate, entire, the dorsal areas linear, the lowest 4 bracts sterile, the lowest pair lanceolate, ca. 3–4 mm long, acute, strongly carinate, the inner pair ovate, ca. 4 mm long, with a short carina

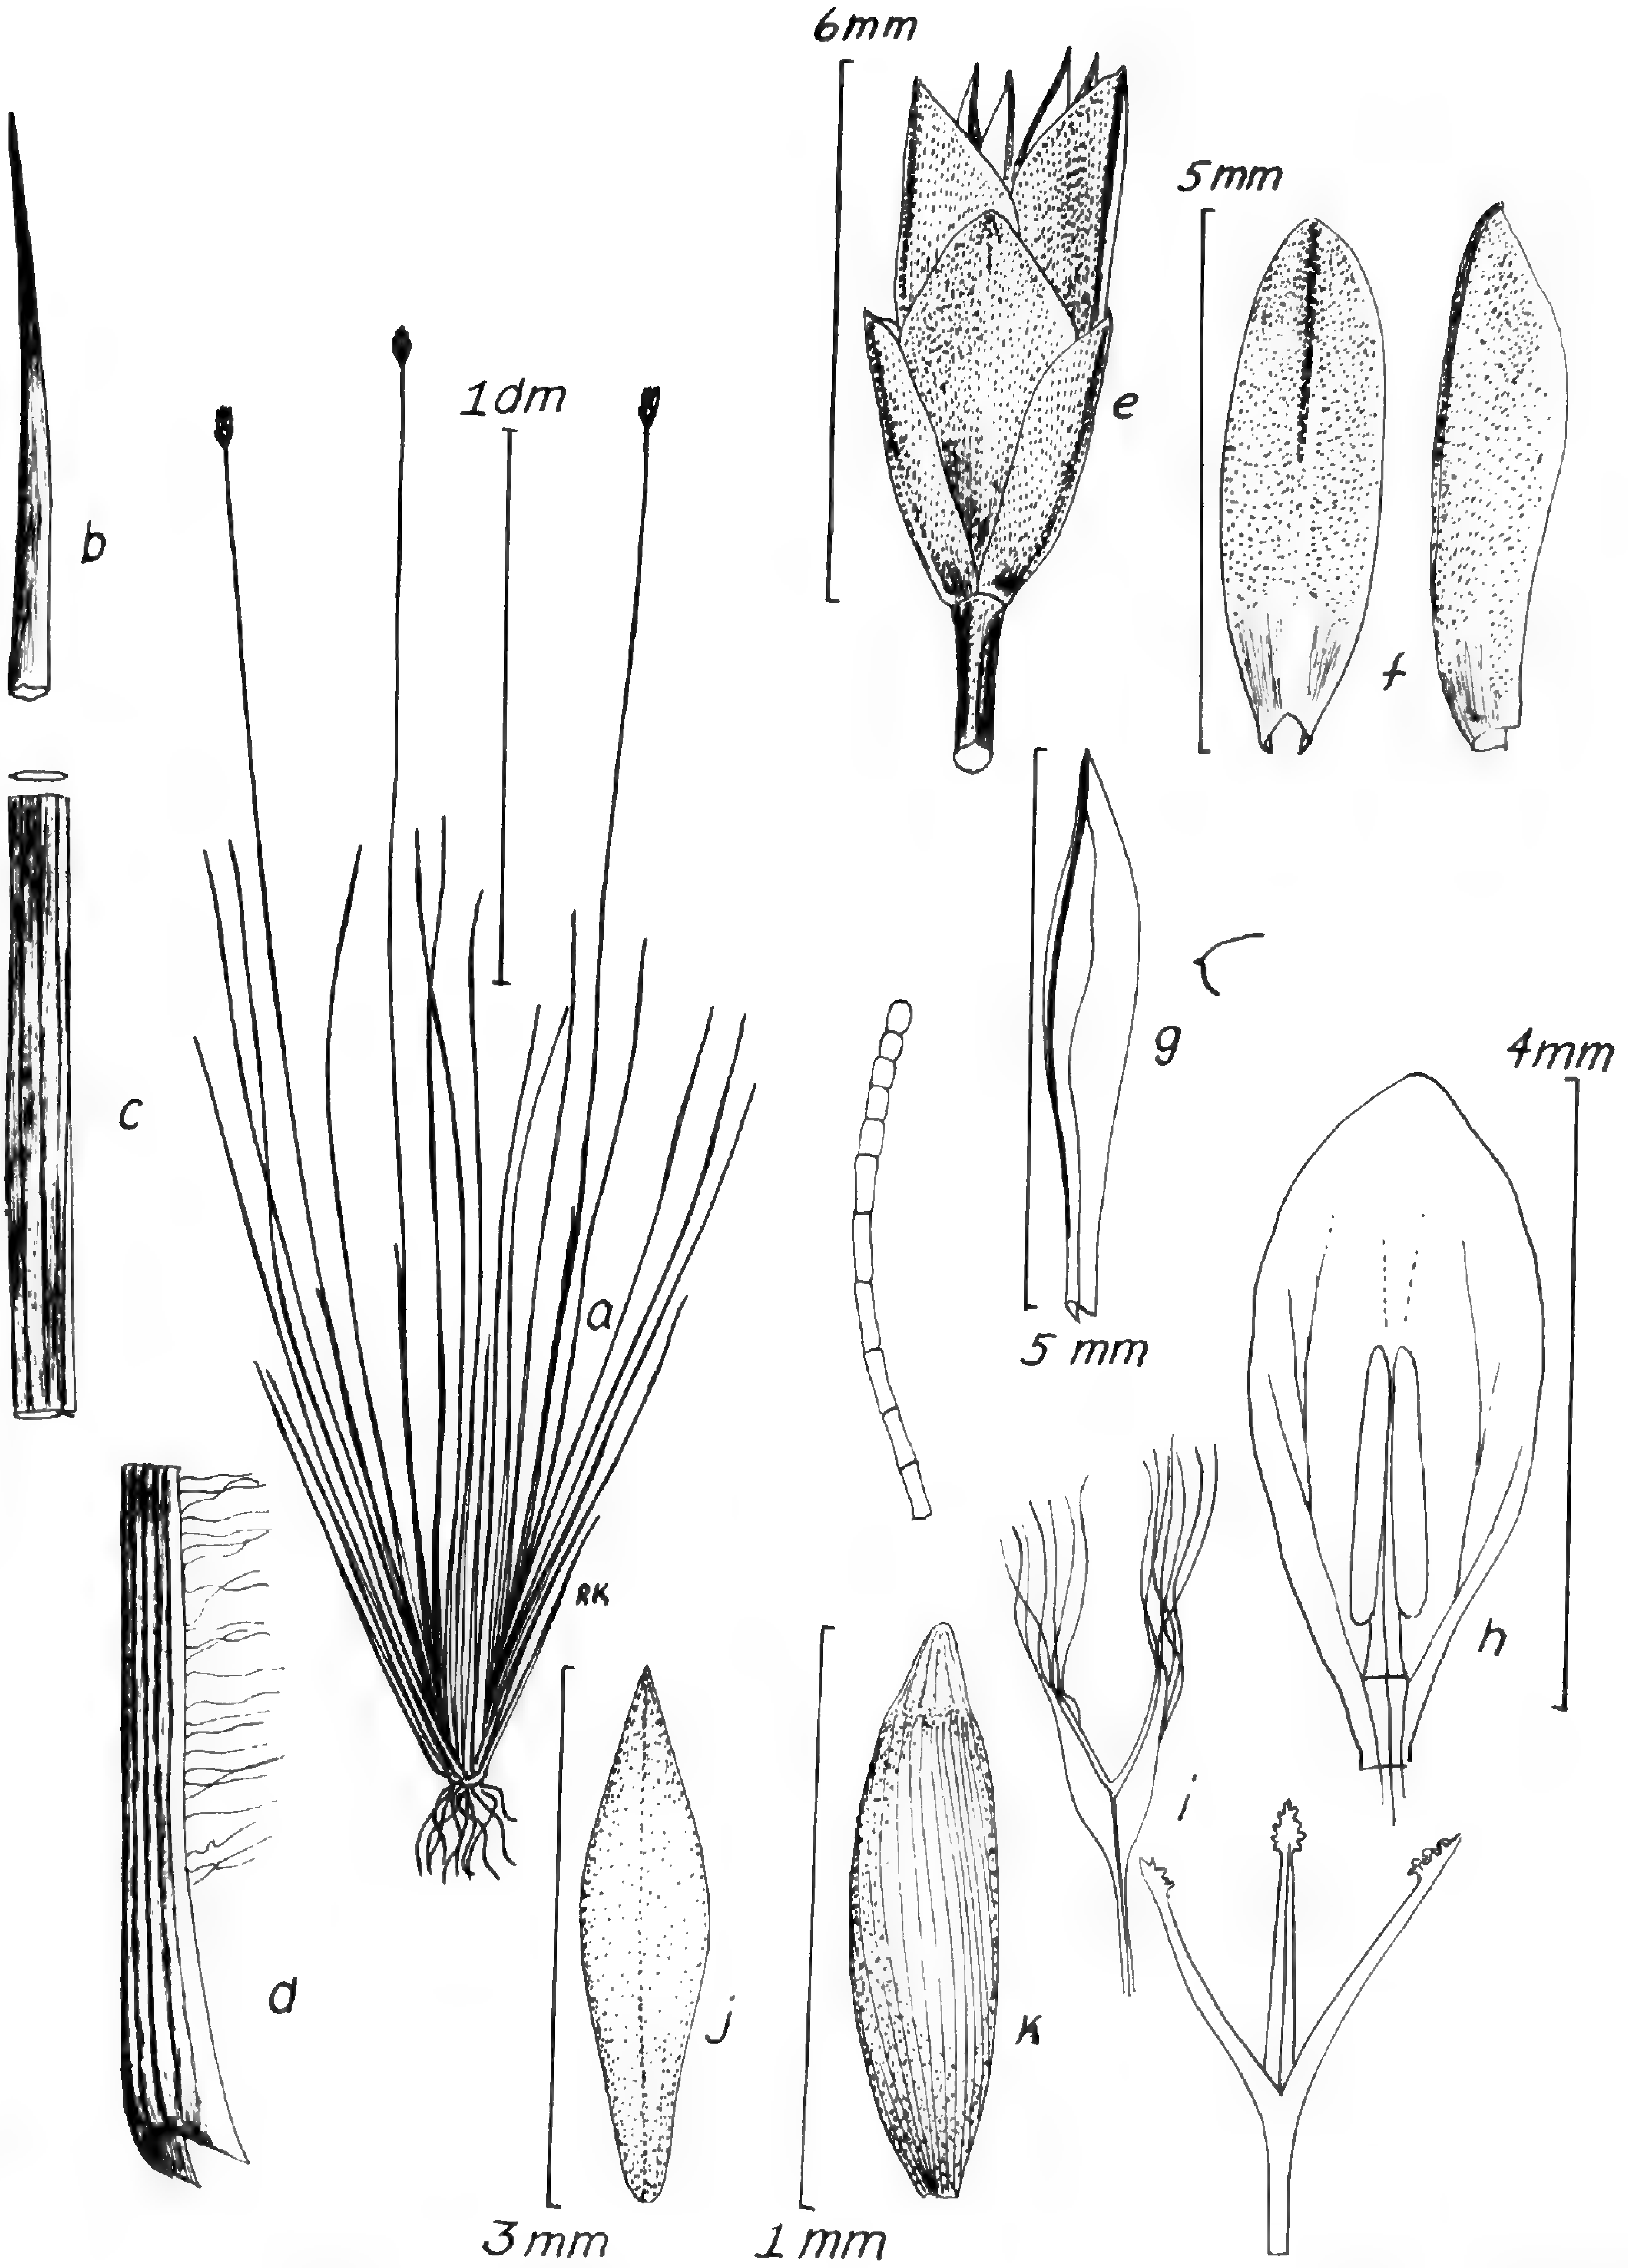

FIGURE 73. Xyris byssacea *(from an isotype)*.—*a. Habit sketch.*—*b. Leaf apex.*—*c. Sector of leaf at blade–sheath junction.*—*d. Leaf base.*—*e. Spike.*—*f. Two views of fertile bract.*—*g. Lateral sepal.*—*h. Petal blade, stamen.*—*i. Staminode, stylar apex.*—*j. Capsule.*—*k. Seed.*

at apex, the dorsal area reduced; fertile bracts 2–4, oblong, 4.5–5 mm long, subconduplicate, narrowly rounded, carinate from middle to apex, the dorsal area linear. Lateral sepals free, inequilateral, narrowly elliptic, ca. 4.5–5 mm long, acute, slightly curvate, the carinal keel narrow but thick, entire. Petal blades narrowly obovate, yellow, ca. 4 mm long, entire. Staminodia bibrachiate, the branches narrowly triangular, long-penicillate. Anthers lanceolate, shallowly bifid and sagittate, ca. 1.5 mm long, on filaments ca. 0.5 mm long. Capsule narrowly ellipsoid, ca. 3 mm long; placenta basal, the funicles elongate. Seeds ellipsoid to cylindric, ca. 1 mm long, translucent, pale red-brown, finely spirally lined longitudinally.

Distribution. Known only from the type area.

This species combines the slender habit of *X. delicatula* and *X. carinata* with the smooth, glassy-scaped character of *X. setigera*; yet the foliage is utterly smooth and the filiform, evenly tapering leaf blades entire. Notable are the spreading arachnoid-ciliate hairs of the sheath margins.

74. Xyris cryptantha Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 16, fig. 2A–E. 1963. TYPE: Venezuela. T. F. Amazonas: Ríos Pacimoni–Yatua–Casiquiare, fls. yellow, locally frequent, Sabana Pacimoni on rt. bank of Río Pacimoni, above mouth 50 km, 100 m, 2 Oct. 1957, *B. Maguire, J. J. Wurdack & C. K. Maguire 41677* (holotype, NY; isotypes, US, NY, VEN). Figure 74.

Mostly low, slender, tufted, fibrillose-based and short-lived perennial or annual 0.6–2.5 dm high, the stems contracted. Leaves erect, 0.5–2 dm long; sheaths floccose-ciliate or pilose-ciliate, less than ½ as long as blades, dilated at very base, broad, castaneous, tapering abruptly, then gradually to blades, eligulate, the blades filiform, subterete or slightly compressed but not sharp-edged, 0.7–1 mm thick, smooth and pale-puncticulate, conic-subulate or incurved-conic at apex. Scape sheaths much shorter than leaves, loosely tubular, with short, erect blades. Scapes linear-filiform, straight or flexuous, slightly twisted, smooth, maroon, pale-puncticulate (stomata), ca. 0.5 mm thick, distally terete, ecostate. Spikes obovoid, 5–9 mm long, reddish brown, few-flowered, the bracts distichous and loose, with large, distinct, pale brown dorsal areas, the sterile bracts ca. 4, the lowest pair distinctly longer than the fertile bracts, narrowly oblong-pandurate, with carinate, cucullate, acute tips arching over spike tip, often there connivent; fertile bracts oblong, 5.5–6 mm long, navicular, erect, the margins entire, scarious, lacerate, the tips rounded. Lateral sepals free, subequilateral, lance-linear, ca. 5.5 mm long, narrowly acute to acuminate, lustrous red-brown, the narrow, firm keel lacerate or friable-fimbriate above middle, later distantly ciliolate. Petal blades broadly obovate, ca. 5.5 mm long, yellow, the broadly rounded apex erose. Staminodia bibrachiate, the branches densely long-penicillate. Anthers ca. 1.5 mm long, deeply bifid at apex, auriculate at base, on filaments 1 mm long. Capsule narrowly ellipsoid-cylindric, 2.5–3 mm long, trilocular, the placentation thus axile, appearing free-central as valves detach. Seeds numerous on short funicles, ovoid or ellipsoid, ca. 0.5 mm long, pale red-brown, apiculate, longitudinally prominently but finely ribbed.

Distribution. Low, sandy savanna, locally abundant, southeastern Colombia, Territorio Federal Amazonas in Venezuela, and a disjunction in the Serra Araca, Amazonas, Brazil.

Additional specimens examined. BRAZIL. AMAZONAS: plateau of northern massif of Serra Aracá, 0°51–57′N, 63°21–22′W, 1,200 m, S side of North Mt., open plateau savanna, 11 Feb. 1984, *G. T. AMAZONAS: la margen izquierda del Río Sipapo a unos 4–6 km aguas abajo de la boca del Río Guayapo, 8 Oct. 1983, *Guánchez & Varadarajan 2524, 2570* (TFAV, VDB); caño "Cabeza de Manteco" a 3–4 km de la boca, 100 m, al norte del medio Río Autana, 12 Nov. 1984, *Guánchez & Melgueiro 3543* (TFAV, VDB); sabanas en los alrededores de Guarinuma, 95 m, 25 Aug. 1978, *Huber 2656* (US, VDB); 2 km al W de San Antonio del Orinoco, 120 m, 20 July 1980, *Huber & Tillett 5423* (VDB, VEN); 5 km al S de la Laguna Yagua, 22 July 1980, *Huber & Tillett 5475* (VDB, VEN); ribera izquierda (Sur) bajo Río Siapa, poco distante de su desembocadura en el Río Casiquiare, 125 m, 7 Feb. 1981, *Huber & Medina 5799* (VDB, VEN); Sabana Pacimoni on rt. bank of Río Pacimoni, 50 km above mouth, 2 Oct. 1957, *Maguire & Wurdack 41667* (NY, US); Sabana El Venado on left bank of Caño Pimichín above Pimichín, 2 July 1959, *Wurdack & Adderley 43294* (NY, U, US, VEN).

This distinctive xyrid, in its low habit, slender foliage, small seeds, and general bract

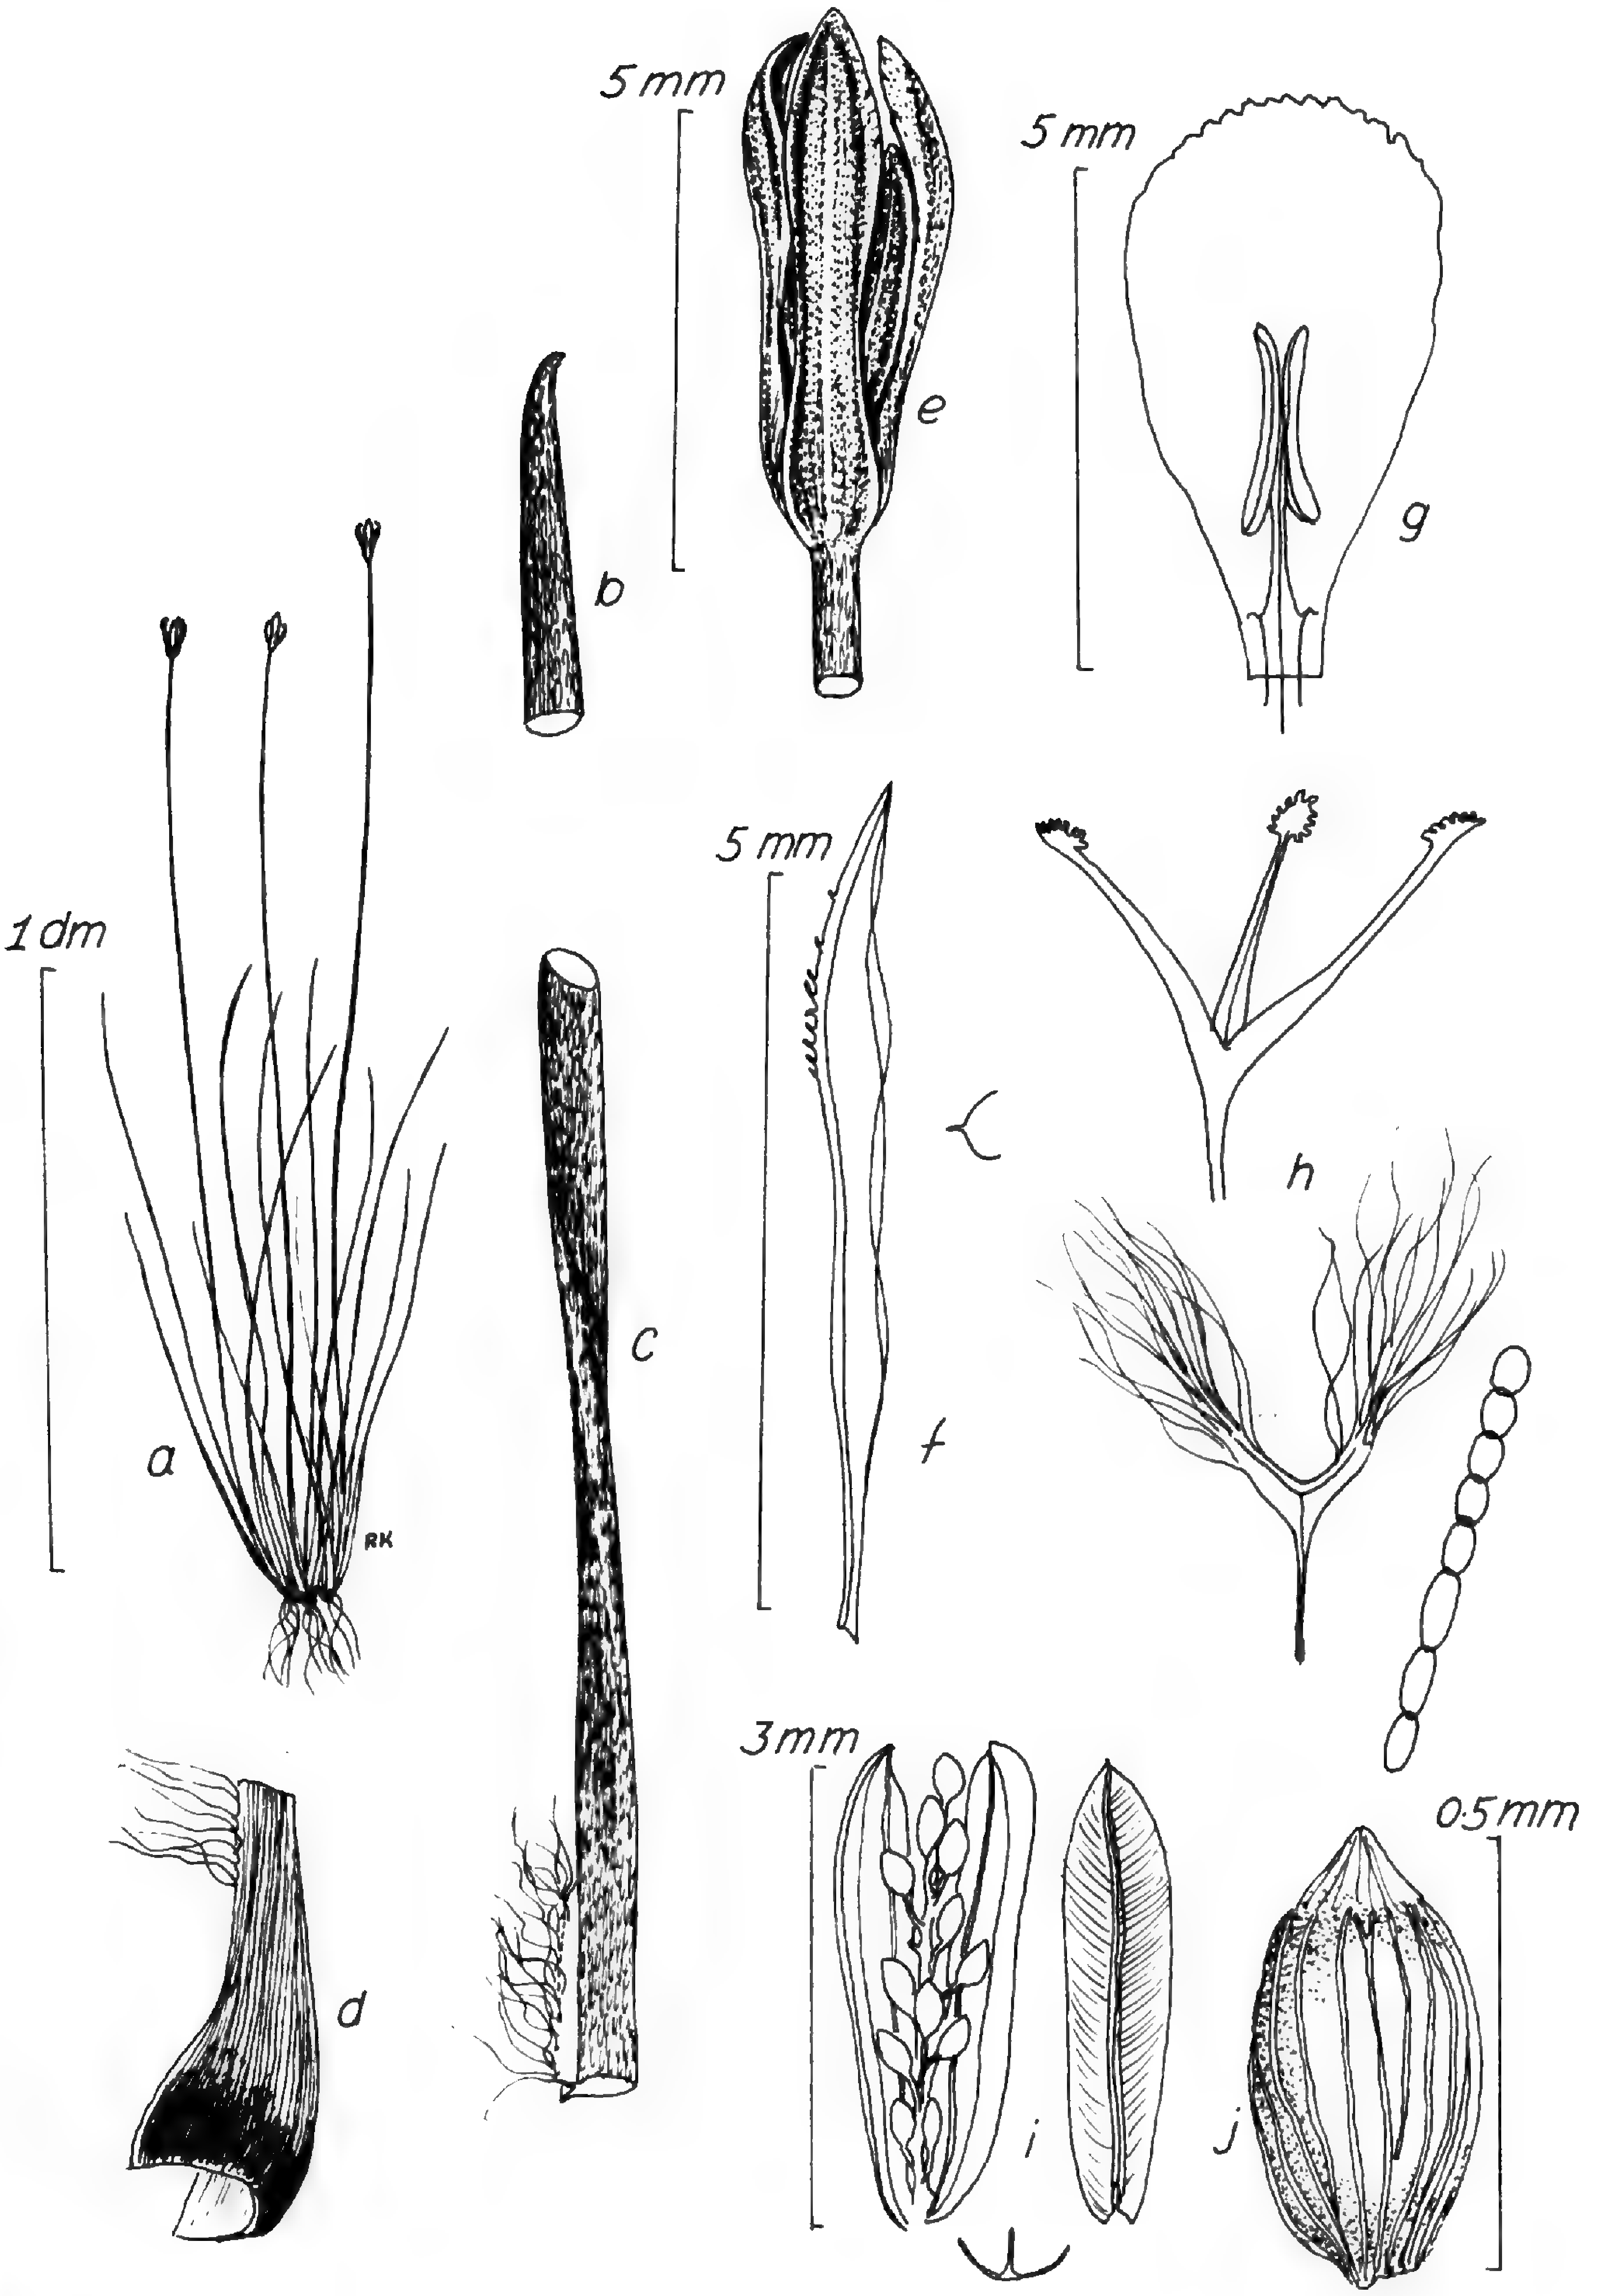

FIGURE 74. Xyris cryptantha (Huber & Tillett 5475).—*a. Habit sketch.—b. Leaf tip.—c. Leaf blade–sheath junction.—d. Leaf base.—e. Spike.—f. Lateral sepal.—g. Petal blade, stamen.—h. Stylar apex, staminode.—i. Capsule; at left with one valve removed; a valve at right.—j. Seed.*

characters definitely lies near *X. oxylepis*, a species with which it is associated in the white-sand savannas.

75. Xyris oxylepis Idrobo & Lyman B. Smith, Caldasia 6(29): 204, fig. 7a–c. 1954. TYPE: Colombia. Vaupés: "Río Kuduyari, cerro Yapoboda, sabanas sobre piedras areniscas," ca. 450 m, 5 Oct. 1951, *R. E. Schultes & I. Cabrera 14234-B* (holotype, COL; isotype, US). Figure 75A, B.

Xyris fusiformis Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 24, fig. 8A–E. 1963. TYPE: Venezuela. T. F. Amazonas: Sabana El Venado on left bank of Caño Pimichín, above Pimichín, 140 m, 10 Oct. 1957, Río Guainía, *B. Maguire et al. 41815* (holotype, NY; isotypes, GH, US).

Slender, low, wiry, cespitose perennial, the bases cloaked in fibrillose-chaffy remnants of old leaves, the stems contracted, the plants 1–3 dm high. Leaves mostly erect, quill-like, sometimes exceeding the scapes; sheaths less than ½ as long as blades, at base dull brown to castaneous, dilated, above brownish or red-brown, the edges villous-ciliate with brown hairs below, tapering gradually to blades and white-cottony-ciliate above, at junction with blade producing a broad, blunt ligule or essentially eligulate; blades subterete, usually with 4 or more rounded ribs and shallow sulci, sometimes with a strong ventral sulcus, narrowly linear, 0.5–0.7(–1) mm thick, apically conic-acute or narrowly triangular, smooth, the surfaces smooth or papillate, often white puncticulate. Scape sheaths much shorter than leaves, tubular and multicostate proximally, distally producing a short blade similar to leaves. Scapes twisted and flexuous, about as broad as leaves, terete distally, smooth, prominently multicostate, the ribs low, white puncticulate. Spikes narrowly ellipsoid or fusiform, aging cylindric, 7–10 mm long, acute, of a few, loosely imbricate, subdecussate, ecarinate bracts with strong dorsal areas; lower 4 bracts sterile, lance-ovate, 5–8 mm long, ½ or more as long as spike, broadly acute or narrowly rounded apically, scarious-edged, with large, elliptic, medially 1-nerved dorsal areas; fertile bracts 2–3, usually slightly longer and often with slightly narrower outline than sterile bracts, ca. 8 mm long, with similar dorsal areas. Lateral sepals free, equilateral, lance-linear to elliptic-linear, 6–7.5 mm long, acute, the narrow, firm keel entire or with scattered cilia above middle. Petal blades obovate, 5–6 mm long, yellow, the broadly or narrowly rounded apex erose or dentate-lacerate. Staminodia bibrachiate, the branches long-penicillate. Anthers oblong, ca. 2–2.5 mm long, nearly ½ bifid, deeply sagittate, on filaments 1.5–2 mm long. Capsule ellipsoid, ca. 3 mm long; valves with strong septa from base to tip, the placentation appearing axile. Seeds short-cylindrical, 0.7–0.8 mm long, pale amber, apiculate, finely anastomosing-ribbed longitudinally.

Distribution. Low-elevation sandy savanna, southeastern Colombia (rare) eastward into southwestern Venezuela, where locally abundant in the Orinoco savannas.

Additional specimens examined. VENEZUELA. T. F. combination of Colombian and Venezuelan material, Figures 75A (from the type of *X. oxylepis*) and 75B (from material of *X. fusiformis*) are presented.

76. Xyris wurdackii Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 24–25, fig. 9A–E. 1963. TYPE: Venezuela. T. F. Amazonas: Yavita–Pimichín trail near Pimichín, 140 m, Río Guainía, 22 Nov. 1953, *B. Maguire, J. J. Wurdack & G. S. Bunting 36366A* (holotype, NY; isotype, US). Figure 76A.

KEY TO THE SUBSPECIES OF *XYRIS WURDACKII*

1a. Most scapes overtopped by principal leaves; leaf blades and scapes prominently white puncticulate; fertile bracts pilose-ciliate at tips .... 76A. *X. wurdackii* subsp. *wurdackii*
1b. Most scapes overtopping principal leaves; leaf blades and scapes not noticeably white puncticulate; fertile bracts completely smooth .... 76B. *X. wurdackii* subsp. *caquetensis*

76A. Xyris wurdackii subsp. wurdackii.

Cespitose or solitary, perennial, sub-bulbous and fibrillose at base, the stems contracted. Leaves erect or ascending, few, the larger ones 1–3 dm long, twisted and flexuous, mostly overtopping scapes; sheaths less than ⅓ as long as blades, dilated at very base, dark brown or castaneous, gradually narrowing above, long-villous-ciliate, at bristly apex narrowing abruptly into blade, producing a broad, short, rounded-tipped ligule; blades linear, smooth, spirally fluted, terete, 1–1.5 mm thick, ventrally deeply sulcate and with numerous spiral lines of punctae, tapering shortly above middle to narrowly conic apices. Scape sheaths very short, mostly hidden in leaf sheaths, short-bladed. Scapes flexuous and twisted, 6–20 cm high, fluted and punctate as in leaf blades, proximally somewhat flattened, distally subterete with several low ridges, ca. as thick as leaf blades. Spikes obovoid, 7–10 mm long, the outer bracts subulate with raised midribs, nearly as long as or as long as the spike, the backs or at least the margins densely villous-tomentose with pale hairs, these often obscuring the bract outlines; bracts slightly widening inward in spike, the lowermost fertile ones the largest, lanceolate, 6–8 mm long, narrowly acute and at upper margins long-villous-pubescent, the convex backs castaneous and with large, lanceolate, pale-punctate dorsal areas, the margins strongly convolute apically. Lateral sepals lance-linear, free, equilateral, ca. 5 mm long, acuminate, the thin keel finely lacerate or flattened-villose toward apex. Petal blades broadly obovate, ca. 5 mm long, yellow, the narrowly rounded apex erose-crenulate. Staminodia bibrachiate, the narrow, flattened branches densely long-penicillate-ciliate. Anthers oblong-linear, ca. 1.5 mm long, on filaments ca. 1–1.5 mm long, deeply bifid, deeply sagittate. Capsule short-cylindric, ca. 3 mm long, the placental zone extending nearly to apex, the narrow valves with strong septa, thus placentation axile. Seeds numerous, ellipsoid, ca. 0.5 mm long, yellow-amber, multiribbed with narrow but distinct, often anastomosing, ridges longitudinally.

Distribution. Low-elevation savannas, southern Territorio Federal Amazonas, Venezuela.

Additional specimens examined. VENEZUELA. T. F. AMAZONAS: ca. a 5 km al W del bajo Río Temi, 100 m, 24 Feb. 1979, *Huber 3427* (US); 2–3 km al SE del bajo Río Guasacavi, 10 Mar. 1980, *Huber 5113* (US); 20 km al S del medio Caño Caname, ca. 100 m, 10 Mar. 1980, *Huber 5144* (US, VDB); 20 km al NW de Yavita, en las cabaceras del Caño Pimichín, 120 m, 11 Feb. 1980, *Huber & Medina 5949a* (VEN).

This subspecies appears to be fairly abundant in and around the type locality. It is very distinct in its combination of terete leaves and long, blonde or silvery, bristly and villose indumentum of spikes and edges of leaf sheaths.

76B. Xyris wurdackii subsp. **caquetensis** Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 24–25. 1963. TYPE: Colombia. Amazonas: frequent in scrub savanna, Araracuara, Río Caque-

ta, 5 Sep. 1959, *B. Maguire, C. K. Maguire & A. Fernandez 44129* (holotype, COL; isotypes, NY, US). Figure 76B.

This subspecies resembles the type subspecies, but most scapes overtop most leaves, and the leaf blades and scapes lack the prominent rows of pale punctae; the lowest sterile bracts are much shorter than spike and shorter than the outer fertile bracts; the inner sterile bracts are progressively less ciliate, becoming totally smooth; and the fertile bracts are entirely smooth. The capsule is narrowly cylindric and ca. 4 mm long; the seeds are slightly narrower and longer (0.5–0.6 mm); and the fine longitudinal ribs are more anastomosing.

Distribution. Known only from the type area.

Paratype. COLOMBIA. AMAZONAS: frequent in Aracuara Savannas, Río Caquetá, *Maguire et al. 44173* (NY).

This is another of the "close" vicariads involving the savannas of southern Colombia and Venezuela.

77. Xyris frequens Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 32–33, fig. 16A–E. 1963. TYPE: Venezuela. T. F. Amazonas: sabanita along Caño Pimichín on right bank 1 km above Pimichín, Río Guainía, 140 m, 24 Nov. 1953, *B. Maguire & J. J. Wurdack 36383* (holotype, NY; isotypes, NY, US). Figure 77.

Firm-based, cespitose perennial 2.5–3.5 dm high, the stems contracted. Leaves erect, the principal ones 1.5–3.5 dm long, the outer ones broad, short, bladeless brown scales; sheaths at intervals villous-ciliate, less than ¼ the length of the blades, pale red-brown, rugulose or nearly smooth, tapering gradually to green, rigid, flexuous or straight, terete or subterete blades 1 mm thick, apically blunt-conic, punctate, tipped (often) with a pale pilose coma, the surfaces smooth distally, proximally rugulose, strongly ribbed or ecostate. Scape sheaths shorter than leaves, open, producing elongate blades similar to leaves. Scapes flexuous and twisted, somewhat compressed, oval in cross section, smooth or finely rugulose. Spikes broadly ellipsoid, drying turbinate, 1–1.4 cm long, bracts several, in several ranks, loosely subdecussate, reddish brown with strong, paler dorsal areas, aging excurvate; sterile bracts several, broadly triangular to ovate, ecarinate, often villous-tufted apically at base, the lowest bracts much smaller than and grading into the fertile bracts, these broadly oblong, rounded-folded, 8–10 mm long, narrowly rounded or acute apically, subentire or erose, when young often villous-ciliate apically and red-bordered, the dorsal areas with a strong midnerve, often with several subparallel laterals. Lateral sepals free, equilateral, lance-linear, ca. 5 mm long, acuminate, the dark, wide, firm keel entire or apically ascending-ciliolate or villous-fimbriolate and coarsely serrate toward base. Petal blades elliptic, ca. 5 mm long, broadly acute and wavy-margined, yellow. Staminodia narrowly bibrachiate, the slender branches penicillate-pilose. Anthers narrowly oblong, 2.5 mm long, deeply bifid, deeply sagittate, on filaments ca. 1 mm long. Capsule ellipsoid-cylindric, ca. 5 mm long, the placentation appearing free-central from base to apex, but each valve detaching with a wide septum, thus placentation actually axile. Seeds numerous on short funiculi, narrowly ellipsoid, 1.5–1.6 mm long, including a pale, conic apiculus, the body finely striate, pale brown, overlain by a coarse, irregularly anastomosing reticulum of dark brown ridges.

Distribution. So far known only from savannas along the Caño Pimichín and those below Cerro Yapacana, Territorio Federal Amazonas, Venezuela. Other than the type, the only records appear to be the following.

Additional specimens examined. VENEZUELA. T. F. AMAZONAS: Savanna III, NW base of Cerro Yapacana, 150 m, 17 Mar. 1953, *B. Maguire & J. J. Wurdack 34572* (NY); Savanna III, Yapacana savannas, 10 Aug. 1983, *Kral & Huber 70706* (MO, NY, US, VDB, VEN).

This species most resembles the more widespread *X. surinamensis* but tends to have

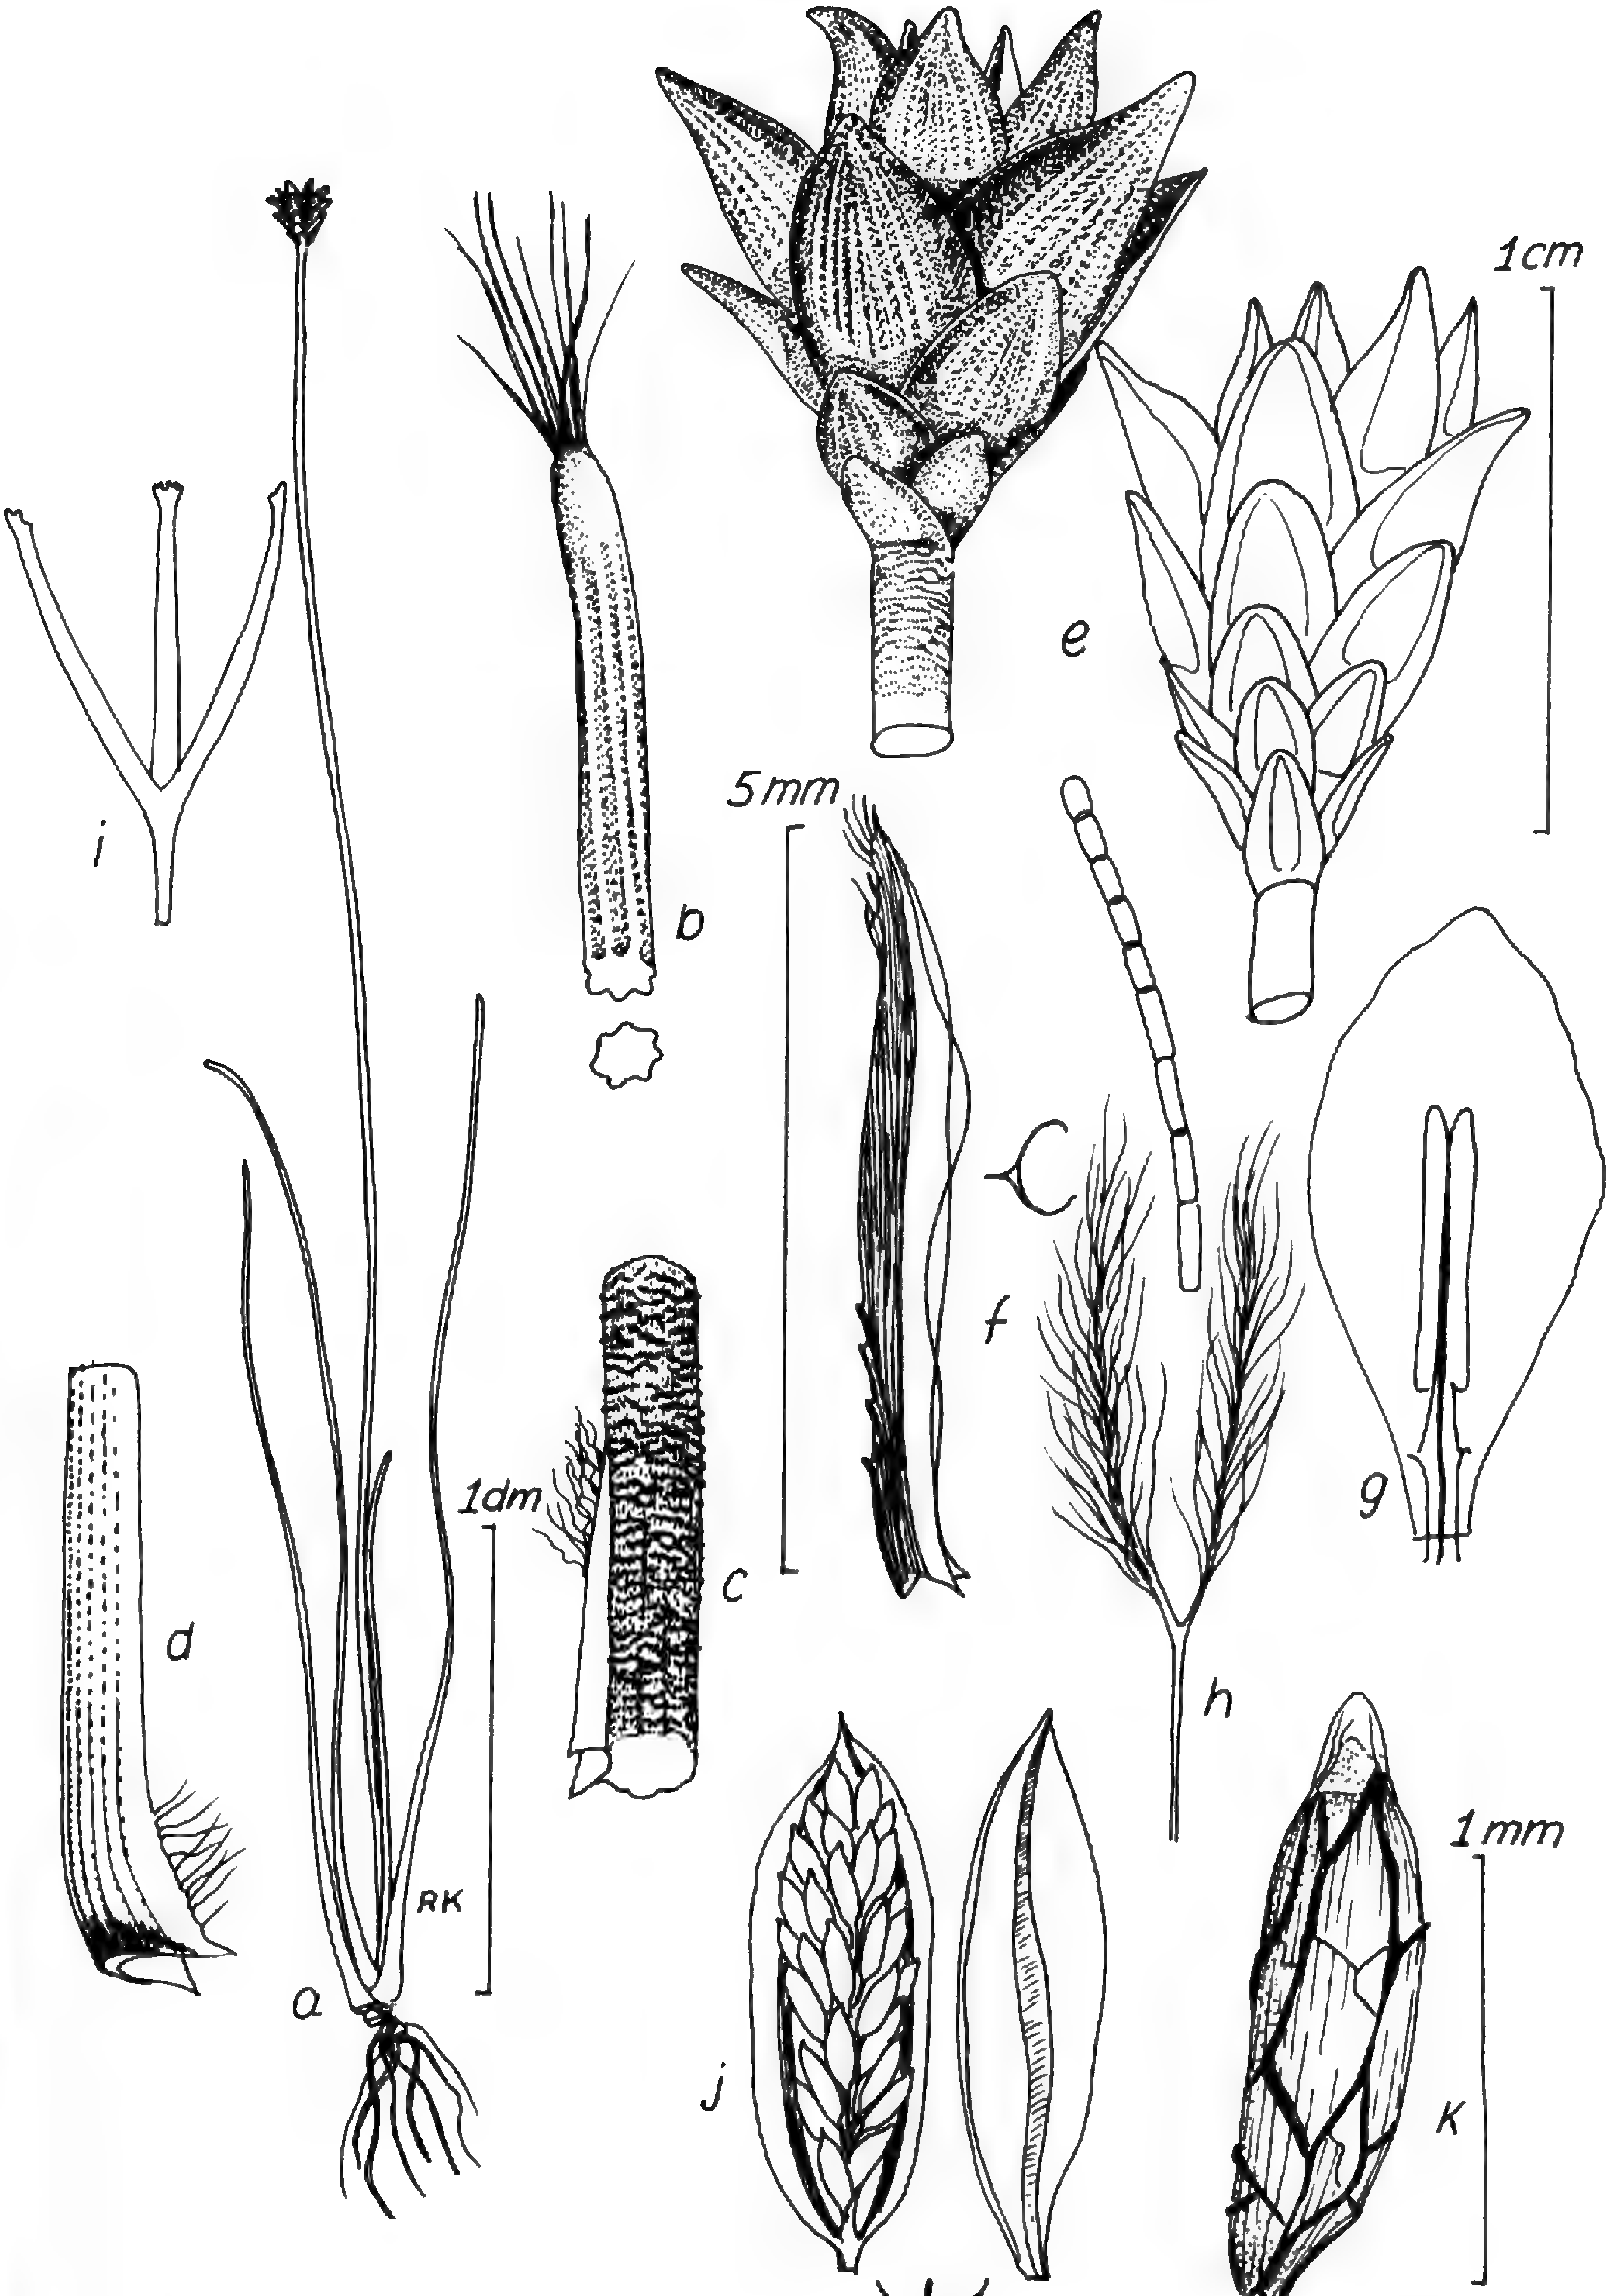

FIGURE 77. Xyris frequens *(from the type).—a. Habit sketch.—b. Leaf apex.—c. Leaf at blade-sheath unction.—d. Leaf base.—e. Spike (at left in fruit, at right dried spike at anthesis).—f. more terete scape and leaf blade and a taller habit. Tips of most principal leaves have conspicuous tufts of pale, bristly trichomes.

78. Xyris subglabrata Malme, Bull. Torrey Bot. Club 48: 322. 1931. TYPE: Venezuela. T. F. Amazonas: Grand Savanna, section 1, in swampy ground, petals crimped, orange-yellow. Esmeralda, ca. 325 ft., 1 Nov. 1928, *G. H. H. Tate 303* (holotype, NY; phototype, F). Figure 78.

Xyris garcia-barrigae Idrobo & Lyman B. Smith, Caldasia 6: 204, fig. 8. 1954. TYPE: Colombia. Amazonas: Sabana de la Angostura, ca. 400 m, Río Caqueta, Araracuara, 21 Dec. 1951, *H. García-Barriga & R. E. Schultes 14168* (holotype, COL; isotypes, NY, US).

Cespitose, hard- and fibrillose-based perennial 1–3.5 dm high, the stems short, up from a stocky, horizontal or ascending rhizome. Leaves erect or ascending (0.7)1–2 dm long; sheaths with margins arachnoid or cottony, or pilose-ciliate, abruptly dilated at very base, reddish brown or castaneous, red-brown above, strongly papillose-rugose or nearly smooth, narrowing gradually to blades, ligulate or eligulate, the scarious edges often densely cottony; leaf blades lineal, terete-fluted, often sulcate and few-ribbed ventrally, 0.5–1 mm thick, dull green or maroon tinted, tapering to narrowly conic tips, these sometimes pilose-tufted, the surfaces smooth or papillose-rugulose toward base. Scape sheaths roughly equal to leaves and appearing like them. Scapes straight or flexuous, pale red-brown, slightly twisted, subterete distally, 0.7–1 mm thick, ecostate or striate, sometimes sulcate, papillose or smooth. Spikes ovoid to broadly ellipsoid, globose or obovoid, ca. 5–7 mm long, dark brown with several firm, spirally imbricate bracts having strong dorsal areas, also often with tips and base of bracts bearing white-villous patches; the lowest sterile bracts less than ½ length of the fertile ones, ovate, ecarinate; fertile bracts broadly obovate, ca. 5–6 mm long, convex-rounded-backed, the apices broadly rounded, entire, the dorsal areas broadly triangular with strong mid and lateral nerves. Lateral sepals free, slightly inequilateral, lanceolate, ca. 4.5–5 mm long, acute, deep lustrous yellow-brown, the firm keel villosulous or ciliate above middle. Petal blades broadly obovate, 4 mm long, yellow, the broadly rounded apices erose-denticulate. Staminodia bibrachiate, the narrow branches long-penicillate. Anthers oblong, ca. 2 mm long, deeply bifid and auriculate, extrorse, on stout filaments ca. 1 mm long. Capsule narrowly obovoid, somewhat compressed dorsiventrally, ca. 3 mm long, placentation appearing free-central, but valves with complete septa toward capsule base. Seeds oblong-short-cylindric or narrowly ovoid, ca. 0.6–0.7 mm long, apiculate, dark amber, finely lined and very finely cross-lined longitudinally.

Distribution. Mostly low-elevation, white-sand savanna, southeastern Colombia, southwestern Venezuela, and contiguous Amazonas, Brazil.

Additional specimens examined. BRAZIL. AMAZONAS: base of Serra Araca, 0–3 km S of central massif, 3 km E of Rio Jauari, 0°49′N, 63°19′W, 8 Feb. 1984, *G. T. This plant, along with *X. setigera* Oliver, often has the corolla attacked by a fungus, the spore masses lending an orange quality to the flower. This color is sometimes recorded on labels, but I have not seen any *Xyris* with healthy orange corollas. Consultation of the type material of *X. garcia-barrigae* and of other material so identified will show no significant differences from the earlier-named *X. subglabrata*.

79. Xyris lithophila Kral & Lyman B. Smith, sp. nov. TYPE: Venezuela. Bolívar: Dist. Roscio, arbustales, sabana rocosa y vegetación ribereña en los alrededores del Salto "La Milagrosa," ca. 15 km al SW de S. Ignacio de Yuruaní. Formando pequeñas colonias sobre rocas en el lecho del río, 4°55′N, 61°14′W, 1,000 m, 22 June 1983, *O. Huber & Clara Alarcon 7568* (holotype, VEN; isotypes, MYF, VDB). Figure 79.

Planta perennis, caespitosa, gracilis. Radices graciles. Caules breves. Folia principalia erecta, subtorta, flexuosa, 0.8–2 dm longa, leviter papilloso-rugulosa, vaginis scaporum longiora; laminae 2–3-plo vagines longiores, filiformes, leviter compressae vel subteretes, 0.5–0.8 mm latae, longitudine leviter nervosae, nitidae, pallide olivaceae vel spadiceae; apices peranguste conicae aut subulatae; vaginae ecarinatae, pallide ferrugineae, ad basin leviter dilatatae, multicostatae, brunneolae, multicostatae, in laminas gradatim decrescentes, aciebus dense longivillosis, trichomatibus pallidis. Vaginae scaporum multicostatae, tubulosae, apicem versus apertae, laminis brevibus. Scapi 2–3.5 dm alti, glabri, leviter torti, nitidi, leviter papillosi, olivacei, ad apicem tereti, leviter striati. Spicae pauciflorae, ellipticae vel obovoideae, 7–9 mm longae, obtusae. Bracteae erectae, laxe spiraliter imbricatae, ecarinatae sed mediane conspicue constatae, integrae, pallide brunneolae, basin versus atrocastaneae; bracteae steriles 4, pari infimo late oblongo, ca. 4–5 mm longo, rotundato, ½–⅔-plo spica longiori; bracteae fertiles late oblongae vel anguste obovatae, ca. 6–6.5 mm longae, rotundatae, area dorsali anguste triangulata, atroferruginea. Sepala lateralia libera, subaequilatera, oblanceolata, 5.5–6 mm longa, leviter curvata, acuta; ala carinali lata a medio ad apicem lacerato-vel-fimbriato-ciliata. Laminae petalorum late obovatae, 4.5–5 mm longae, luteolae, ad late rotundatum apicem erosae. Staminodia bibrachiata, brachiis a basi ad apicem longipenicillatis. Antherae anguste oblongae, ca. 2 mm longae, profunde bifidae et sagittatae, filis ca. 1.5 mm longis. Capsula matura non visa sed quasi maturas capsulas et seminas vidi: sic, fructificatio cylindrica, ca. 3 mm longa et placenta centralis, valvis capsulae profunde septatis a basi ad apicem; semina numerosa ellipsoidea, ca. 0.7 mm longa, translucida, longitudine leviter multilineata.

Slender, tufted perennial; roots slender; stems short. Main foliage leaves erect, slightly twisted and flexuous, 0.8–2 dm long, lightly papillose-rugulose, longer than the scape sheaths; blades 2–3 times longer than the sheaths, filiform, slightly compressed or subterete, 0.5–0.8 mm wide, longitudinally finely nerved, shining, pale olive green to brownish; tips narrowly conic or subulate; sheaths ecarinate, pale reddish brown, slightly dilated at base, multicostate, brownish, gradually narrowing into blades, the margins densely long-villous, the trichomes pale. Scape sheaths multicostate, tubular, opening toward apex, short-bladed. Scapes 2–3.5 dm high, smooth, slightly twisted, shining, lightly papillose, olivaceous, terete toward apex, finely striate. Spikes few-flowered, elliptic to obovoid, 7–9 mm long, obtuse. Bracts erect, loosely spirally imbricate, ecarinate but with conspicuous midrib, entire, pale brown, deep castaneous toward base. Lateral sepals free, subequilateral, oblanceolate, 5.5–6 mm long, slightly curvate, acute; keel broad, lacerate- to fimbriate-ciliate from middle to apex. Petal blades broadly obovate, 4.5–5 mm long, yellow, the broadly rounded apex erose. Staminodia bibrachiate, the branches long-penicillate from

base to tip. Anthers narrowly oblong, ca. 2 mm long, deeply bifid and sagittate on filaments ca. 1.5 mm long. Nearly mature fruit cylindric, ca. 3 mm long, the capsule valves deeply septate, the placentae central.

Distribution. Known only from the type locality.

The complex to which this slender plant belongs involves *X. setigera*, *X. delicatula*, and *X. carinata*, all of which are slender-leaved with foliage variously rugulose, the very thin sheath margins delicately pilose or villose. This taxon is distinguished primarily on the basis of smooth scapes (as in *X. setigera*) and conic-subulate tips to its slender leaves. The leaf tips not excentrically pointed, bract edges entire, and bract backs with very distinct dorsal areas are not usual in the complex.

80. Xyris carinata Maguire & Lyman B. Smith, Mem. New York Bot. Gard. 10: 36, fig. 21A–E. 1963. TYPE: Venezuela. T. F. Amazonas: occasional in *Bonnetia*–grass savanna, summit Cerro Guanay, Caño Guaviarito, 1,800 m, Río Manapiare, Río Ventuari, 4 Feb. 1951, *B. Maguire, K. D. Phelps, C. B. Hitchcock & G. Budowski 31773* (holotype, NY; isotypes, US, VEN). Figure 80.

Slender, cespitose perennial 2–3 dm high, the stem short. Leaves erect or ascending, 1–1.5 dm long; sheaths mostly less than ½ as long as blades, pilose-ciliate, at very base brown or stramineous and papillose-rugulose, more scabrid and rugose above, reddish, tapering to blade, eligulate or with a short, broad, rounded-scarious ligule, ecarinate; blades narrowly lineal, twisted and flexuous, flattened (oblong in cross section), 0.8–1 mm wide, narrowed above middle, then abruptly bluntly conic-tipped, smooth, the edges thick and rounded, tuberculate-rugose, the sides strongly verrucose-rugose, green with maroon tints. Scape sheaths shorter than leaves, tubular, twisted and costate, open distally, tipped with cusplike, erect, blunt blades. Scapes flexuous and twisted, distally terete, 0.7–0.8 mm thick, papillose-rugulose. Spikes ellipsoid, aging obovoid, 7–8 mm long, dull brown or tan, of several erect but loosely imbricate, firm, spirally arranged bracts with narrowly elliptic, subapical dorsal areas and papillose, rounded backs; lowest sterile bracts much smaller than the fertile bract, ovate, narrowly rounded, grading into the fertile bracts, the outer fertile bracts narrowly obovate or oblong, ca. 7–8 mm long, narrowly rounded, subentire, with narrow, short, subapical carinae, the inner bracts progressively more folded and carinate. Lateral sepals free, subequilateral, oblanceolate, ca. 6 mm long, acute, tan with the thin, darker keel ascending-ciliate from middle to apex. Petal blades narrowly obovate, ca. 5 mm long, yellow. Staminodia bibrachiate or (anomalously) compound, 2- or 4-branched, the branches long-penicillate. Anthers oblong, deeply bifid, deeply sagittate, ca. 2 mm long on filaments ca. 1 mm long. Capsule narrowly obovoid-cylindric, ca. 4 mm long, the ovary trilocular with septa breaking from axis at maturity, falling with valves. Seeds numerous, ellipsoid, ca. 0.7 mm long, acute, dark amber, longitudinally with ca. 12–14 strong ribs per side.

Distribution. High, sandy rocky savanna at medium to high (over 1,000 meters) elevations, southern Venezuela and contiguous Brazil.

Additional specimens examined. BRAZIL. TERR. RÓRAIMA: vic. Auaris 4°3′N, 64°22′W, upper slopes of Serra Parima, S of Auaris, 1,400–1,520 m, rocky outcrop in seepage, Feb. 1969, *Prance et al. 9808* (F, K, U, US); same locality, 1,200 m, 30 July 1974, *Prance et al. 21564* (U, NY, US, GH).
